AMERICAN ACADEMY OF HIV MEDICINE, *et al.*, *Plaintiffs*, v. HEALTH RESOURCES AND SERVICES ADMINISTRATION, *et al.*, *Defendants*.	Case No. 1:26-cv-12638-WGY **ORAL ARGUMENT REQUESTED**

PLAINTIFFS' MOTION FOR PRELIMINARY RELIEF UNDER 5 U.S.C. § 705 AND PRELIMINARY INJUNCTION

Pursuant to 5 U.S.C. § 705 and Federal Rule of Civil Procedure 65(a), and Local Rule 7.1, Plaintiffs hereby respectfully move for preliminary relief under 5 U.S.C. § 705 and a preliminary injunction prohibiting Defendants from implementing, enforcing, effectuating, or giving effect to certain agency policies, including those set forth in the FY 2026 HRSA General Terms and Conditions, issued on March 11, 2026, and in Notices of Funding Opportunity ("NOFOs") relating to the Ryan White HIV/AIDS Program, created under the Ryan White Comprehensive AIDS Resources Emergency Act, codified as amended at 42 U.S.C. §§ 300ff–11 to 300ff–140, which prohibit Ryan White funding recipients from acknowledging, affirming, and/or respecting the identities of transgender patients or from providing gender-affirming medical care under the Ryan White Program, and that incorporate or implement Executive Order 14168, "Defending Women From Gender Ideology Extremism and Restoring Biological Truth to the Federal Government."

In support of this request for preliminary relief under 5 U.S.C. § 705 and a preliminary injunction, Plaintiffs rely on the memorandum of law, declarations, and other evidence filed in support of this motion. Plaintiffs respectfully request that the Court grant preliminary relief under

5 U.S.C. § 705 and enter a preliminary injunction in the form set forth in the proposed order attached to this motion.

REQUEST FOR ORAL ARGUMENT

Pursuant to Local Rule 7.1(d), Plaintiffs respectfully suggest that oral argument may assist the Court in considering this motion for preliminary relief under 5 U.S.C. § 705 and a preliminary injunction.

Dated: June 10, 2026

Respectfully submitted,

/s/ Omar Gonzalez-Pagan

IN THE UNITED STATES DISTRICT COURT
FOR THE DISTRICT OF MASSACHUSETTS

AMERICAN ACADEMY OF HIV MEDICINE; et al., *Plaintiffs*, v. HEALTH RESOURCES AND SERVICES ADMINISTRATION; et al., *Defendants*.	Case No. 1:26-cv-12638-WGY

[PROPOSED] ORDER GRANTING PLAINTIFFS' MOTION FOR PRELIMINARY RELIEF UNDER 5 U.S.C. § 705 AND PRELIMINARY INJUNCTION

Pursuant to 5 U.S.C. § 705 and Federal Rule of Civil Procedure 65(a), Plaintiffs have moved this Court for preliminary relief under 5 U.S.C. § 705 and a preliminary injunction prohibiting Defendants from implementing, enforcing, effectuating, or giving effect to certain agency policies, including those set forth in the FY 2026 HRSA General Terms and Conditions, issued on March 11, 2026, and in Notices of Funding Opportunity ("NOFOs") relating to the Ryan White HIV/AIDS Program, which prohibit Ryan White funding recipients from acknowledging, affirming, and/or respecting the identities of transgender patients or from providing gender-affirming medical care under the Ryan White Program, and that incorporate or implement Executive Order 14168, "Defending Women From Gender Ideology Extremism and Restoring Biological Truth to the Federal Government."

The Court may issue a preliminary injunction when a plaintiff establishes that: "(1) it is likely to succeed on the merits; (2) it is likely to suffer irreparable harm in the absence of preliminary relief; (3) the balance of equities tips in its favor; and (4) an injunction is in the public

interest." *New Jersey v. Trump*, 131 F.4th 27, 33 (1st Cir. 2025) (citation modified). The Court may also stay final agency action to prevent irreparable injury pursuant to 5 U.S.C. § 705 under the same standard. *California v. Kennedy*, 802 F. Supp. 3d 273, 281 (D. Mass. 2025). The Court finds that Plaintiffs have carried their burden to satisfy each of those factors and that immediate relief is appropriate.

Having considered all relevant submissions, evidence, declarations, briefing, and arguments of counsel, and good cause appearing therefore, the Court **GRANTS** Plaintiffs' Motion for Preliminary Relief under 5 U.S.C. § 705 and Preliminary Injunction and **ORDERS THAT**:

1. Pursuant 5 U.S.C. § 705, the provisions of the FY 2026 HRSA General Terms and Conditions, issued on March 11, 2026, and the Notices of Funding Opportunity ("NOFOs") relating to the Ryan White HIV/AIDS Program, including the NOFOs for the Ryan White Program's Part B Supplemental, Part C, and Part F issued in June 2026, which prohibit Ryan White funding recipients from acknowledging, affirming, and/or respecting the identities of transgender patients or from providing gender-affirming medical care under the Ryan White Program are hereby temporarily stayed, postponed, and set aside during the pendency of this litigation. These provisions (hereafter the "Challenged Conditions") include the following:

    a. With regards to the FY 2026 HRSA General Terms and Conditions, the following terms and conditions are hereby temporarily stayed, postponed, and set aside:

        i. The requirement that funding recipients "apply[] sex-based definitions grounded in biological reality";

        ii. The requirement that funding recipients "ensure that all activities funded" under the program be "implemented in a manner consistent with HRSA's mission and strategic priorities," such that they (a) must comply with the

"HRSA priority to recognize that a person's sex as either male or female is unchangeable and determined by objective biology, and to ensure its programs accurately reflect science, including the biological reality of sex"; (b) may not affirm transgender people's identities or provide gender-affirming medical care, which HRSA has deemed "social or medical experimentation" that is part of "radical ideological agendas and policies"; or (c) must certify that they are "compliant with Title IX of the Education Amendments of 1972, as amended, 20 U.S.C. §§ 1681 et seq., including the requirements set forth in Presidential Executive Order 14168 titled Defending Women From Gender Ideology Extremism and Restoring Biological Truth to the Federal Government," and "will remain compliant for the duration of the Agreement" and that these are "material terms of the Agreement"; and

iii. any provision of the Health Resources and Services Administration's General Terms and Conditions, including any version incorporated into or enforced through the Ryan White HIV/AIDS Program NOFOs challenged in this action, or through any future Ryan White HIV/AIDS Program NOFO, award, continuation award, renewal, supplement, or other grant process that is materially similar to the challenged terms and would prohibit Ryan White Program funding recipients from acknowledging, affirming, and/or respecting the identities of transgender patients or from providing gender-affirming medical care under the Ryan White Program.

b. With regards to the Ryan White Program NOFOs issued in June 2026, or thereafter, the following terms and conditions are hereby temporarily stayed, postponed, and set aside:

   i. The requirement that Ryan White Program funding recipients must ensure that "[a]ll activities proposed in [an] application and budget narrative must align with applicable law, including but not limited to statutes, executive orders, federal regulations and applicable judicial holdings," such that it requires alignment and compliance with Executive Order 14168;

   ii. The requirement that funding awards "shall not be used to fund, promote, encourage, subsidize, or facilitate . . . denial by the recipient of the sex binary in humans, or the belief that sex is a chosen or mutable characteristic";

   iii. The requirement that Ryan White Program funding recipients comply with any of the Challenged Conditions in the FY 2026 HRSA General Terms and Conditions, as set forth above; and

   iv. any provision in a current or future Ryan White HIV/AIDS Program NOFO, or in any future notice of award, continuation award, renewal, supplement, or other grant process that is materially similar to the challenged terms herein and would prohibit Ryan White Program funding recipients from acknowledging, affirming, and/or respecting the identities of transgender patients or from providing gender-affirming medical care under the Ryan White Program.

2. Pursuant to Federal Rule of Civil Procedure 65, Defendants, including their employees, agents, servants, attorneys, successors and any person or entity in active concert or participation with them, are ENJOINED from implementing, enforcing, effectuating, or giving effect to the Challenged Conditions—or any materially similar policy that prohibits Ryan White funding recipients from acknowledging, affirming, and/or respecting the identities of transgender patients or from providing gender-affirming medical care under the Ryan White Program—against Provider Plaintiffs and Associational Plaintiffs' Members.

3. It is further ORDERED that the security requirement is hereby waived because Defendants will not suffer any costs from the preliminary injunction and imposing a security requirement would pose a hardship for Plaintiffs. *See* Fed. R. Civ. P. 65(c).

4. Nothing in this Order shall prohibit Defendants from administering the Ryan White HIV/AIDS Program in a manner otherwise consistent with federal law and this Order.

IT IS SO ORDERED.

MEMORANDUM OF LAW IN SUPPORT OF PLAINTIFFS' MOTION FOR PRELIMINARY RELIEF UNDER 5 U.S.C. § 705 AND PRELIMINARY INJUNCTION

TABLE OF CONTENTS

TABLE OF CONTENTS ii

TABLE OF AUTHORITIES iv

INTRODUCTION 1

BACKGROUND 2

A. HIV/AIDS Disproportionately Affects Transgender People. 2

B. Providing Gender-Affirming Medical Care Through the Ryan White Program Furthers the Program's Purpose, as Set by Congress. 3

C. The Challenged Conditions Prevent Healthcare Providers from Acknowledging their Transgender Patients and Providing Gender-Affirming Medical Care. 5

D. The Challenged Conditions Are Part of a Broader Systematic Campaign Against Transgender People. 7

E. The Challenged Conditions Will Cause Harm to Plaintiffs and Their Patients. 7

LEGAL STANDARD 10

ARGUMENT 10

I. Plaintiffs Have Standing. 10

A. Provider Plaintiffs Have Standing. 10

B. Associational Plaintiffs Have Standing. 11

II. Plaintiffs Are Likely to Succeed on the Merits. 13

A. The Challenged Conditions are Final Agency Actions for Purposes of the APA. 13

B. The Challenged Conditions Violate the APA Because They Are Arbitrary and Capricious. 14

1. The Challenged Conditions Are Contrary to the Purpose and Structure of the Ryan White Program. 15

2. The Agency's Change in Policy Ignores the Evidence Before Defendants and Ignores Important Reliance Interests. 17

C. The Challenged Conditions Violate the APA Because They Are Not in Accordance with Law. 21

1. The Challenged Conditions Are Contrary to the Ryan White Program's Enabling Statute. 21

2. The Challenged Conditions Violate Section 1554 of the ACA. 23

D. The Challenged Conditions Violate the APA Because They Are in Excess of Statutory Authority and Violate the Separation of Powers. 26

E. The Challenged Conditions Unlawfully Discriminate Based on Transgender Status and Sex. 29

F. The Challenged Conditions Violate the Right to Free Speech. 34

III. Provider Plaintiffs, Associational Plaintiffs' Members, and Their Transgender Patients Will Suffer Irreparable Harm Absent a Preliminary Injunction. 37

IV. The Remaining Factors Favor Preliminary Relief. 39

V. The Court Should Require No Bond. 40

H. Rep. 109-695 (2006) 16

Health Res. & Servs. Admin., U.S. Dep't of Health & Hum. Servs., Ryan White HIV/AIDS Program: Legislation (Dec. 2024), https://tinyurl.com/4m3hkcfe [https://perma.cc/D7DK-PZSL] 4

S. Rep. No. 106-294 (2000) 15, 16, 28

INTRODUCTION

Effectively addressing the HIV/AIDS epidemic requires affirming, culturally competent healthcare tailored to the health needs of LGBTQ people living with HIV, including transgender people living with HIV. Yet, seeking to turn back the clock to the early days of the HIV/AIDS epidemic, the current administration is deliberately attacking the ability of transgender patients living with HIV who rely on the Ryan White HIV/AIDS Program ("the Ryan White Program") to access needed healthcare. The government thus threatens not only the health and wellbeing of transgender people living with HIV, but also our Nation's ability to finally end the HIV/AIDS epidemic.

As part of the administration's campaign to repudiate the existence of transgender people and single them out for discrimination and opprobrium, Defendants have adopted a policy to prohibit healthcare providers participating in the Ryan White Program from acknowledging, affirming, or respecting their transgender patients' identities, including by prohibiting the provision of gender-affirming medical care as treatment for gender dysphoria. This policy, which effectuates one of the President's executive orders targeting transgender people, is set forth in guidance documents, the Health Resources and Services Administration's ("HRSA") general terms and conditions, and notices of funding opportunity relating to the Ryan White Program (hereafter the "Challenged Conditions," further defined in Plaintiffs' Complaint (at ¶¶ 164–187) and at Background § C, *infra*).

Providers who do not abide by these conditions risk losing access to the critical funding that allows them to care for *all* people living with HIV that rely on the Ryan White Program, which supports over half of all Americans living with HIV. Congress specifically intended Ryan White funding to support comprehensive healthcare for the most vulnerable populations. But when providers are compelled to disavow their transgender patients' existence and deny them necessary

medical care, the trust between the patients and their doctors will be broken and transgender patients will stop showing up for HIV care, risking their lives and public health generally. It is no understatement to say that, because of the Challenged Conditions, people will die.

The Challenged Conditions are not just harmful; they are illegal. They violate the Administrative Procedure Act ("APA"), the Affordable Care Act ("ACA"), the Fifth Amendment, and the First Amendment. Accordingly, and because the Challenged Conditions will cause immediate and grave harm to Plaintiffs, as well as threaten to damage the Ryan White Program's remarkable public health success, Plaintiffs and their patients, respectfully request that this Court temporarily set aside or enjoin the Challenged Conditions pending resolution of this case, just as other courts have done with regard to similar policies and executive action. The status quo will protect not only the lives, health, and wellbeing of the transgender people living with HIV who rely on the Ryan White Program for their healthcare, but also our Nation's HIV care infrastructure.

BACKGROUND

Provider Plaintiffs and Associational Plaintiffs' members are healthcare providers who offer comprehensive HIV care and primary care, including gender-affirming medical care, to their transgender patients living with HIV, through the Ryan White Program.[1] They, along with their transgender patients living with HIV who rely on the Ryan White Program for their healthcare needs, will suffer irreparable harm should the Challenged Conditions go into effect.[2]

A. HIV/AIDS Disproportionately Affects Transgender People.

Transgender people—particularly transgender women—bear a profoundly disproportionate burden of the country's HIV epidemic. Notwithstanding progress to end the

[1] Brody Decl. ¶ 20; Fox Decl. ¶¶ 31–34; Collins-Ogle Decl. ¶¶ 20–23; Doe Decl. ¶¶ 22–27; Roe Decl. ¶ 20; Packett Decl. ¶ 23; Weddle Decl. ¶ 10; Zuniga Decl. ¶ 13.
[2] Brody Decl. ¶¶ 5, 17; Fox Decl. ¶¶ 42–45; Collins-Ogle Decl. ¶¶ 5, 15–16; Roe Decl. ¶ 7; Doe Decl. ¶¶ 8, 14; Packett Decl. ¶¶ 5–6; Weddle Decl. ¶¶ 5–6, 17–18; Zuniga Decl. ¶¶ 5–6.

epidemic, HIV continues to be a major public health concern among sexual and gender minority populations.[3] The risk of acquiring HIV among transgender and other gender-minority individuals is thirteen times that of the cisgender population.[4] According to the Centers for Disease Control and Prevention ("CDC"), transgender people make up 2% of new HIV diagnoses in recent year-to-year data despite comprising only about 1% of the United States population aged 13 and older. *Id.* The CDC further estimates that approximately 14% of transgender women in the United States are living with HIV, with prevalence rates reaching 44% among Black transgender women and 26% among Hispanic/Latina transgender women.[5] This disproportionate impact is driven by structural barriers like stigma, discrimination, poverty, homelessness, and lack of access to culturally competent and gender-affirming healthcare, all of which significantly impair access to HIV prevention and treatment services.[6]

B. Providing Gender-Affirming Medical Care Through the Ryan White Program Furthers the Program's Purpose, as Set by Congress.

Congress created the Ryan White Program as a comprehensive, integrated system of HIV care. The goal of the Program is to offer a safety net for people living with HIV by providing outpatient HIV care, treatment, and support services to those without health insurance or who experience gaps in coverage.[7] Following its initial adoption and implementation, the Ryan White Program was expanded by Congress to address the unmet care and treatment needs of people living with HIV by focusing funding on primary healthcare and support services to enhance access to and retention in care and adherence to daily treatment.[8]

Because HIV is a complex, chronic condition that disproportionately affects medically and

[3] Zuniga Decl. ¶ 19.
[4] Zuniga Decl. ¶ 20.
[5] Abrigo Decl., Ex. A
[6] Zuniga Decl. ¶¶ 24–25; *see also* Zuniga Decl., Ex. D at 1–2.
[7] Weddle Decl. ¶ 16. Packett Decl. ¶ 25.; Collins-Ogle Decl. ¶ 5.
[8] Weddle Decl. ¶ 17.

socially vulnerable populations, Congress structured the Ryan White Program to address the full spectrum of health and supportive service needs of people living with HIV.[9] It does so to prevent new HIV infections, improve health outcomes for people living with HIV, reduce the health disparities affecting people living with HIV, and achieve integrated and coordinated efforts that address the HIV/AIDS epidemic. *Id.* Over half of all people diagnosed with HIV are served through the Ryan White Program, and many would not have access to necessary healthcare services and treatment without the program.[10]

The Ryan White statute repeatedly references coordinated "systems of care," continuity of care, retention in care, and outpatient primary healthcare for people living with HIV. *See* 42 U.S.C. §§ 300ff–11, 300ff–12(b)(4), 300ff–21, 300ff–23(a), (c), 300ff–51, 300ff–71. Consistent with that structure, as HRSA explains, the various parts of the Ryan White Program "give [Ryan White] recipients flexibility to address HIV care needs."[11] The statute authorizes broad categories of outpatient and ambulatory health services, mental health treatment, substance use treatment, medical case management, transportation, outreach, and adherence support services. *See* 42 U.S.C. §§ 300ff–14(c)–(d), 300ff–22(b)–(c), 300ff–51(c)–(d), 300ff–71(b).

Under the Ryan White statute, local planning councils and state consortia are charged with assessing local epidemiological data; identifying unmet service needs among affected subpopulations and historically underserved communities; establishing funding priorities based on the priorities of the communities with HIV for whom the services are intended; and designing coordinated systems of care pursuant to the statute's broad purpose, as set by Congress. *See* 42 U.S.C. §§ 300ff–12(b)(1), (b)(4)(B)(ii), (d); 300ff–23(a), (c); 300ff–27(b)(7)(B).

---

[9] Packett Decl. ¶ 25.
[10] Weddle Decl. ¶ 15.
[11] Health Res. & Servs. Admin., U.S. Dep't of Health & Hum. Servs., *Ryan White HIV/AIDS Program: Legislation* (Dec. 2024), https://tinyurl.com/4m3hkcfe [https://perma.cc/D7DK-PZSL].; *see also* Packett Decl. ¶ 27.

Providing affirming healthcare (i.e., care that is mindful and respectful of a transgender patient's identity) and medical treatment for gender dysphoria (i.e., "gender-affirming medical care"), such as gender-affirming hormone therapy, through the Ryan White Program furthers the Program's central goals of retention in care, treatment adherence, and long-term viral suppression for people living with HIV.[12] Patients living with HIV are more likely to remain engaged in treatment when they receive integrated and affirming care addressing their broader healthcare needs.[13] Ryan White-funded providers have long incorporated gender-affirming medical care into integrated HIV treatment models designed to improve adherence and retention in care.[14] Ryan White planning councils, planning bodies, and consortia across the country likewise recognize transgender people as a priority population disproportionately affected by HIV and have prioritized strategies that fund and emphasize gender-affirming care to improve engagement in HIV treatment and health outcomes. *See* Compl. ¶¶ 116–125 (collecting guidance).

C. The Challenged Conditions Prevent Healthcare Providers from Acknowledging their Transgender Patients and Providing Gender-Affirming Medical Care.

This case challenges conditions imposed on recipients of Ryan White funding through Defendants' implementation of Executive Order 14168, *Defending Women From Gender Ideology Extremism and Restoring Biological Truth to the Federal Government*, 90 Fed. Reg. 8650 (Jan. 20, 2025) ("Gender Order"), which directs that federal funding not be used to promote "gender ideology," including through the FY 2026 HRSA General Terms and Conditions ("Updated FY2026 General Terms"), issued on March 11, 2026, and the Ryan White Program Notices of Funding Opportunity ("NOFOs") issued or projected to be issued in June 2026.[15]

---

[12] Brody Decl. ¶¶ 5, 17; Fox Decl. ¶¶ 5, 16–18; Collins-Ogle Decl. ¶ 5; Roe Decl. ¶ 7.
[13] Brody Decl. ¶¶ 13–15; Fox Decl. ¶¶ 16–18; Collins-Ogle Decl. ¶¶ 5–16.
[14] Brody Decl. ¶¶ 5, 12–17; Fox Decl. ¶¶ 5, 11, 16–18; Collins-Ogle Decl. ¶¶ 5, 10, 14–15; Weddle Decl. ¶¶ 10, 12, 17; Zuniga Decl. ¶¶ 13–14.
[15] Abrigo Decl., Ex. B (HRSA GTC), Ex. I (Part B Suppl. NOFO), Ex. J (Part C NOFO), Ex. K (Part F NOFO).

The Updated FY2026 General Terms require Ryan White funding recipients to "apply[] sex-based definitions grounded in biological reality" and incorporate HRSA's "strategic priorities," which specify that, "[i]t is a HRSA priority to recognize that a person's sex as either male or female is unchangeable and determined by objective biology, and to ensure its programs accurately reflect science, including the biological reality of sex."[16] The NOFOs incorporate the Updated FY2026 General Terms and further implement them in various ways, such as by prohibiting the use of Ryan White funds for "sex-trait modification procedures" or "to fund, promote, encourage, subsidize, or facilitate . . . denial by the recipient of the sex binary in humans, or the belief that sex is a chosen or mutable characteristic."[17]

The Updated FY2026 General Terms and the NOFOs implement the Gender Order. The Gender Order commands federal agencies to reject recognition of transgender identities and implement policies based on sex assigned at birth, including by denying gender-affirming medical care for transgender people.[18]

Together, the Updated FY2026 General Terms, any similar terms in the NOFOs, and any other actions implementing the Gender Order with regard to the Ryan White Program constitute the "Challenged Conditions" in this case. *See* Compl. ¶¶ 164-187; *see also id.* ¶¶ 156-157.

The Challenged Conditions apply or will apply across Ryan White funding streams, including Parts A, B, C, D, and F, incorporated through HRSA grant conditions and various Notices of Award. Compl. ¶¶164-187. In concert, the Challenged Conditions impose restrictions on Ryan White-funded providers providing integrated HIV care to transgender patients, including hormone therapy and other affirming care delivered as part of outpatient primary healthcare. Compl. ¶¶ 90–

[16] Abrigo Decl., Ex. B (HRSA GTC) and Ex. C (HRSA Priorities).
[17] Abrigo Decl., Ex. D (ADAP NOFO), Ex. I (Part B Suppl. NOFO), Ex. J (Part C NOFO), Ex. K (Part F NOFO).
[18] Abrigo Decl. Ex. E.

103, 164–187. Compliance with the Challenged Conditions would require providers to either (1) refrain from acknowledging, affirming, or respecting the identities of transgender people and from using federal funds to provide medically indicated gender-affirming medical care to transgender patients living with HIV or (2) risk losing critical Ryan White funding necessary to operate their HIV programs and to care for their patients living with HIV, including transgender people.[19]

D. The Challenged Conditions Are Part of a Broader Systematic Campaign Against Transgender People.

The Challenged Conditions do not arise in isolation. They are part of a broader government-wide effort to erase recognition of transgender people and restrict access to gender-affirming medical care. *See generally* Compl. ¶¶ 130–163. They are "part of a constellation of close-in-time executive actions directed at transgender Americans that contained powerfully demeaning language." *Orr v. Trump*, 778 F.Supp.3d 394, 417 (D. Mass. 2025) (documenting actions), *appeal dismissed as moot and injunction vacated on other grounds,* No. 25-1579 (1st Cir. June 5, 2026); *see also Endocrine Soc'y v. Fed. Trade Comm'n*, No. CV 26-512 (JEB), 2026 WL 1257289, at *2 (D.D.C. May 7, 2026); *Talbott v. United States*, 775 F.Supp.3d 283, 330-32 (D.D.C. 2025), *aff'd in part*, *vacated in part, remanded,* No. 25-5087, 2026 WL 1532205 (D.C. Cir. 2026).

E. The Challenged Conditions Will Cause Harm to Plaintiffs and Their Patients.

The Challenged Conditions are particularly harmful in the context of the HIV epidemic because transgender people, especially transgender women of color, experience disproportionately high rates of HIV and significant barriers to healthcare. *See* Background Section A, *supra*.[20] The Challenged Conditions undermine longstanding public health efforts designed to improve engagement in HIV care for populations disproportionately affected by HIV and threaten to

[19] Brody Decl. ¶¶ 5, 17; Fox Decl. ¶¶ 5, 16–18; Collins-Ogle Decl. ¶¶ 5, 15–16; Roe Decl. ¶ 7; Doe Decl. ¶¶ 8, 14, 19; Packett Decl. ¶¶ 5–6; Weddle Decl. ¶¶ 5–6, 17–18; Zuniga Decl. ¶¶ 5–6; Compl. ¶¶ 188–202; Abrigo Decl. Ex. L.
[20] Weddle Decl. ¶ 6; Zuniga Decl. ¶ 6; Brody Decl. ¶¶ 11, 17; Roe Decl. ¶¶ 7, 13.

destabilize integrated HIV treatment systems developed over decades through the Ryan White Program.[21]

The Challenged Conditions thus threaten immediate and concrete harm to Provider Plaintiffs, Associational Plaintiffs' members, and their patients. Ryan White-funded HIV programs are structured around integrated models of care that depend on providers being able to offer affirming, comprehensive, and continuous treatment to transgender patients living with HIV.[22]

Transgender patients living with HIV already face substantial barriers to healthcare engagement, including stigma, discrimination, unstable housing, mental health conditions, and distrust of medical systems.[23] Integrated gender-affirming medical care and care that respects patients' identities promotes trust, retention in care, medication adherence, and long-term viral suppression.[24]

The Challenged Conditions directly threaten those treatment relationships. Being able to acknowledge and respect the identities of transgender patients who rely on the Ryan White Program for their HIV care and other health needs, and to provide them with gender-affirming medical care when indicated through Ryan White funds, is "critical to maintaining patient trust, adherence to antiretroviral therapy, retention in care, and sustained viral suppression." Collins-Ogle Decl. ¶ 5. "Research . . . consistently shows that when transgender people feel supported and affirmed in their identity by health care providers, they are more likely to access HIV testing, engage with pre-exposure prophylaxis, adhere to ART [antiretroviral therapy], and achieve viral suppression." Zuniga Decl. ¶ 35. If Ryan White-participating clinics and providers are prohibited

[21] Weddle Decl. ¶¶ 6, 15–18; Packett Decl. ¶¶ 5–6, 10–13; Zuniga Decl. ¶¶ 6, 12–14; Collins-Ogle Decl. ¶¶ 5, 12–15; Compl. ¶¶ 81–125, 126–129, 143–163.
[22] Brody Decl. ¶¶ 13–17; Fox Decl. ¶¶ 5, 10–11; Collins-Ogle Decl. ¶¶ 14–16; Doe Decl. ¶¶ 13, 22.
[23] Compl. ¶¶ 54–57, 99–103; Brody Decl. ¶¶ 5, 11, 17; Packett Decl. ¶ 32; Zuniga Decl. ¶ 38.
[24] Brody Decl. ¶ 5; Fox Decl. ¶¶ 16–18; Collins-Ogle Decl. ¶¶ 15–16.

from acknowledging and respecting the identities of their transgender patients or lose their ability to provide gender-affirming medical care, patients will be less "open and honest with their healthcare providers about symptoms, behaviors, and healthcare needs," which will lead to "misdiagnosis, missed diagnosis, not being offered preventative health services like screenings, and other adverse health outcomes." Fox Decl. ¶ 40. Causing "transgender patients to lose trust in their healthcare providers and [] clinic[s] in general," in turn, "lead[s] to a lack of engagement in healthcare and avoidance of dealing with acute or chronic illness." Brody Decl. ¶ 17.[25] This can result in "missed medications," "treatment interruptions," "loss of viral suppression," and "significant deterioration in mental health, including increased depression and suicidality," *Id.* as well as resistance to medications that were previously effective, limiting treatment options.[26] Transgender patients who disengage from care may develop preventable complications of their HIV infection and other conditions, "which are significantly more difficult to treat once they have progressed." Brody Decl. ¶ 37.

These harms are especially acute in medically underserved communities, including rural and non-Medicaid expansion jurisdictions where Ryan White-funded HIV clinics often serve as the only viable source of competent HIV care and gender-affirming medical care for transgender patients living with HIV,[27] as well as for homeless patients who "often have lasting consequences because re-engagement is extremely challenging." Brody Decl. ¶ 53.

The Challenged Conditions also harm Plaintiffs and their members by disrupting integrated HIV care programs and interfering with their ability to deliver evidence-based HIV treatment

[25] Fox Dec. ¶ 40; Doe Decl. ¶ 44; *see also* Packett Decl. ¶ 31; Brody Decl. ¶ 26; Roe Decl. ¶ 36.
[26] Packett Decl. ¶¶ 32, 42; Zuniga Decl. ¶ 38; Weddle Decl. ¶ 53; Doe Decl. ¶¶ 43–45; Roe Decl. ¶¶ 35–37; Brody Decl. ¶ 5.
[27] Collins-Ogle Decl. ¶¶ 11–12; Roe Decl. ¶¶ 7, 9, 11.

consistent with accepted medical standards.[28]

Absent preliminary relief, Plaintiffs and their patients are likely to suffer irreparable harm, including disruption of treatment relationships, loss of medically necessary care, reduced retention in HIV treatment, worsening health outcomes, and increased risk of HIV transmission.[29]

LEGAL STANDARD

A party seeking a preliminary injunction must show: "(1) it is likely to succeed on the merits; (2) it is likely to suffer irreparable harm in the absence of preliminary relief; (3) the balance of equities tips in its favor; and (4) an injunction is in the public interest." *New Jersey v. Trump*, 131 F.4th 27, 33 (1st Cir. 2025) (citation modified). The final two factors merge where the government is the opposing party. *See Nken v. Holder*, 556 U.S. 418, 435 (2009). The APA independently authorizes a reviewing court to stay final "agency action" to "prevent irreparable injury." 5 U.S.C. § 705. The standard for granting a § 705 stay is the same as that for obtaining a preliminary injunction. *See California v. Kennedy*, 802 F.Supp.3d 273, 281 (D. Mass. 2025).

ARGUMENT

I. Plaintiffs Have Standing.

"To have standing, a plaintiff must present an injury that is concrete, particularized, and actual or imminent; fairly traceable to the defendant's challenged behavior; and likely to be redressed by a favorable ruling." *Dep't of Com. v. New York*, 588 U.S. 752, 766 (2019) (citation modified). Each Provider Plaintiff and Associational Plaintiff satisfies this standard.

A. Provider Plaintiffs Have Standing.

Provider Plaintiffs have standing under the APA because they are regulated parties adversely affected by agency action and their interests are "within the zone of interests to be

[28] Packett Decl. ¶¶ 5–6, 11–13; Weddle Decl. ¶¶ 5–6, 11–13; Zuniga Decl. ¶¶ 5–6, 11–14, 31.
[29] Brody Decl. ¶¶ 5, 17; Fox Decl. ¶ 20; Collins-Ogle Decl. ¶¶ 15–16; Roe Decl. ¶ 7.

protected or regulated by the statute." *See Food & Drug Admin. v. R.J. Reynolds Vapor Co.*, 606 U.S. 226, 232–33 (2025). Plaintiffs are Ryan White-funded HIV providers directly regulated by the Challenged Conditions and are precisely the entities Congress intended to operate the comprehensive systems of HIV care established under the Ryan White Program.

As a direct result of Defendants' conduct, Provider Plaintiffs face immediate and concrete injuries to their medical practices, professional obligations, and Ryan White-funded HIV programs. The Challenged Conditions force providers to choose between continuing to provide affirming healthcare and gender-affirming medical care to transgender patients living with HIV and risk losing critical Ryan White funding or ending their provision of respectful, medically appropriate care to their transgender patients in violation of accepted standards of medicine and thereby disrupting longstanding treatment relationships.[30]

Provider Plaintiffs also have third-party standing to assert the rights of their transgender patients living with HIV. Courts have consistently recognized that healthcare providers may assert the constitutional and statutory rights of their transgender patients where challenged government action interferes with the provision of medical care. *See*, *e.g.*, *Am. Ass'n of Physicians for Hum. Rts., Inc. v. Nat'l Institutes of Health*, 795 F.Supp.3d 678, 693–94 (D. Md. 2025) ("*GLMA*"); *San Francisco A.I.D.S. Found. v. Trump*, 786 F.Supp.3d 1184, 1212–13 (N.D. Cal. 2025) ("*SFAF*"); *Washington v. Trump*, 768 F.Supp.3d 1239, 1258 (W.D. Wash. 2025); *Whitman-Walker Clinic, Inc. v. U.S. Dep't of Health & Hum. Servs.*, 485 F.Supp.3d 1, 34–36 (D.D.C. 2020); *City & Cnty. of S.F. v. Azar*, 411 F.Supp.3d 1001, 1011 (N.D. Cal. 2019).

B. Associational Plaintiffs Have Standing.

Associational Plaintiffs satisfy the requirements for associational standing because: "(a)

[30] Doe Decl. ¶¶ 51–52; Brody Decl. ¶ 39; Fox Decl. ¶¶ 44–45.

[their] members would otherwise have standing to sue in their own right; (b) the interests [they] seek[] to protect are germane to the organization[s'] purpose[s]; and (c) neither the claim asserted nor the relief requested requires the participation of individual members in the lawsuit." *See Hunt v. Wash. State Apple Advert. Comm'n*, 432 U.S. 333, 343 (1977); *see also Students for Fair Admissions, Inc. v. President & Fellows of Harvard Coll.*, 600 U.S. 181, 199–201 (2023).

First, Associational Plaintiffs each have members who independently possess standing for the same reasons Provider Plaintiffs have standing.[31]

Second, the interests Associational Plaintiffs seek to protect are germane to their organizational missions: The Academy exists to support HIV practitioners and promote accessible, quality HIV care, including through education, credentialing, and advocacy relating to integrated HIV treatment; HIVMA advances access to healthcare services for people living with HIV and supports a robust and culturally competent HIV workforce; and IAPAC's mission is to expand access to and improve the quality of HIV prevention, care, treatment, and support services for people living with HIV worldwide.[32] Ensuring that their members can continue to provide evidence-based care for transgender patients living with HIV falls squarely within those missions.

Third, neither Plaintiffs' claims nor the requested relief requires participation of individual members. *See United Food & Com. Workers Union Loc. 751 v. Brown Grp*., Inc., 517 U.S. 544, 546 (1996) ("individual participation is not normally necessary when an association seeks prospective or injunctive relief for its members") (citation omitted). Plaintiffs challenge the legality of Defendants' nationwide funding conditions under the APA, Section 1557 of the Affordable Care Act, and the Constitution. They seek declaratory and injunctive relief prohibiting

[31] Packett Decl. ¶¶ 5–6, 11–13; Weddle Decl. ¶¶ 5–6, 10, 15–18; Zuniga Decl. ¶¶ 5–6, 12–14; Brody Decl. ¶¶ 16–20; Fox Decl. ¶¶ 31–34; Collins-Ogle Decl. ¶¶ 20–25; Roe Decl. ¶¶ 20–21; Doe Decl. ¶¶ 22–28.
[32] Packett Decl. ¶¶ 7–13; Weddle Decl. ¶¶ 7–13; Zuniga Decl. ¶¶ 7–11.

their enforcement. Because the claims turn on the lawfulness of Defendants' policies, not member-specific factual determinations, any relief would benefit all affected members and their patients alike and does not require their individual participation. *See Warth v. Seldin*, 422 U.S. 490, 515 (1975).

Furthermore, Associational Plaintiffs have derivative standing to assert claims on behalf of the transgender patients of its provider members. *See Pa. Psychiatric Soc'y v. Green Spring Health Servs., Inc.*, 280 F.3d 278, 293 (3d Cir. 2002) ("If on remand the Pennsylvania Psychiatric Society warrants associational standing to represent its members, we conclude it also may have derivative authority to raise the claims of its members' patients.").

II. Plaintiffs Are Likely to Succeed on the Merits.

A. The Challenged Conditions are Final Agency Actions for Purposes of the APA.

The APA authorizes judicial review of "final agency action." 5 U.S.C. § 704. An agency action is final when it "mark[s] the consummation of the agency's decisionmaking process" and determines "rights or obligations . . . from which legal consequences will flow." *Bennett v. Spear*, 520 U.S. 154, 177–78 (1997) (citation modified).

The Challenged Conditions, including the Updated FY2026 General Terms and the Part B Supplemental, Part C, and Part F NOFOs, are final agency action under the APA. Assessing a previous version of the HRSA General Terms and Conditions at issue here, another court in this Circuit held that "[t]he insertion of the Challenged Conditions into prospective and current grant agreements" constitutes final agency action. *Rhode Island Coal. Against Domestic Violence v. Kennedy*, 812 F.Supp.3d 180, 191 (D.R.I. 2025) ("*R.I. Coalition*") (finding prior version of HRSA's general terms as well as NOFOs to be final agency action), *appeal dismissed sub nom. Rhode Island Coal. Against Domestic Violence v. United States Dep't of Hous. & Urb. Dev.*, No. 25-2229, 2026 WL 926474 (1st Cir. Jan. 5, 2026).

"As numerous other courts have likewise explained, the decision to attach the conditions [to NOFOs] can be final even if the final decision to award the funds and issue the NOFOs is still pending." *Illinois v. Fed. Emergency Mgmt. Agency*, 801 F.Supp.3d 75, 89 (D.R.I. 2025) (holding that final agency action had occurred where "the challenged conditions remain applicable to all FY 2025 grants"); *see also Freedom Network USA v. Trump*, Civ. Act. No. 25 C 12419, 2026 WL 800392, at *19 (N.D. Il. Mar. 23, 2026) (conditions attached to NOFOs "demonstrated the consummation of [defendant's] decision-making process regarding its priorities and considerations in evaluating grant applications" and they "require[] an immediate and significant change in the plaintiffs' conduct of their affairs with serious penalties attached to noncompliance.").

Accordingly, the Challenged Conditions—funding requirements that compel grantee conduct "in no uncertain terms"—constitute final agency action. *See Freedom Network USA*, 2026 WL 800392, at *19.[33]

B. The Challenged Conditions Violate the APA Because They Are Arbitrary and Capricious.

The APA directs reviewing courts to "hold unlawful and set aside agency action[s]" that are arbitrary or capricious. 5 U.S.C. § 706(2)(A). Agency action is arbitrary and capricious when it "relie[s] on factors which Congress has not intended it to consider, entirely fail[s] to consider an important aspect of the problem, offer[s] an explanation for its decision that runs counter to the evidence before the agency, or is so implausible that it could not be ascribed to a difference in view or the product of agency expertise." *Motor Vehicle Ass'n v. State Farm Mut. Auto. Ins.*, 463 U.S. 29, 43 (1983). Agency action is also arbitrary and capricious when the agency has failed to "consider[] the factors relevant to" its decision "that will best serve the purposes" of the statute it

[33] In addition, as numerous courts have found, the agency action here—the implementation of grant terms and conditions—is not committed to exclusive agency discretion. *See R.I Coalition*, 812 F.Supp.3d at 192-93. Accordingly, the Challenged Conditions are subject to judicial review under the APA.

is applying. *Am. Paper Inst., Inc. v. Am. Elec. Power Serv. Corp.*, 461 U.S. 402, 413 (1983); *see also River Street Donuts, LLC v. Napolitano*, 558 F.3d 111, 117 (1st Cir. 2009) (same).

In addition, when agency action deviates from past policy or practice, the agency must provide a "more detailed justification than what would suffice for a new policy created on a blank slate." *FCC v. Fox Television Stations, Inc.*, 556 U.S. 502, 515 (2009). And when the prior policy "has engendered serious reliance interests," *id.*, the agency must "assess [those] reliance interests, determine whether they were significant, and weigh any such interest against competing policy concerns," *Dep't of Homeland Sec. v. Regents of the Univ. of Cal.*, 591 U.S. 1, 33 (2020).

The Challenged Conditions are arbitrary and capricious for multiple reasons, any one of which is sufficient to render them unlawful. Plaintiffs are therefore likely to succeed on Count I.

1. The Challenged Conditions Are Contrary to the Purpose and Structure of the Ryan White Program.

The Challenged Conditions contravene the purpose and structure of the Ryan White Program. Congress set forth several clear purposes that Defendants were required to consider in structuring the Ryan White Program. *First*, Congress directed that the Program provide comprehensive care for *all* individuals living with HIV, and particularly "those communities and populations that have been historically most underserved, as well as those that are experiencing rapid increases in HIV infection and AIDS case counts." S. Rep. No. 106-294, 12 (2000); *see also*, 42 U.S.C. § 300ff–12(b) (requiring local planning councils to determine the needs of the local population living with HIV and establish priorities paying "particular attention to" the needs of "disproportionately affected and historically underserved groups"); 42 U.S.C. § 300ff–52(a)(2) (directing that funding recipients "shall serve underserved populations"). *Second*, Congress directed Ryan White funds to be used to "improve the quality of life for those infected or affected" by the HIV epidemic by strengthening care retention rates, increasing viral suppression, and

bettering overall health outcomes. H. Rep. 109-695, 2 (2006). *Third*, Congress "recognize[d] and affirm[ed]" that the HIV epidemic is "best addressed through a local process" spearheaded by decisionmakers familiar with "shifting trends in the local epidemic, disparities in healthcare access and outcomes, and the need for capacity developing with the HIV health care infrastructures." S. Rep. No. 106-294, 13; *see also* 42 U.S.C. § 300ff–12(b) (requiring the creation of local planning councils); § 300ff–23(a), (c) (establishing consortia and directing them to demonstrate a record of service to subpopulations that reflect local incidence of HIV, based on identified needs of those communities).

The Challenged Conditions flout those congressional mandates. *First*, instead of supporting historically underserved groups, such as transgender people, the Challenged Conditions require Plaintiffs to discriminate against transgender patients by refusing to acknowledge, respect, or affirm their identities in any respect, even if unconnected to the provision of gender-affirming medical care, and prohibit Plaintiffs from providing gender-affirming medical care.[34] As the statute contemplated, "Ryan White-funded clinics open the door for treatment for transgender patients who often do not access routine healthcare because clinicians can address patients' comprehensive health needs, including gender-affirming medical care, when administering HIV care." Zuniga Decl. ¶ 35.[35] But the Challenged Conditions would discourage many prospective patients from accessing and retaining HIV-related care altogether.[36]

Second, the Challenged Conditions would harm the health, wellbeing, and quality of life for individuals infected or affected by HIV by reducing care retention rates, decreasing viral suppression, and worsening overall health outcomes population-wide, which will "create[] an

[34] S*ee* Weddle Decl. ¶ 22; Zuniga Decl. ¶¶ 19–26, 34.
[35] *See also* Collins-Ogle Decl. ¶¶ 20, 23, 36; Fox Decl. ¶ 29; Roe Decl. ¶ 19–21.
[36] *See* Collins-Ogle Decl. ¶¶ 28–30, 41–45; Fox Decl. ¶ 30; Roe Decl. ¶ 24–31; Zuniga Decl. ¶ 38; *cf.* Weddle Decl. ¶ 49 (noting the likely economic impact of the Challenged Conditions)

exponential problem that compromises public health." Weddle Decl. ¶¶ 54–55.[37] By dissuading transgender patients from accessing and retaining HIV-related care, the Challenged Conditions are likely to "increas[e] the risk of transmitting HIV . . . [to] the community-at-large" across demographic groups. Weddle Decl. ¶ 53.[38] This will diminish overall patient- and community-health outcomes across the country well-beyond the community of individuals living with HIV who are transgender.[39]

Third, the Challenged Conditions ignore Congress's determination that local entities, specifically, the State Consortia and local planning councils—not Defendants—are best equipped to analyze shifting trends in local HIV epidemics, to address disparities in healthcare access and outcomes in local communities, and to build effective local HIV health-care infrastructure. *See* Background Section B, *supra*. Instead, Defendants seek to impose a global rule that prohibits respectful and affirming care for an entire population without considering local conditions or priorities.

2. The Agency's Change in Policy Ignores the Evidence Before Defendants and Ignores Important Reliance Interests.

The Challenged Conditions fail to acknowledge—let alone justify—Defendants' departure from their prior policies supporting respecting transgender patients' identities and the use of Ryan White funding for gender-affirming medical care. Those prior policies were based on the scientific consensus that gender-affirming medical care is beneficial and medically necessary for people with gender dysphoria and enhances treatment adherence. Further, those prior policies "engendered serious reliance interests," *Fox Television*, 556 U.S. at 515, that Defendants also failed to adequately assess, *see Regents of the Univ. of Cal.*, 591 U.S. at 33.

[37] *See* Collins-Ogle Decl. ¶¶ 30, 35, 41–48; Packett Decl. ¶ 42; Zuniga Decl. ¶ 38; Weddle Decl. ¶ 53.
[38] *See also* Collins-Ogle Decl. ¶ 64; Weddle Decl. ¶ 42; Zuniga Decl. ¶ 38.
[39] *See* Collins-Ogle Decl. ¶¶ 41–48; Zuniga Decl. ¶ 38.

As Defendants themselves acknowledged in 2021: "Providing gender-affirming medical care is an important strategy to effectively address the health and medical needs of transgender people with HIV." Weddle Decl., Ex. J. Defendants explained that healthcare providers could use Ryan White funds to help transgender patients receive a variety of forms of gender-affirming medical care including by "purchas[ing] and maintain[ing] private health insurance, Medicaid, and Medicare coverage" that can support the health needs of transgender people with HIV; providing mental health services for individuals suffering from gender dysphoria and social and emotional stress stemming from anti-transgender discrimination, stigma, and rejection; and providing housing, case management, and substance use disorder treatment services for transgender individuals. *Id.* at 2.

Similarly, 2024 guidance published by HHS previously affirmed, *inter alia*, that "[a]dherence to [gender-affirming] hormone therapy correlates with adherence to ART," that "integrating HIV care with gender care facilitates treatment and is associated with higher rates of viral suppression," that "care integration makes it easier to discuss concerns about drug–drug interactions between HIV treatment and gender-affirming medications," that "HIV care services should be provided within a gender-affirmative care model to reduce potential barriers to ART [antiretroviral therapy] adherence and to maximize the likelihood of achieving sustained viral suppression," and that "[i]ntegrating hormone therapy with HIV services is the recommended practice." Weddle Decl., Ex. F at I-102–03. Not only did HHS delete the chapter "Transgender People with HIV" from the 2025 version of the guidelines, without any explanation, but the Challenged Conditions completely ignore this guidance.[40]

The Challenged Conditions abandon this guidance and now prohibit the very forms of care

[40] Weddle Decl. ¶ 32; *see also* Weddle Decl., Ex. G (2025 version of HHS guidelines); Compl. ¶ 158.

that Defendants previously encouraged, without any acknowledgement of the change, much less the "more detailed justification" that such an about-face requires. *See Fox Television*, 556 U.S. at 515.

In reversing course now, Defendants ignore the strong scientific consensus that gender-affirming medical care is evidence-based and, for many transgender patients living with HIV, necessary to achieve long-term positive health outcomes for the patient and for the broader community.[41] That consensus is shared by nearly every major medical association.[42] What is more, Defendants ignore that access to gender-affirming medical care is crucial to encouraging continued participation in comprehensive healthcare, including HIV treatment, which in turn helps maintain viral suppression and control the spread of HIV infections in the larger population.[43]

Defendants have also altogether failed to "assess whether there were reliance interests" in their prior policy, "determine whether they were significant, and weigh any such interest against competing policy concerns." *Regents of the Univ. of Cal.*, 591 U.S. at 33. In a recent case, a court preliminarily enjoined similar funding conditions that barred the promotion of "gender ideology." *R.I. Coalition*, 812 F.Supp.3d at 199. That court found a likelihood of success on the merits that the conditions were arbitrary and capricious in part because "it is impossible for this Court to find that the Defendants considered the harmful impact their decision would have on . . . the vulnerable populations they serve." *Id*. at 193 (quotation omitted).

Plaintiffs have used Ryan White funds to structure entire care models that improve

[41] *See* Weddle Decl. ¶¶ 40–41, 53.
[42] *See* Abrigo Decl., Ex. F (collecting statements from, *inter alia*, the American Medical Association, American Academy of Pediatrics, American College of Physicians, American Psychiatric Association, American Psychological Association, Endocrine Society, World Health Organization, and World Professional Association for Transgender Health); *see also* Abrigo Decl., Ex. G. *See also Grimm v. Gloucester Cnty. Sch. Bd.*, 972 F.3d 586, 595 (4th Cir. 2020), *as amended* (Aug. 28, 2020); *Edmo v. Corizon, Inc.*, 935 F.3d 757, 769 (9th Cir. 2019).
[43] *See* Zuniga Decl. ¶ 34; Packett ¶ 17; Weddle Decl., Ex. F (2024 HHS guidelines) at I-102–03.

retention rates and viral suppression among transgender individuals living with HIV.[44] Plaintiffs and their members have made significant investments in staffing and facilities to provide holistic care to people living with HIV—interweaving gender-affirming medical care as a part of treatment plans that include other necessary medical treatment, family support, case management, medical transportation, access to specialists, and hospice care.[45]

The Challenged Conditions will disrupt that infrastructure by forcing providers to forgo crucial government support for current staff and programs unless they are willing to abandon their commitments to offer comprehensive and effective care to *all* their patients.[46] Such abandonment of care would shatter patients' trust, which in turn would undermine their reliance interests, jeopardize their health and wellbeing, and damage the Ryan White Program's public health goal of controlling the spread of HIV.[47] The Updated FY2026 General Terms worsen that impact by barring Plaintiffs from communicating with transgender patients living with HIV using the pronouns and other language that aligns with their identities, even when providing medical services not banned by the Challenged Conditions. *See* Updated FY2026 General Terms § 5(b) (requiring "sex-based definitions grounded in biological reality"). This would make it impossible for Plaintiffs—often the only providers to whom transgender individuals have access—to provide any care at all.[48]

* * *

All told, the Challenged Conditions are not the products of reasoned decision-making

[44] *See* Collins-Ogle Decl. ¶¶ 17, 21–22; Doe Decl. ¶ 23; Brody Decl. ¶ 20.
[45] *See* Brody Decl. ¶¶ 11–12; Doe Decl. ¶ 23.
[46] *See* Doe Decl. ¶¶ 22, 31–41; Packett Decl. ¶ 35.
[47] *See* Roe Decl. ¶¶ 14–16, 27–28; Plackett Decl. ¶ 31.
[48] *See* Fox Decl. ¶ 39 ("If we cannot continue to . . . use a patient's name, gender identity, and pronouns, it is likely that our transgender patients would stop coming and would drop off from all care, including HIV care."); Roe Decl. ¶ 25 ("[B]eing able to acknowledge and affirm my transgender patients' identities[] is essential to building trust with [them]. . . . That trust directly affects whether my patients remain in care.").

proceeding from a rational assessment of data, evidence, potential impact, or reliance interests. Defendants can offer no coherent explanation of how the Challenged Conditions serve Congress's purposes in providing Ryan White funding. Nor have they attempted to justify singling out one type of recipient (transgender people) and one form of medical treatment from all other types of core medical services (both HIV-specific and non-HIV-specific) funded by Ryan White. This lack of explanation renders the Challenged Conditions arbitrary and capricious. *See Massachusetts v. Nat'l Institutes of Health*, 770 F.Supp.3d 277, 305 (D. Mass. 2025) ("*Massachusetts v. NIH*") ("[A]gencies must provide reasons that both exhibit sufficient consideration of the relevant factors and pertinent aspects of the problem and demonstrate a rational connection between the facts and choice that was made."), *judgment entered,* No. 1:25-CV-10338, 2025 WL 1063760 (D. Mass. Apr. 4, 2025), and *aff'd*, 164 F.4th 1 (1st Cir. 2026).

Instead, the Challenged Conditions self-evidently reflect "unjustifiable bias." *Level the Playing Field v. FEC*, 961 F.3d 462, 464 (D.C. Cir. 2020). The Challenged Conditions thus appear to be yet another attempt from the current Administration to target and stigmatize the transgender community—all while ignoring the considered judgments of Congress and the state and regional councils and consortia that Congress empowered to formulate treatment priorities.

C. The Challenged Conditions Violate the APA Because They Are Not in Accordance with Law.

The APA directs reviewing courts to "hold unlawful and set aside agency action[s]" that are "not in accordance with law." 5 U.S.C. § 706(2)(A). "An agency action that violates a statute is not in accordance with law within the meaning of the APA." *Ctr. for Biological Diversity v. Zeldin*, 171 F.4th 356, 376 (D.C. Cir. 2026) (citation modified). Plaintiffs are likely to succeed on Count II because the Challenged Conditions contravene the plain text of both the Ryan White statute and the Affordable Care Act.

1. The Challenged Conditions Are Contrary to the Ryan White Program's Enabling Statute.

The Challenged Conditions disregard both the foundational principles and the statutory scheme codified in the Ryan White statute. The Ryan White statute mandates that funding be provided to establish a system of comprehensive care that "improve[s] the quality, availability[,] and organization of health care services for individuals and families with HIV/AIDS." 42 U.S.C. § 300ff-21 (Part B); *see also id.* § 300ff-11(a) (Part A); *id*. § 300ff-29a (Part B Supp.); *id*. § 300ff-51 (Part C); *id*. § 300ff-71 (Part D). The Ryan White statute further requires that funding be used to provide "core medical services" and "support services" for persons living with HIV, to improve access to and retention of HIV-related care, increase viral suppression, and improve overall health outcomes. *See* 42 U.S.C. § 300ff-14(c)–(d) (Part A); *id.* § 300ff-22(a) (Part B); *id.* § 300ff-29a (Part B Supp.); *id.* § 300ff-51(b) (Part C); *id.* § 300ff-71 (Part D). The statute defines "core medical services" to encompass "outpatient and ambulatory health services," "including services regarding the co-occurring conditions of the individual" for an individual living with HIV/AIDS. 42 U.S.C. §§ 300ff-14(c), 300ff-22(b) (identical), 300ff-51(c) (identical).

Core medical services can include gender-affirming medical care. "The term 'outpatient care' means care and treatment of a disability, and preventive health services, furnished to an individual other than hospital care or nursing home care." 38 U.S.C. § 1803.[49] And according to the Ryan White Statute, "[t]he term 'co-occurring conditions' means one or more adverse health conditions in an individual with HIV/AIDS, without regard to whether the individual has AIDS

[49] This is consistent with the ordinary meaning of the term. *See*, *e.g.*, *Outpatient Services*, Health Library, New York-Presbyterian Hospital, (May 1, 2025) https://tinyurl.com/z3vhrdxy [https://perma.cc/9V9C-TYFS] ("Outpatient services are medical procedures, surgeries, therapies, classes, or tests that are done in a qualified medical center without the need for an overnight stay.").

and without regard to whether the conditions arise from HIV." 42 U.S.C. § 300ff-88(2).[50] And gender dysphoria is a serious medical condition "that is characterized by debilitating distress and anxiety resulting from the incongruence between an individual's gender identity and birth-assigned sex." *Grimm*, 972 F.3d at 594–95. Gender-affirming medical care, more specifically, gender-affirming hormone therapy, falls squarely within these ordinary definitions.

Accordingly, Plaintiffs use Ryan White funding to maintain integrated care models that provide holistic care and "core medical services" to patients living with HIV, which includes not only HIV specialty care but also, *inter alia*, sexual healthcare, counseling, mental-health support, medication monitoring, and, when appropriate, gender-affirming medical care for the co-occurring condition of gender dysphoria.[51]

By forcing Plaintiffs to exclude gender-affirming medical care from these models, the Challenged Conditions "directly undermine" their efforts to provide *comprehensive* care and core medical services to patients living with HIV.[52] The Challenged Conditions will thus "fragment care, exclude necessary services for" transgender HIV patients, and "create gaps that [Plaintiffs'] [i]ntegrated [p]lans are specifically designed to prevent." Doe Decl. ¶ 48. This violates the Ryan White statute.

2. The Challenged Conditions Violate Section 1554 of the ACA.

Section 1554 of the ACA prohibits HHS from promulgating any regulation that, *inter alia*, "creates any unreasonable barriers to the ability of individuals to obtain appropriate medical care," "impedes timely access to health care services," "interferes with communications regarding a full

[50] A co-occurring condition, also known as a comorbid condition, refers to a condition "existing simultaneously with and usually independently of another medical condition." *Comorbid*, *Merriam-Webster.com Dictionary*, Merriam-Webster, https://tinyurl.com/33c2ajee (accessed June 9, 2026).
[51] *See* Doe Decl. ¶ 21; Collins-Ogle Decl. ¶ 22; Fox Decl. ¶¶ 15–17; Zuniga Decl. ¶ 34.
[52] Packett Decl. ¶ 46; Doe Decl. ¶ 32; Weddle Decl. ¶ 46; *see also* Zuniga Decl. ¶ 40 ("The restriction would also undermine our members' ability to treat their patients by erasing data on transgender people living with or at risk of HIV.").

range of treatment options between the patient and the provider," "restricts the ability of health care providers to provide full disclosure of all relevant information to patients making health care decisions," "violates . . . the ethical standards of health care professionals," or "limits the availability of health care treatment for the full duration of a patient's medical needs." 42 U.S.C. § 18114. The Challenged Conditions offend Section 1554 in numerous ways.

First, the Challenged Conditions create unreasonable barriers to the ability of transgender patients living with HIV to obtain appropriate HIV medical care as well as gender-affirming medical care for their gender dysphoria and impede timely access to such care. At its essence, this case is "about placing limits on the ability to act" of providers participating in the Ryan White Program. *See Mayor of Baltimore v. Azar*, 973 F.3d 258, 288 (4th Cir. 2020). Pursuant to the Challenged Conditions, healthcare providers participating in the Ryan White Program must "abstain" from respecting their transgender patients' identities while providing HIV-related care and from providing gender-affirming medical care. *See Whitman-Walker.*, 485 F.Supp.3d at 53. In doing so, the Challenged Conditions "make[] it harder" for transgender patients living with HIV to access HIV care and gender-affirming medical care, thereby imposing an "unreasonable barrier" to medical care. *Planned Parenthood of Maryland, Inc. v. Azar*, No. 20-cv-00361-CCB, 2020 WL 3893241, at *9 (D. Md. July 10, 2020). In other words, they impose a "substantive barrier" to the ability of transgender patients living with HIV to obtain "appropriate medical care." *Whitman-Walker*, 485 F.Supp.3d at 53 (quoting *California ex rel. Becerra v. Azar*, 950 F.3d 1067, 1094–95 (9th Cir. 2020) (en banc)).

The Challenged Conditions erect myriad barriers to appropriate care. As to HIV care, the Challenged Conditions would prohibit HIV care providers from providing integrated health services that comprehensively attend to the primary healthcare needs of patients and have been

shown to have positive impacts with regards to HIV treatment.[53] For example, this would prevent providers from addressing interactions between medications provided as part of HIV treatment and those provided as part of gender dysphoria treatment.[54] In addition, by prohibiting the acknowledgement and affirmation of transgender patients' identities and the provision of medically indicated gender-affirming medical care, the Challenged Conditions will cause transgender patients living with HIV who rely on Ryan White funding to disengage from HIV care.[55] This in turn will cause reduced antiretroviral therapy adherence and lower levels of viral suppression.[56] But as HHS's own guidelines regarding HIV care acknowledge, "HIV care services should be provided within a gender-affirmative care model to reduce potential barriers to ART [antiretroviral therapy] adherence and to maximize the likelihood of achieving sustained viral suppression." Weddle Decl., Ex. F at I-103. And the Ryan White Program is often the only means by which transgender patients may obtain gender-affirming medical care, so the Challenged Conditions would effectively cut off access to such care.[57] The Challenged Conditions thus "amount to direct government interference with health care by requiring providers or patients to perform or abstain from certain conduct." *See Whitman-Walker*, 485 F.Supp.3d at 53 (quoting *California ex rel. Becerra*, 950 F.3d at 1094) (citation modified).

Second, the Challenged Conditions interfere with communications between HIV care providers and their transgender patients living with HIV regarding the full range of treatment options and information they need to make informed and clinically appropriate healthcare decisions. Acknowledging a transgender patient's identity and gender incongruence would, in

[53] Weddle Decl. ¶ 30.
[54] Weddle Decl. ¶¶ 33, 34; Fox Decl. ¶ 20.
[55] Brody Decl. ¶¶ 26–27, 33–35; Fox Decl. ¶¶ 41, 41, 43; Collins-Ogle Decl. ¶ 33; Doe Decl. ¶ 45; *cf.* Doe Decl. ¶¶ 34-40 (providing patient example).
[56] Packett Decl. ¶ 42; Zuniga Decl. ¶ 38; Brody Decl. ¶ 55; Fox Decl. ¶ 43; Roe Decl. ¶¶ 32–34; Collins-Ogle Decl. ¶ 39.
[57] Zuniga Decl. ¶ 39; Collins-Ogle Decl. ¶¶ 40–42; Roe Decl. ¶¶ 38–40; Doe Decl. ¶ 59.

Defendants' view, "promote gender ideology" and "promote, encourage, . . . or facilitate . . . denial by the recipient of the sex binary in humans, or the belief that sex is a chosen or mutable characteristic." *E.g.*, Abrigo Decl. Ex. E (Gender Order), Ex. I (Part B Suppl. NOFO). HIV care providers, therefore, will be prohibited from discussing concerns about drug interactions between HIV treatment and gender-affirming hormone therapy, patient priorities regarding care, treatment options regarding gender dysphoria, and other issues related to a patient's particularized needs and circumstances.[58] As such, the Challenged Conditions "quite clearly 'interfere[] with communications' about medical options between a patient and her provider" and "require[] health care providers to hide the ball from their patients." *Mayor of Baltimore*, 973 F.3d at 288 (quoting 42 U.S.C. § 18114(3)).

Third, the Challenged Conditions require healthcare providers to violate the ethical standards of their professions by denying medical care they consider necessary and essential for the care of their patients and forcing them to discriminate against their patients. *See Mayor of Baltimore*, 973 F.3d at 288.[59]

In short, the Challenged Conditions are unlawful because they are contrary to the plain text and structure of the Ryan White statute and are contrary to Section 1554.

D. The Challenged Conditions Violate the APA Because They Are in Excess of Statutory Authority and Violate the Separation of Powers.

The APA directs reviewing courts to "hold unlawful and set aside agency action" that is "in excess of statutory jurisdiction, authority, or limitations, or short of statutory right," 5 U.S.C. § 706(2)(C), or "contrary to constitutional right, power, privilege, or immunity," *id.* § 706(2)(B). To determine whether an agency has exceeded its authority, "the court looks to the scope of the

[58] Weddle Decl., Ex. F at I-102–03; Zuniga Decl. ¶¶ 38, 41; Brody Decl. ¶ 42; Fox Decl. ¶¶ 27, 29; Doe Decl. ¶ 56.
[59] *See also* Packett Decl. ¶ 36; Weddle Decl. ¶¶ 46–48; Brody Decl. ¶¶ 39–41; Fox Decl.¶ 45; Collins-Ogle Decl. ¶¶ 47–51.

agency's statutory authority and discretion and determines whether the agency's statutory authority encompasses the action taken." *Nat'l Educ. Ass'n v. U.S. Dep't of Educ.*, 779 F.Supp.3d 149, 197 (D.N.H. 2025) (citation modified). "Phrased simply, the question is 'whether the agency has gone beyond what Congress has permitted it to do.'" *Id.* (quoting *City of Arlington v. FCC*, 569 U.S. 290, 298 (2013)).

Here, nothing in the Ryan White statute authorizes Defendants to impose the Challenged Conditions on recipients of Ryan White funds. Absent such Congressional authorization, the Constitution bars Defendants from exercising that power unilaterally.

First, the Challenged Conditions violate the Appropriations Clause of the Constitution. "The Appropriations Clause . . . gives Congress exclusive power over federal spending." *Nat'l Council of Nonprofits v. Off. of Mgmt. & Budget*, 763 F.Supp.3d 36, 55 (D.D.C. Feb. 3, 2025) (citation modified); *see also Biden v. Nebraska*, 600 U.S. 477, 505 (2023). Indeed, the Clause "was intended as a restriction upon the disbursing authority of the Executive [Branch]." *Cincinnati Soap Co. v. United States*, 301 U.S. 308, 321 (1937).

Consistent with those principles, Congress, not Defendants, "may impose appropriate conditions on the use of federal property or privileges," including federal grants. *Massachusetts v. United States*, 435 U.S. 444, 461 (1978). And when Congress intends to place conditions on federal funds, "it has proved capable of saying so explicitly." *Pennhurst State Sch. & Hosp. v. Halderman*, 451 U.S. 1, 17–18 (1981); *see*, *e.g.*, 42 U.S.C. § 300ff-1 (proscribing use of Ryan White funds to provide "individuals with hypodermic needles or syringes so that such individuals may use illegal drugs"); Further Consolidated Appropriations Act, Pub. L. No. 118-47, § 526 (2024) (grant conditions regarding provision of sterile needles); *id.* § 202 (grant condition regarding salary caps). But the Executive Branch "does not have the power to place conditions on federal funds" that run

counter to the will of Congress. *Cnty. of Santa Clara v. Trump*, 250 F.Supp.3d 497, 531 (N.D. Cal. 2017); *cf. Fed. Elec. Comm'n v. Cruz*, 596 U.S. 289, 301 (2022) (An agency "'literally has no power to act'—including under its regulations—unless and until Congress authorizes it to do so by statute." (quoting *La. Pub. Serv. Comm'n v. FCC*, 476 U.S. 355, 374 (1986)).

The Ryan White Program is no exception to these rules. Congress did not condition the issuance of Ryan White grants on whether the recipient promotes "gender ideology," denies the "sex binary" in humans, expresses the belief that sex is a "chosen or mutable characteristic," or provides gender-affirming medical care. To the contrary: Congress explicitly directed the Executive Branch to *refrain* from taking actions that burden access to and communications regarding appropriate healthcare, or that discriminate based on sex. *See* 42 U.S.C. §§ 18114(1)–(5), 18116. And it expressly structured the Ryan White Program so that entities and individuals like Plaintiffs would be able to provide care to *all* individuals living with HIV, especially historically underserved communities "experiencing rapid increases" in HIV case counts, like the transgender population. S. Rep. No. 106-294, at 12 (2000).

Here, the Challenged Conditions "run[] headlong into the Ryan White Program's statutory mandate" to provide for the provision of outpatient services for the co-occurring conditions of patients living with HIV. *SFAF*, 786 F.Supp.3d at 1230. What's more, the Challenged Conditions "contravene the antidiscrimination requirements within the ACA." *Id.* at 1231; *see* Section II.E, *infra*. In so doing, the Challenged Conditions unconstitutionally intrude upon the Congressional prerogative to control the public fisc. *See California v. Trump*, 786 F.Supp.3d 359, 388–89 (D. Mass. 2025) (holding that Election Assistance Commission acted outside statutory authority in attempting to "impose an extra-statutory condition on the disbursement" of Congressionally approved funding); *New York v. Trump*, 764 F.Supp.3d 46, 51 (D.R.I. 2025); *City of Chicago v.*

Noem, No. 25 C 12765, 2025 WL 3251222, at *7 (N.D. Ill. Nov. 21, 2025).

Second, the Challenged Conditions also contravene Articles I and II of the Constitution. Article I requires that every bill pass both the House of Representatives and the Senate before it is presented to the President. U.S. Const. art. I, § 7, cl. 2. These procedural "steps" are non-negotiable: They were designed to "erect enduring checks on each Branch and to protect the people from the improvident exercise of power by mandating certain prescribed steps." *INS v. Chadha*, 462 U.S. 919, 957 (1983). And Article II requires the Executive Branch to "take Care that the Laws be faithfully executed[.]" U.S. Const. art. II, § 3. This means that the Executive Branch has an "'affirmative[]'" duty to execute duly enacted law, *PFLAG, Inc. v. Trump*, 769 F.Supp.3d 405, 432 (D. Md. 2025), irrespective of what "policy reasons" it might have "for wanting to spend less than the full amount appropriated by Congress for a particular project or program," *In re Aiken Cnty.*, 725 F.3d 255, 261 n.1 (D.C. Cir. 2013) (Kavanaugh, J.).

Neither Article I nor Article II authorizes Defendants to effectively amend the Ryan White statute by issuing the Challenged Conditions. Instead of abiding by the "single, finely wrought and exhaustively considered procedure" for adding substantive grant conditions to Ryan White, *Chadha*, 462 U.S. at 951, Defendants have attempted to "impose by brute force [such] conditions" through the grant application process, *City of Providence v. Barr*, 954 F.3d 23, 30, 34 (1st Cir. 2020) (holding DOJ imposed unlawful conditions on grantees of the Byrne JAG Grant Program when it attempted to "superimpose its policy views on [the recipients'] law enforcement efforts"). That brute force approach defies Articles I and II. *See New York*, 764 F.Supp.3d at 51 (stating that should the Executive "believe[] that appropriations are inconsistent with the President's priorities—it must ask Congress, not act unilaterally.").

Plaintiffs are likely to succeed in showing that the Challenged Conditions are "in excess of

statutory . . . authority," and are "contrary to constitutional right, power, privilege, or immunity" because they violate the separation of powers. 5 U.S.C. § 706(2)(B)–(C). Plaintiffs are therefore likely to succeed on Counts III and IV.

E. The Challenged Conditions Unlawfully Discriminate Based on Transgender Status and Sex.

The Challenged Conditions impermissibly discriminate based on transgender status and sex, in violation of the ACA and the Fifth Amendment, such that Plaintiffs are likely to prevail on Counts II, IV, V, and VI. Effectively, the Challenged Conditions seek to prohibit transgender people from accessing federally funded healthcare if it is provided in a way that respects their identities. However, the federal government cannot engage in discrimination, either directly or by forcing grantees to engage in discrimination, that is directly prohibited by federal law or the Constitution.

Section 1557 of the ACA provides that an individual shall not, on the basis of, *inter alia*, any ground prohibited by Title IX of the Education Amendments of 1972, "be excluded from participation in, be denied the benefits of, or be subjected to discrimination under, any health program or activity, any part of which is receiving Federal financial assistance." 42 U.S.C. § 18116(a). To succeed on a Section 1557 claim asserting discrimination on the basis of sex, a plaintiff must show: (1) the defendant is a health program or activity, any part of which is receiving Federal financial assistance; (2) the plaintiff was excluded from participation in, denied the benefits of, or subjected to discrimination on the basis of sex; and (3) the plaintiff's claim is enforceable under Title IX. *See* 42 U.S.C. § 18116(a).

Plaintiffs easily meet this standard. *First*, Defendants HHS and HRSA are covered entities that fall within the scope of Section 1557. *See* 45 C.F.R. § 92.4 (defining "covered entity" to include "The Department;" defining "Department" to mean "U.S. Department of Health and Human Services;" and defining "health program or activity" to include projects that "[p]rovide or

administer health-related services" or "[p]rovide clinical, pharmaceutical, or medical care").

Second, Plaintiffs allege that they and their patients will be excluded from participation in, denied the benefits of, and subjected to discrimination under the Ryan White program. As a condition of receiving Ryan White funding, the Challenged Conditions require that grantees stop respecting their transgender patients' identities and stop providing gender-affirming medical care. However, as Plaintiffs have asserted, providing integrated care is the norm and developing a relationship of trust is crucial both to engaging and maintaining patients in HIV care and to treating their conditions effectively.[60] The Challenged Conditions put Plaintiffs in an untenable position: They and their members can either continue to acknowledge their transgender patients' identities and provide necessary gender-affirming medical care but be excluded from the Ryan White Program, or they can stop providing affirming care and exclude their transgender patients.

Third, discrimination based on transgender status constitutes discrimination on the basis of sex in violation of Title IX. In *Bostock v. Clayton County*, the Supreme Court held that "it is impossible to discriminate against a person for being . . . transgender without discriminating against that individual based on sex." 590 U.S. 644, 660 (2020). While the First Circuit has not directly addressed the applicability of *Bostock* to Title IX claims, the First Circuit generally interprets Title IX's protections consistently with Title VII. *See*, *e.g.*, *Ing v. Tufts Univ.*, 81 F.4th 77, 82 (1st Cir. 2023) ("[T]he standards governing claims arising under Title VII and Title IX are the same."). And numerous courts of appeal, as well as district courts in the First Circuit, have applied *Bostock* to Title IX claims. *See*, *e.g.*, *Grimm*, 972 F.3d at 616-17; *Doe v. Snyder*, 28 F.4th 103, 114 (9th Cir. 2022); *Tirrell v. Edelblut*, 748 F.Supp.3d 19, 42-43 (D.N.H. 2024); *Carlan v. Fenway Cmty. Health Ctr., Inc.*, No. CV 23-12361-MJJ, 2025 WL 1000478, at *5 (D. Mass. Mar.

[60] *E.g.*, Fox Decl. ¶¶ 5, 17–19, 40; Brody Decl. ¶¶ 23–24, 35.

28, 2025), *appeal pending*, No. 25-1315 (1st Cir.).

Other courts have preliminarily enjoined policies with virtually identical language to the Challenged Conditions or involving the Gender Order, which the Challenged Conditions implement, because they facially discriminated on the basis of transgender status and therefore sex. *See*, *e.g.*, *GLMA*, 795 F.Supp.3d at 695; *SFAF*, 786 F.Supp.3d at 1231; *PFLAG*, 769 F.Supp.3d at 444. In finding that the Gender Order's prohibition on using grant money to "promote gender ideology" and its statement that "[i]t is the policy of the United States to recognize two sexes, male and female. These sexes are not changeable" discriminated based on sex, likely violating Section 1557 (and the Fifth Amendment), one court stated: "The Court cannot fathom discrimination more direct than the plain pronouncement of a policy resting on the premise that the group to which the policy is directed does not exist." *PFLAG*, 769 F.Supp.3d at 443–44. The same is true here.

For similar reasons, the Challenged Conditions violate the Equal Protection Component of the Fifth Amendment because they discriminate based on sex and transgender status and because they are motivated by animus towards an unpopular minority. Classifications based on sex or gender are subject to intermediate scrutiny and must be "substantially related to achieving an important governmental objective." *Massachusetts v. U.S. Dep't of Health & Hum. Servs.* (*Massachusetts v. HHS*), 682 F.3d 1, 9 (1st Cir. 2012). The burden of justification "is demanding and it rests entirely on the State." *Tirrell*, 748 F.Supp.3d at 30 (quoting *United States v. Virginia*, 518 U.S. 515, 533 (1996)). The government's justification for the policy "must be genuine, not hypothesized or invented *post hoc* in response to litigation." *Virginia*, 518 U.S. at 533.

Classifications based on transgender status are classifications based on sex and so warrant intermediate scrutiny. *See*, *e.g.*, *Doe v. Horne*, 115 F.4th 1083, 1107 (9th Cir. 2024); *Grimm*, 972 F.3d at 608-09; *Tirrell*, 748 F.Supp.3d at 33–36; *Doe v. Austin*, 755 F.Supp.3d 51, 68-69 (D. Me.

2024); *Bos. All. of Gay, Lesbian, Bisexual & Transgender Youth v. United States Dep't of Health & Hum. Servs.*, 557 F.Supp.3d 224, 244 (D. Mass. 2021) (citing *Bostock*, 590 U.S. at 669). Further, discrimination based on the failure of transgender people to conform to sex stereotypes is sex discrimination and subject to heightened scrutiny. *See*, *e.g.*, *Tirrell*, 748 F.Supp.3d at 37–38; *Evancho v. Pine-Richland Sch. Dist.*, 237 F.Supp.3d 267, 285–86, 296–97 (W.D. Pa. 2017).[61]

By prohibiting Plaintiffs from acknowledging, affirming, and respecting transgender patients' identities or providing outpatient services to transgender patients (and only transgender patients) for a co-occurring condition, the Challenged Conditions classify based on transgender status and therefore sex, and are thus subject to heightened scrutiny. However, there is no important governmental interest that is served by and could justify excluding Plaintiffs and their patients from the Ryan White Program. The wholesale exclusion of healthcare that supports transgender people conflicts with Congress's directive to support minority populations under the Ryan White Statute, and with HRSA's past practice of funding these services, and does not constitute an important state interest. *See GLMA*, 795 F.Supp.3d at 697–98.

Finally, even if the Challenged Conditions were not subject to heightened scrutiny based on transgender status and sex, under First Circuit precedent, the Court must apply a more searching review than ordinary rational basis scrutiny for policies targeting groups that have "long been the subject of discrimination." *Massachusetts v. HHS*, 682 F.3d at 11. As other courts have acknowledged, "transgender people have been the subject of a long history of discrimination that continues to this day." *F.V.*, 286 F.Supp.3d at 1145. In fact, just the disclosure of a person's transgender status may "expose[] transgender individuals to a substantial risk of stigma,

[61] Courts have also held that classifications based on transgender status independently warrant heightened scrutiny, which warrants applying heightened scrutiny here. *See*, *e.g.*, *Grimm*, 972 F.3d at 608; *Karnoski v. Trump*, 926 F.3d 1180, 1200-01 (9th Cir. 2019); *Talbott*, 775 F.Supp.3d at 319–22; *F.V. v. Barron*, 286 F.Supp.3d 1131, 1144–45 (D. Idaho 2018); *Evancho*, 237 F.Supp.3d at 288; *Adkins v. City of New York*, 143 F.Supp.3d 134, 140 (S.D.N.Y. 2015).

discrimination, intimidation, violence, and danger." *Arroyo González v. Rosselló Nevares*, 305 F.Supp.3d 327, 333 (D.P.R. 2018).

The Supreme Court has recognized that "a bare . . . desire to harm a politically unpopular group cannot constitute a *legitimate* governmental interest." *Romer v. Evans*, 517 U.S. 620, 634-35 (1996) (quoting *U.S. Dep't of Agric. v. Moreno*, 413 U.S. 528, 534 (1973)) (emphasis in original). Yet, this is exactly what is occurring here. The Challenged Conditions are just one piece of the Administration's sustained campaign against transgender people. *See* Background Section D, *supra*; *see also Orr*, 778 F.Supp.3d at 417–18 (discussing the Gender Order among the Administration's other executive actions that "are built on a foundation of irrational prejudice" toward transgender Americans and finding that "such targeting of a politically unpopular group" violates equal protection). So, "[i]n addition to facially discriminating based on transgender status," the Challenged Conditions "purposefully discriminate based on transgender status." *SFAF*, 786 F.Supp.3d at 1216. This purposeful targeting violates *Romer* regardless of what level of scrutiny would otherwise apply.

For all these reasons, Plaintiffs are likely to succeed on their claims that the Challenged Conditions violate Section 1557 of the ACA and the Constitution's guarantee of Equal Protection.

F. The Challenged Conditions Violate the Right to Free Speech.

The First Amendment prohibits the government from abridging the freedom of speech. *See Reed v. Town of Gilbert*, 576 U.S. 155, 163 (2015); U.S. Const. amend. I. Ordinarily, "the government may not regulate speech based on its substantive content or the message it conveys." *Rosenberger v. Rector & Visitors of Univ. Va.*, 515 U.S. 819, 828 (1995). In the context of federal funding, the government may attach certain conditions to eligibility for that funding, *Agency for Int'l Dev. v. All. for Open Soc'y Int'l, Inc.*, 570 U.S. 205, 213–15 (2013) ("*AID*"); however, there are limitations on the types of conditions that the government may attach to federal funds without

violating the First Amendment. Funding conditions "can result in an unconstitutional burden on First Amendment rights" if the conditions "seek to leverage funding to regulate speech outside the contours of the program itself," *AID*, 570 U.S. at 214–15, or if the conditions seek to achieve a censorious purpose and suppress a recipient's dangerous ideas independent of any objective of the federally funded program, *Nat'l Endowment for the Arts v. Finley*, 524 U.S. 569, 587 (1998).

The Challenged Conditions express a disparaging and unscientific view of gender identity, repudiate the existence of transgender people, deem their identities to be false, order their exclusion from government recognition and protection, and seek to coerce others to do the same by threatening termination of federal funding and other penalties. This violates the First Amendment in two distinct ways.

First, the Challenged Conditions create a funding condition that does not further the objectives of the Ryan White Program and thus place an unconstitutional burden on the First Amendment rights of Provider Plaintiffs and Associational Plaintiffs' members. While the government is permitted to impose conditions on funding that are "relevant to the objectives of the program" itself, placing such conditions is impermissible where, as here, "the Government has placed a condition on the *recipient* of the subsidy rather than on a particular program or service." *AID*, 570 U.S. at 214, 218–19 (quoting *Rust v. Sullivan*, 500 U.S. 173, 197 (1991)) (emphasis in original). Indeed, the Ryan White statute, which establishes a program to provide HIV care, has "no programmatic message" that allows the government to regulate speech concerning *gender* as "deemed necessary" for the Ryan White Program's "legitimate objectives." *Legal Servs. Corp. v. Velazquez*, 531 U.S. 533, 548 (2001). Rather, the Challenged Conditions seek to coerce and penalize federal funding recipients, including Provider Plaintiffs and Associational Plaintiffs' members, whose speech, trainings, research, and services acknowledge the existence of

transgender people and advocate for their equality and respect. *Cf. Thakur v. Trump*, No. 25-4249, 2026 WL 1466303, at *7-11 (9th Cir. May 26, 2026) (per curiam) (applying same First Amendment analysis to hold that policies implementing executive orders, including the Gender Order, that require the termination of funding for research that is DEI-related constitute unlawful viewpoint discrimination).

Second, "even in the provision of subsidies, the government may not 'ai[m] at the suppression of dangerous ideas.'" *Nat'l Endowment for the Arts*, 524 U.S. at 587 (quoting *Regan v. Taxation with Representation of Wash.*, 461 U.S. 540, 550 (1983)). Through the Challenged Conditions, the government unlawfully violates the First Amendment by administering subsidy programs with a censorious purpose. *See Student Gov't Ass'n v. Bd. of Tr. of Univ. of Massachusetts*, 868 F.2d 473, 479 (1st Cir. 1989) (acknowledging such government conditions on subsidies or benefits based on viewpoint may violate both free speech and equal protection rights); *see also Koala v. Khosla*, 931 F.3d 887, 898 (9th Cir. 2019) (recognizing the Supreme Court's continued cautionary admonition that First Amendment will not tolerate the administration of subsidy programs with a censorious purpose).

The Challenged Conditions are designed and intended to silence, defund, and otherwise penalize Plaintiffs for acknowledging that transgender people exist and providing them with healthcare services under the Ryan White Program in a manner that affirms who they are. As another court stated in preliminarily enjoining grant terms and conditions that incorporated the Gender Order: "The categorial and expansive nature of the Challenged Conditions telegraph that the Defendants will deny federal funding to a whole class of programs based on viewpoint alone. It cannot be mistaken that in this case federal funding is being employed as a carrot to impose a "disproportionate burden calculated to drive 'certain ideas or viewpoints from the marketplace.'"

R.I. Coalition, 812 F.Supp.3d at 195 (quoting *Nat'l Endowment for the Arts*, 524 U.S. at 587). Provider Plaintiffs and Associational Plaintiffs' members, as well as the transgender patients they serve under the Ryan White Program, suffer irreparable harm as a direct result of the unlawful imposition of the Challenged Conditions. Accordingly, Plaintiffs are likely to succeed on their First Amendment claims (Counts IV and VII).

III. Provider Plaintiffs, Associational Plaintiffs' Members, and Their Transgender Patients Will Suffer Irreparable Harm Absent a Preliminary Injunction.

It is well-established that acts that "diminish[] access to high-quality health care" cause irreparable harm. *PFLAG*, 769 F.Supp.3d at 449; *see also Planned Parenthood S. Atl. v. Baker*, 941 F.3d 687, 707 (4th Cir. 2019); *GLMA*, 795 F.Supp.3d at 699; *SFAF*, 786 F.Supp.3d at 1233 ("Without an injunction against those provisions, Plaintiffs' patients and clients will suffer irreparable harm in being deprived [of] vital healthcare services."). As such, courts within this district have held that "threats to patients' lives represent[] a dire risk of a quintessentially irreparable nature." *Massachusetts v. NIH*, 770 F.Supp.3d at 320. Unless enjoined, Defendants' actions will cause Plaintiffs and their transgender patients to suffer irreparable harm, including threats to patients' lives, loss of healthcare, loss of provider trust, harm to careers and income, loss of human capital and talent, psychological distress, and the deprivation of constitutional rights. *See* Background Section E, *supra*.

Transgender patients are less likely to remain engaged in HIV care if providers cannot acknowledge their identities or provide medically indicated gender-affirming care as part of integrated care programs.[62] Disruptions in care risk missed appointments, reduced medication adherence, viral rebound, drug resistance, and increased HIV transmission.[63]

[62] Brody Decl. ¶ 17; Fox Decl. ¶¶ 30, 41.
[63] Brody Decl. ¶¶ 5, 17; Collins-Ogle Decl. ¶¶ 5, 15–16; Fox Decl. ¶ 42–43; Doe Decl. ¶ 45; Packett Decl. ¶ 42; Weddle Decl. ¶ 53; Zuniga Decl. ¶ 38.

Moreover, given the nature of the Ryan White Program, the program is often the only means by which patients may be able to access healthcare services, so the restrictions created by the Challenged Conditions would result in the loss of access to healthcare for many transgender patients living with HIV.[64]

Beyond these quintessentially irreparable harms to patients, the Challenged Conditions will cause irreparable harm to Plaintiff healthcare providers by threatening their ability to comply and follow established medical standards of care, their ethical duties and responsibilities, and state and federal anti-discrimination laws.[65] *Cf. Oregon v. Kennedy*, No. 6:25-CV-02409-MTK, 2026 WL 1048354, at *19 n.3 (D. Or. Apr. 18, 2026) ("A policy categorically superseding professionally recognized standards of care as to gender-affirming care causes irreparable harm to Plaintiffs' interests and obligations under state law to ensure access to gender-affirming care[.]"). Further, the First Circuit has acknowledged that the nonpecuniary effects from a loss of federal funding may constitute irreparable harm warranting a preliminary injunction. *New York v. Trump*, 171 F.4th 1, 24 (1st Cir. 2026) (discussing "possible layoffs, reductions in service, and closures of childcare programs; and significant impediments to the delivery of basic health care services to vulnerable populations") (citation modified).[66]

In addition, even temporary deprivation of individual constitutional rights in and of itself constitutes irreparable injury supporting preliminary injunctive relief. *See*, *e.g.*, *Talbott v. United States*, No. 25-5087, 2026 WL 1532205, at *18 (D.C. Cir. June 1, 2026) (equal protection); *Sindicato Puertorriqueño de Trabajadores v. Fortuño*, 699 F.3d 1, 15 (1st Cir. 2012) (free speech);

[64] Zuniga Decl. ¶ 39; Doe Decl. ¶ 59; Roe Decl. ¶¶ 39–40; Collins-Ogle Decl. ¶¶ 60–63.
[65] Packett Decl. ¶ 36; Weddle Decl. ¶ 47; Doe Decl. ¶ 54; Roe Decl. ¶ 41; Brody Decl. ¶ 40; Fox Decl. ¶ 45.
[66] Packett Decl. ¶ 35; *see also* Zuniga Decl. ¶ 29 (discussing operational disruptions from prior Trump Administration actions, including "closure of programs, reduction in ability to provide services, and adjustment of staffing, including staff layoffs.").

Free the Nipple-Fort Collins v. City of Fort Collins, 916 F.3d 792, 806 (10th Cir. 2019) (equal protection); *SFAF*, 786 F.Supp.3d at 1232–33 (free speech and equal protection).

Finally, even if the showing of harm were not so clear-cut—although it is here—where, as here, "the likelihood of success on the merits is great, a movant can show somewhat less in the way of irreparable harm and still garner preliminary injunctive relief." *E.E.O.C. v. Astra U.S.A., Inc.*, 94 F.3d 738, 743 (1st Cir. 1996).

IV. The Remaining Factors Favor Preliminary Relief.

The balance of equities and the public interest merge when the government is the party opposing the preliminary injunction, *Nken*, 556 U.S. at 435, and also strongly favor relief here.

"There is a substantial public interest in having governmental agencies abide by the federal laws that govern their existence and operations." *New York v. McMahon*, 784 F.Supp.3d 311, 372 (D. Mass. 2025) (quotation omitted). Where, as here, Plaintiffs have "demonstrated a high likelihood of success" on the merits, that "is a strong indicator that a preliminary injunction would serve the public interest." *Id.* (citation modified).

There is also "a strong public interest in health and safety." *Massachusetts v. NIH*, 770 F.Supp.3d at 326. Besides the adverse effects on the health of the transgender patients who depend on the Ryan White Program, the Challenged Conditions "will increase the viral load population-wide and increase transmission rates" because of diminished HIV care adherence. Fox Decl. ¶ 43.[67] The impact of the Challenged Conditions in destabilizing the country's HIV service system "will necessarily cause long-term public health crises." Packett Dec. ¶ 42. In addition, the Challenged Conditions are likely to create an increased financial and workforce burden on the

[67] *See also* Brody Decl. ¶ 49; Zuniga Decl. ¶ 38; Doe Decl. ¶ 45.

healthcare system.[68]

By contrast, Defendants will suffer no harm if the Court grants Plaintiffs a preliminary injunction. "There is generally no public interest in the perpetuation of unlawful agency action." *League of Women Voters of United States v. Newby*, 838 F.3d 1, 12 (D.C. Cir. 2016). Defendants have not articulated any public health goals consistent with Congress's mandate that would be frustrated by preliminarily enjoining the Challenged Conditions. Because an injunction would merely delay implementation of Defendants' likely illegal actions and would protect Plaintiffs' proven treatment models and further public health and safety, the balance of the equities and the public interest strongly weigh in favor of Plaintiffs' requested relief.

V. The Court Should Require No Bond.

The Court should exercise its discretion to forgo a bond because Defendants will not suffer any harm from the absence of one. *See Pineda v. Skinner Servs., Inc.*, 22 F.4th 47, 57 (1st Cir. 2021) (courts have substantial discretion to dictate terms of injunction bonds). A bond is additionally inappropriate because "[t]he First Circuit has recognized an exception to the bond requirement in suits to enforce important federal rights or public interests, as is precisely the case here." *McMahon*, 784 F.Supp.3d at 373 (internal citation omitted).

CONCLUSION

For the foregoing reasons, the Court should grant Plaintiffs' motion preliminary relief under 5 U.S.C. § 705 and for a preliminary injunction and enter the attached proposed order.

[68] *See*, *e.g.*, Weddle Decl. ¶ 56 (noting the Challenged Conditions will contribute to "undue workforce strain and attrition"); *id.* at ¶ 54 (stating that the Challenged Conditions will cause exponential costs as each new infection requires lifetime treatment ranging from $500,000 to $1.2 million per person); Brody Decl. ¶ 38 (noting overall health costs increase as patients turn to emergency care settings); Fox Decl. ¶ 38 (noting that if clinicians no longer provided HIV care and gender-affirming medical care together, a "generation of providers" will lose knowledge and experience, degrading the HIV specialty profession); Doe Decl. ¶ 54 (describing likelihood that a colleague will leave her job if the restriction goes into effect).

Dated this 10th day of June 2026.

FOR THE DISTRICT OF MASSACHUSETTS

AMERICAN ACADEMY OF HIV MEDICINE; HIV MEDICINE ASSOCIATION, a division of the INFECTIOUS DISEASES SOCIETY OF AMERICA; INTERNATIONAL ASSOCIATION OF PROVIDERS OF AIDS CARE; JENNIFER K. BRODY, MD; and CHRISTOPHER B. FOX, NP, *Plaintiffs*, v. HEALTH RESOURCES AND SERVICES ADMINISTRATION; THOMAS J. ENGELS, in his official capacity as the Administrator of the Health Resources and Services Administration; U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES; and ROBERT F. KENNEDY, JR., in his official capacity as Secretary of the U.S. Department of Health and Human Services, *Defendants*.	Case No.

DECLARATION OF BRUCE J. PACKETT II, EXECUTIVE DIRECTOR OF THE AMERICAN ACADEMY OF HIV MEDICINE

I, Bruce J. Packett II, hereby state as follows:

1. I am over 18 years of age, of sound mind, and in all respects competent to testify.

2. I have personal knowledge of the facts set forth in this declaration and would testify competently to those facts if called to do so.

3. I am the Executive Director of The American Academy of HIV Medicine ("The Academy"), which is an organizational plaintiff in this case bringing claims on behalf of its members and the transgender patients of its members.

4. I first joined the Academy in 2005, as part of its policy staff, and then served as the Director of Educational Programming and Deputy Executive Director. Since 2019, I have served as the Academy's Executive Director. For the last 21 years, as part of the Academy's staff, I have been engaged in HIV advocacy on behalf of medical providers, including support to the Academy's member; clinical education and curriculum development relating to HIV care; nonprofit business management and development; board management; publication of the Academy's textbook, Fundamentals of HIV Medicine; and oversight and execution of government grants, donor relationships, and partnerships at the Academy.

5. I submit this declaration in support of Plaintiffs' Motion for Preliminary Relief under 5 U.S.C. § 705 and for a Preliminary Injunction, which seeks to prevent Defendants from giving effect to certain conditions relating to transgender people and gender-affirming medical care set forth in Ryan White HIV/AIDS Program ("Ryan White Program" or "RWHAP") Notices of Funding Opportunity issued or forecasted to be issued in 2026 and the 2026 Updated HRSA General Terms and Conditions, issued on March 11, 2026 (collectively, "Challenged Conditions").

6. In this declaration, I explain that HIV providers are under significant stress due to mass retirements, health disparities, and funding challenges amid already high rates of medical provider burnout. I then describe how the Ryan White Program is vital for Academy members' ability to provide comprehensive HIV care, including gender-affirming medical care, and that the effect of a gender-affirming medical care restriction under Ryan White will cause disruptions of operations and patients' HIV care and force Academy members to act against their ethical obligations as medical providers. I conclude by explaining that these problems together will result in future long-term public health crises.

I. Background on the Academy

7. The Academy is a 501(c)(3) nonprofit membership organization and one of the nation's largest independent HIV provider organizations, supporting the HIV practitioners and promoting accessible, quality care for all Americans living with HIV disease.

8. The Academy's membership of HIV practitioners and credentialed providers, which together amount to over 5,000 HIV care providers, give direct care to the majority of HIV patients in the United States.

9. The Academy's mission is to ensure that healthcare professionals have the resources needed to provide prevention, treatment, and care for those with or at risk for HIV and related conditions to achieve optimal health. The Academy works to create an empowered, skilled, and robust healthcare workforce able to intervene at all levels of prevention, care, and treatment for those at risk for or living with HIV. Through a focus on overall wellness, we aim to see a reduction in HIV transmission, an increased quality of life for those living with HIV, and ultimately, an end to the HIV/AIDS epidemic.

10. The Academy was founded in 1999 when there was no specialization for HIV care and no sub-specialty for HIV medicine in medical schools. The Academy created HIV-focused professional certifications in 2001, which are the first and only credentials offered to physicians, nurse practitioners, physician assistants, and pharmacists specializing in advanced-level HIV care. HIV specialty recognition is important because it signals competency to patients, but more broadly, it prepares medical professionals to provide the highest quality of care. The complex nature of HIV care includes evolving clinical guidelines based on best available evidence, complex co-infections and co-morbidities, and a deep understanding of the social drivers of HIV and the cultural competencies that are needed to address the full picture of medical care.

11. The Academy leverages the unique perspective and powerful collective voice of HIV health care providers to address policy issues impacting HIV care practice, patients with and at risk for HIV, sexual health and HIV prevention, and care access and delivery. As an organization and through strategic partnerships, we advocate for Ending the Epidemic initiatives, with a clear emphasis on underserved populations, such as transgender people with HIV, geographic disparities, and elimination of structural and intersectional stigma around those with and at risk for HIV.

12. The Academy's educational and professional development programs help HIV care providers remain current with HIV's rapidly evolving treatment and prevention landscape. The Academy's programs and curricula expand beyond just HIV disease to include clinical issues of primary care and wellness, Hepatitis C ("HCV") and other common co-conditions, overall sexual health, mental health, substance use disorder, and common conditions of an aging population.

13. The Academy's credentialing programs promote standards of care as an independent verification of a provider's knowledge of HIV and HCV care, professional ethics, and overall sexual health competencies. It is nationally recognized for training and certifying medical professionals, known as HIV Specialists™, HIV Experts™, and HIV Pharmacists™, guaranteeing the healthcare professionals' ability to provide robust HIV care.

14. The Academy's credentialing program is so well respected that some Ryan White Planning Councils, the Ryan White-mandated groups that make recommendations regarding the allocation of funding under the Ryan White Program, request that providers be credentialed through the Academy. Similarly, certain specialty pharmacies also require their pharmacists to be Academy credentialed. Several states codify the Academy's credentialing under the state-recognized definition of HIV specialty care, including California, Maryland, and New York.

15. The Academy's training materials provide a complete overview of HIV care, including gender-affirming medical care for transgender patients. In support of this training, the Academy publishes a comprehensive and authoritative reference on the clinical care of HIV/AIDS. Created by over 50 expert clinicians, *Fundamentals of HIV Medicine* is a clinical textbook on HIV care, which includes the latest science, research, and guidelines for care. *Fundamentals of HIV Medicine* highlights the various needs of transgender patients with HIV, providing discussions on evaluations, health maintenance, health disparities, HIV care and prevention for special populations, and gender-affirming medical care.

16. Many of the Academy's members provide medical care to their HIV patients through the Ryan White Program, including through funding under all its parts, as well as any supplementary funding. For their transgender HIV patients, this often includes hormone therapy as treatment for their gender dysphoria (also known as "gender-affirming hormone therapy" or "gender-affirming medical care").

17. Recognizing how integral gender-affirming medical care is to ensure access and adherence to HIV care for transgender patients with HIV, the Academy issued a statement titled "The American Academy of HIV Medicine Statement on Transgender Care and Gender-Diverse Care," in September 2023. The Academy's statement observed, in part, as follows:

> [P]roviding health care for the whole person, including gender-affirming care, is an integral part of status-neutral care delivery and the federal Ending the HIV Epidemic initiative. We will not achieve the goal of ending the HIV epidemic without providing comprehensive medical care for transgender and gender-diverse (TGD) individuals. The Academy's mission is to ensure health care professionals have the resources needed to provide prevention, treatment, and care for those with or at risk for HIV and related conditions to achieve optimal health. In upholding our mission, we support gender-affirming care for TGD individuals, because barriers to comprehensive gender-affirming care exacerbate existing health inequities and prevent TGD individuals from accessing HIV prevention and treatment services that may be appropriate for them.

A copy of the Academy's statement is attached as **Exhibit A.**

18. In addition, the Academy has created a "Transgender Health Resource Center" within its website (https://aahivm.org/transgender-health-resource-center), where it provides resources to its members and other HIV care providers, including webinars regarding the care of transgender patients with HIV and links to practice guidelines relating to HIV care and gender-affirming medical care.

II. Current Stress on HIV Providers

19. Since its inception, the Academy has specifically focused on the needs of the HIV provider workforce.

20. With significant effort and sustained funding, the world of HIV care has dramatically transformed for the better. While HIV care was scaled up to handle the increased demand, over the last decade, the supply of HIV specialists waned as many early experts retired from the field. By 2018, nearly one-third of the Academy's providers were considering retirement. Then the COVID-19 pandemic hit. This put significant stress on every aspect of medical care, especially for the HIV providers who had to help their immunocompromised patients survive a new deadly disease. Today, many Academy members are overwhelmed trying to navigate growing health disparities and funding challenges. Burnout of healthcare providers remains a problem in the medical field, as rates remain worryingly high. Moreover, most medical professionals work for large organizations, which restrict their autonomy. Physician burnout worsens the quality of patient care, increases the risk of medical errors, and decreases patient satisfaction. It also leads to medical professionals leaving the workforce, increasing the workload for those who stay.

21. The number of HIV specialists in the United States is also steadily decreasing as the need for HIV care and prevention is expected to increase. In my experience, a significant number of current HIV clinicians plan to leave the field within the next five years. Reasons for

leaving included burnout, retirement, administrative burdens, and inadequate support. Academy members report increased funding and staffing as the top priorities needed to improve HIV services in the face of burnout and an approaching wave of retirements.

III. Ryan White Funding and Gender-Affirming Medical Care

22. When HIV providers say they are worried about funding, they are primarily worried about Ryan White funding. Approximately 37% of Academy members and credentialed providers rely in part on the Ryan White funding to provide HIV care. This funding is essential to support HIV care, as it more often than not involves caring for patients who are uninsured, underinsured, or marginalized. Indeed, as a whole, HIV-infected patients are appropriately classified as a medically underserved and vulnerable population. Even those members who do not receive Ryan White Program grants are increasingly concerned about Ryan White Program funding cuts negatively impacting other parts of the fragile health coverage system.

23. Academy members rely on each part of the Ryan White Program to provide care for their patients. For example, the Ryan White Program can pay for part or all of the salaries for doctors and nurses to provide gender-affirming medical care, for therapists who serve transgender patients, and for administrative staff support.

24. Because so much of HIV care in the United States, including that provided by Academy members, is affected and funded by the Ryan White Program, as executive director of the Academy, I am aware of the contours of the program and how it affects the Academy's members.

25. The Ryan White Program is a care model designed to provide comprehensive healthcare for people with HIV. The Ryan White Program has four main goals: 1) preventing new HIV infections, 2) improving health outcomes for people with HIV, 3) reducing health disparities

and health inequities for people with HIV, and 4) achieving integrated and coordinated efforts that address the HIV epidemic. Because Ryan White funding reaches so far and wide, it serves most people diagnosed with HIV in the United States. By addressing the full spectrum of needs for people living with HIV, Ryan White has been extraordinarily successful.

26. The Ryan White Program is broken up into different parts based on the type of grant recipient or the purpose of the grant. Part A formula grants are directed at local governments (cities and county governments), and Part B formula grants are directed at States and territories. HIV care providers and organizations receive Part A and Part B funding as passthrough funding from local, state, and territorial entities. Funding is provided to states and territories (Part B), cities and counties (Part A), and directly to providers, community-based organizations (CBOs), and other institutions (Parts C, D, and F) in the form of grants. Funding recipients under Parts A, B, and C must provide comprehensive primary health care to eligible HIV patients.

27. In recognition of the varying nature of the HIV epidemic, Ryan White funding recipients are typically given broad discretion to design key aspects of their programs, including service priorities.

28. Academy members rely on all parts of Ryan White funding to provide care for their HIV patients.

29. Gender-affirming medical care is primary healthcare—or in Ryan White terminology, "a core medical service"—and an essential part of HIV care. As the Academy's Chief Medical Officer noted in a recent Clinical Research Update from the Academy in reference to a study by Reisner, et al. published in March 2025[1], "Gender affirming hormone therapy can be

[1] Sari L. Reisner et al., *HIV Seropositivity and Viral Non-suppression in Transgender, Non-binary, and Gender-diverse People in Primary Care Receiving Gender-affirming Hormone Therapy in the USA Between 2013 and 2019 (LEGACY): An Observational, Longitudinal, Cohort Study*, 12 THE LANCET HIV e283 (2025).

effectively integrated within primary care settings, and results of this unique longitudinal study help affirm the role and necessity of gender-affirming hormone therapy (and low barrier access to such services) on key HIV outcomes, namely HIV seropositivity and viral non-suppression." Copies of the Academy's Clinical Research Update and the Reisner et al. study are attached hereto as **Exhibits B** and **C**.

30. Of the Academy members who rely on Ryan White program funding, 40% of them report providing gender-affirming medical care, although the actual number is likely even higher. Gender-affirming medical care is necessary for Academy members to effectively treat transgender people living with HIV. In fact, Academy members report that transgender patients receiving gender-affirming medical care from Ryan White providers have high rates of maintaining consistent HIV treatment.

31. The Academy knows that Ryan White funding is vital for patients' health. Without it, many Ryan White Program patients would have no access to HIV care because they are generally low-income, uninsured, or underinsured, making them reliant on the program as a payer of last resort for high-cost medicine and support services. The program serves as a critical safety net for the patients of the Academy's members that fills gaps in coverage not met by Medicaid, Medicare, or private insurance, particularly in states that have not expanded Medicaid.

32. Ryan White funding is particularly important for the transgender patients of Academy members and credentialed providers. These providers use Ryan White funds to facilitate both HIV care and gender-affirming medical care, which is crucial for retaining transgender patients in HIV care. Integration of gender-affirming medical care with HIV care improves viral suppression and retention in treatment by building trust and reducing the stigma that often deters transgender people from seeking medical treatment. Additionally, we know that many clinics

funded by Ryan White specialize in transgender health, which helps to overcome historic medical mistrust and discrimination that act as barriers to HIV care. Trust in a provider is one of the most vital components of successful HIV care. If Ryan White clinics and providers specializing in medical care for transgender patients are prohibited from acknowledging and respecting the identities of their transgender patients, as required by the HRSA terms, or lose their ability to provide gender-affirming medical care, transgender patients will lose trust in their providers, and providers will lose patients.

33. Other medical funding sources are unable to cover the loss caused by a restriction on providing gender-affirming medical care under Ryan White and the restriction on acknowledging and respecting transgender patients' identities. Medicaid coverage for gender-affirming medical care is restricted in many states, Medicare cannot, by its nature, cover all transgender patients, and most Ryan White patients do not have private insurance. Without the Ryan White Program, most transgender patients have nowhere else to go. Indeed, in rural settings and in some states, Academy members report that many patients have lost access to gender-affirming medical care through Medicaid, and in some cases, clinical care for gender-affirming medical care has stopped entirely. Based on survey research by the Emergency HIV Clinic Response Task Force, of which the Academy is a member, we know that already 18% of HIV medical professionals report disruptions in their ability to provide gender-affirming medical care. A copy of the Emergency HIV Clinic Response Task Force's report, titled *HIV Response in U.S. Experiencing Renewed Strain* and published in 2026, is attached hereto as **Exhibit D.**

IV. The Impact of the Challenged Conditions on Academy Members and Their Patients

34. The effects of a gender-affirming medical care restriction under Ryan White and the conditioning of funding on not acknowledging and respecting transgender patients' identities

would immediately impact patient care. Academy members would be forced to disrespect their patients and to stop providing essential medical care, that as the Academy's own statement acknowledges is often lifesaving, and I expect that patients would stop showing up.

35. This restriction will cause both immediate and long-term operational disruptions. Compliance with the Challenged Conditions would require clinics and providers to unnecessarily dismantle integrated models of care. This drain on resources would result in needless operational burdens, such as service reductions, hiring freezes, layoffs of support staff, delayed procurements, program closures, and general loss of income for medical practices.

36. A gender-affirming medical care restriction will also force Academy members to act against their ethical obligations as medical providers. Gender-affirming medical care is evidence-based care that can be medically necessary for transgender patients who experience gender dysphoria. And it is, in many cases, lifesaving. Compliance with the prohibition on the use of Ryan White funding for gender-affirming medical care makes providers unnecessarily deviate from standards of care and their own professional judgement. The restriction, as well as the conditioning of funding on not acknowledging and respecting transgender patients' identities, will result in Academy members and credentialed providers being compelled to make an impossible choice: protect either the Ryan White funding that enables them to care for all their HIV patients or fulfill their duty of care to their transgender patients with HIV and risk losing essential funding. These restrictions cause providers to feel disillusioned and stressed by their inability to provide the care that they are sworn to provide and want to provide. As a result, Academy members will lose their credibility as scientific and medical authorities, and the trust between patients and providers could be permanently eroded.

37. In the absence of public health leadership that is guided by evidence and our goal to end the HIV epidemic, it is falling on the Academy to monitor the strains on providers and patients so we can address the challenges in real time. To better understand the impact on providers today, the Academy and the Emergency HIV Clinical Response Task Force surveyed our members about the ongoing challenges they face in providing competent HIV care. The Academy's provider-members believe that restrictions, such as the upcoming Ryan White restriction on providing gender-affirming medical care, will cause massive operational changes, including workflow changes, service disruptions, staffing adjustments, hiring freezes, delayed procurements, staff layoffs, and program closures. They report that HIV clinical and supportive service disruptions have already affected one population more than any other, and that is their transgender patients with HIV. When asked about the most urgent needs to safeguard the continuity of HIV services, providers said they were particularly concerned about the funding landscape, with a specific emphasis on Ryan White funding. The restriction on the use of Ryan White funding for gender-affirming medical care, as well as the conditioning of funding on not acknowledging and respecting transgender patients' identities, would devastate a population that is already teetering on the line of falling out of care.

38. Academy members are already trying to alter how they secure and deliver resources to provide their transgender patients with HIV with the gender-affirming medical care that they need in response to these federal restrictions. And while many have begun seeking alternative funding streams to maintain their patients currently in care, no source of funding is sufficient to replace the funding provided by the Ryan White Program. Nor can any alternative source of funding cure the harms caused by the HRSA Terms' conditioning of funding on recipients not acknowledging and respecting transgender patients' identities.

39. Given the environment created by the current administration's actions relating to transgender people and gender-affirming medical care, some of the Academy's members are scared to talk about gender-affirming medical care and fear publicly disclosing the fact they offer this essential care to their transgender patients due to safety and security concerns, as well as concerns of retaliation, including loss of funding.

40. Academy members and credentialed providers have shared how incredibly concerned they are with the changing HIV prevention and care environment. Our members are experiencing compounding emotional fatigue from witnessing the harm their patients have endured because of this administration's misguided healthcare policies, alongside their own challenges in navigating a discriminatory environment. Many of these same providers experienced the early days of the epidemic, and they know how many lives will be unnecessarily lost without immediate action. Not long ago, we were close to ending the HIV epidemic in this country. Now, we appear to be moving backwards.

41. The unnecessary stress caused by the Challenged Conditions restricting the use of Ryan White funding will exacerbate the problems facing an already strained system and result in worse health outcomes for patients. In my opinion, current clinicians will leave the field or retire earlier, and the small pool of new medical professionals interested in HIV specialization will be discouraged from joining the field. The remaining providers will navigate their already challenging jobs with workforce shortages and accelerated burnout. The lack of providers will create a gap in care for all people living with HIV and increase the operational burden of clinics, causing the destabilization of the United States' HIV care.

42. The destabilization of HIV services will necessarily cause long-term public health crises in the future. Once patients fall out of care, community viral load and HIV transmissions

increase. Limiting these disruptions is vital to safeguarding lives and decades of progress in the United States' HIV response. If the Ryan White gender-affirming medical care restriction and the conditioning of funding on not acknowledging and respecting transgender patients' identities are allowed to go into effect and be incorporated into the Ryan White funding streams, the effects will be devastating and the fight against HIV will be lost for decades.

I declare under penalty of perjury that the foregoing is true and correct.

21 Sep The American Academy of HIV Medicine Statement on Transgender Care and Gender-Diverse Care

Posted at 17:20h in Press Releases by Adrianne Wyatt • 0 Comments • 0 Likes • Share

Transgender care, gender-diverse care, and gender-affirming care is life-saving health care. As an organization whose members are comprised of health care providers and clinicians, the Academy unequivocally supports transgender care, gender-diverse care, and gender-affirming care as well as the professionals who provide it. We uphold the sanctity of the patient-provider relationship and the individual decisions regarding the provision of health care that the patient and their provider make together.

Additionally, providing health care for the whole person, including gender-affirming care, is an integral part of status-neutral care delivery and the federal Ending the HIV Epidemic initiative. We will not achieve the goal of ending the HIV epidemic without providing comprehensive medical care for transgender and gender-diverse (TGD) individuals. The Academy's mission is to ensure health care professionals have the resources needed to provide prevention, treatment, and care for those with or at risk for HIV and related conditions to achieve optimal health. In upholding our mission, we support gender-affirming care for TGD individuals, because barriers to comprehensive gender-affirming care exacerbate existing health inequities and prevent TGD individuals from accessing HIV prevention and treatment services that may be appropriate for them.

HIV seropositivity and viral non-suppression in transgender, non-binary, and gender-diverse people in primary care receiving gender-affirming hormone therapy in the USA between 2013 and 2019 (LEGACY): an observational, longitudinal, cohort study

Sari L Reisner, David R Pletta, Kenneth H Mayer, Madeline B Deutsch, Tonia Poteat, Jennifer Potter, Andrea L Wirtz, Alexander Harris, Juwan Campbell, Alex S Keuroghlian, Jaclyn M W Hughto, Alex Gonzalez, Asa E Radix

Summary

Background Gender-affirming hormone therapy is medically necessary for many transgender, non-binary, and gender-diverse (trans) individuals and might improve HIV clinical outcomes for trans people. This study evaluated gender-affirming hormone therapy delivered in primary care as an intervention to improve HIV outcomes for trans adults in the USA.

Methods LEGACY is a longitudinal cohort of trans adult participants receiving primary care at two US federally qualified health centres: Fenway Health (Boston, MA, USA) and Callen-Lorde Community Health Center (New York, NY, USA). Eligibility criteria were age at least 18 years, gender identity differing from assigned sex at birth, past 12-month medical visit, and signed consent with no research exclusion documented in electronic health record data. Eligible participants contributed electronic health data from 2013 to 2019. The exposure was gender-affirming hormone therapy prescription. Clinical outcomes were HIV seropositivity (all participants) and viral non-suppression (participants with HIV; ≥200 copies per mL) in the past 12 months. Log-Poisson generalised estimating equations assessed the longitudinal association of gender-affirming hormone therapy prescription (puberty blockers, anti-androgens, oestrogens, progesterone, and testosterone) with outcomes, adjusting for individual-level confounders.

Findings Among the 8109 trans participants in 2019, median age was 29 years (IQR 24–37). 2960 (36·5%) were transgender women, 2541 (31·3%) were transgender men, 1507 (18·6%) were non-binary, and 1101 (13·6%) were another trans identity. 4446 (54·8%) were White, 1323 (16·3%) were Black or African American, 498 (6·1%) were multiracial, and 1663 (20·5%) were Hispanic or Latinx. 2736 (33·7%) of 8109 participants were publicly insured and 451 (5·6%) participants were uninsured. In 2013, 2549 (85·5%) of 2983 participants were prescribed gender-affirming hormone therapy, 272 (9·1%) of 2983 participants were HIV seropositive, and 61 (22·4%) of 272 participants were not virally suppressed. In 2019, 7252 (89·4%) of 8109 participants were prescribed gender-affirming hormone therapy, 560 (6·9%) of 8109 participants were HIV seropositive, and 88 (15·7%) of 560 participants were not virally suppressed. Gender-affirming hormone therapy prescription was associated with reduced rates of HIV seropositivity (adjusted risk ratio [RR] 0·63, 95% CI 0·56–0·70) and viral non-suppression (adjusted RR 0·56, 95% CI 0·45–0·69) across follow-up.

Interpretation Gender-affirming care is important for optimising HIV outcomes among trans people. Our results underscore the vital role of gender-affirming models of care and access to gender-affirming hormone therapy for trans people.

Introduction

In the USA, transgender, non-binary, and gender-diverse (trans) people who have a gender identity that differs from the sex assigned to them at birth are highly burdened by HIV and have suboptimal HIV clinical outcomes, including high viral non-suppression rates.[1,2] Trans people, particularly transgender women and Black transgender people, were a prioritised population in the National HIV/AIDS Strategy (NHAS) for 2022–25.[3] For example, NHAS 2022–25 had a goal of increasing viral suppression among transgender women from the baseline of 80·5% to 95·0%.[3] According to Health Resources and Services Administration Ryan White HIV/AIDS Program data from 2021, viral suppression in transgender people was 84·8%, well below the national goal.[4] Gender-affirming hormone therapy is medically

Research in context

Evidence before this study

In the USA, transgender, non-binary, and other gender-diverse (trans) people were prioritised in the National HIV/AIDS Strategy. Gender-affirming hormone therapy is medically necessary for many trans people and might improve HIV outcomes.
We searched PubMed and Google Scholar using Medical Subject Headings and keyword terms for US-based publications reporting gender-affirming hormone therapy, HIV, and viral non-suppression between Jan 1, 2014, and July 31, 2024, for articles published in English. The HIV burden in trans people was high, with suboptimal viral non-suppression rates. For example, a meta-analysis of 22 US studies from 2006 to 2021 on HIV outcomes in trans people by Becasen and colleagues found the weighted mean proportion of transgender women currently virally suppressed was 59·3% (95% CI 49·5–68·4), well below national targets. Our search identified only two studies of transgender men and none of non-binary people. Few investigations assessed gender-affirming hormone therapy alongside viral non-suppression, with existing studies restricted to transgender women and having mixed findings. Most studies were cross-sectional and had small sample sizes with short follow-up periods, which might, in part, account for the inconsistent results. There is a need for additional longitudinal research and larger sample sizes to address these limitations.

Added value of this study

Our study included a large and diverse cohort of transgender, non-binary, and gender-diverse primary care participants drawn from federally qualified health centres in the USA, laboratory-confirmed outcomes from electronic health record data, and unprecedented longitudinal data on gender-affirming hormone therapy and HIV outcomes. We evaluated gender-affirming hormone therapy delivered in primary care as an intervention to improve HIV outcomes for trans adults. Compared with trans participants not prescribed gender-affirming hormone therapy, those prescribed gender-affirming hormone therapy had a lower risk of past-year HIV seropositivity and, among those with HIV, a lower risk of viral non-suppression during the 7 years of follow-up. Our consideration of gender identity, gender-affirming hormone therapy, and HIV outcomes is important, given that US HIV surveillance efforts do not routinely collect these data.
Our findings contribute to the evidence base for the health-promoting role of gender-affirming hormone therapy, showing that gender-affirming hormone therapy is associated with reduced HIV morbidity longitudinally for trans people, and underscore the vital role of gender-affirming models of care and access to gender-affirming hormone therapy for trans people. Our results could inform gender-affirming interventions to mitigate HIV inequities for trans people, including those incorporating gender-affirming hormone therapy.

Implications of all the available evidence

Integrating gender-affirming hormone therapy with HIV testing and care delivery is recommended for trans people. Gender-affirming care is important for optimising HIV outcomes among trans people.

necessary for many trans people and is known to improve many health outcomes.[5] However, few studies have assessed the association between gender-affirming hormone therapy and HIV acquisition in trans individuals. Furthermore, studies evaluating the association of gender-affirming hormone therapy with viral load suppression have had mixed findings.[6–9] Notably, most previous research has been cross-sectional,[9,10] and most existing longitudinal studies have small sample sizes[11] or short follow-up periods (or both),[8] which might, in part, account for the inconsistent results. Studies with larger sample sizes of trans people living with HIV have not assessed gender-affirming hormone therapy.[6] There is a need for additional longitudinal research to address these limitations and to examine differences by gender identity among trans people, including disaggregating for trans men and non-binary individuals, given the dearth of research about these groups.[1]

In this study, we sought to evaluate gender-affirming hormone therapy delivered in primary care as an intervention to improve HIV outcomes for trans adults. We assessed whether gender-affirming hormone therapy was associated with reduced rates of HIV seropositivity and viral non-suppression in the past 12 months for 7 years of follow-up in a cohort of adult trans individuals in primary care who were diverse in age, race, ethnicity, and gender identity. We hypothesised that gender-affirming hormone therapy would reduce HIV seropositivity and viral non-suppression incidence. We use trans as a collective term throughout this paper to refer to transgender, non-binary, and gender-diverse populations but do not intend to exclude or minoritise populations contained within this phrasing, and we acknowledge those who use other terms.

This manuscript was accepted before Executive Orders were issued by US President Trump related to gender ideology and diversity, equity, and inclusion in the USA, which have made some of the materials referenced in this Article inaccessible. The references were available upon acceptance of the manuscript.

Methods

Study design and participants

LEGACY is a longitudinal cohort of trans adult participants receiving primary care at two US federally qualified health centres: Fenway Health (Boston, MA, USA) and Callen-Lorde Community Health Center (New York, NY, USA).[12] Both federally qualified health centres specialise in provision of gender-affirming health care, including delivery of gender-affirming hormone

therapy using an informed consent protocol.[5] 8109 LEGACY participants were followed up from 2013 to 2019. In this period, gender-affirming hormone therapy was delivered as part of primary care according to the same established standards by both federally qualified health centres.[5] Qualitative research with trans people informed cohort implementation,[13] and a community advisory board oversaw the study. The detailed LEGACY protocol has been published elsewhere.[12]

Participants were considered eligible for LEGACY if they had a gender identity different to their assigned sex at birth (verified using a two-step method to cross-categorise sex and gender identity self-reported on participant registration or ICD-10 code of F64·0–9); were aged at least 18 years; were a primary care patient with at least one medical visit in the past 12 months; and had a signed informed consent form on file and no research exclusion indicated in their patient chart. All study procedures were approved by the Fenway Health institutional review board (FWA00000145).

Procedures

Eligible trans participants contributed to the LEGACY research database. De-identified electronic health record data were extracted (eg, laboratory testing data and provider-documented diagnoses) and harmonised across sites. We compared 12-month HIV seropositivity (for all participants) and viral non-suppression (for participants with HIV) in groups who did and did not receive gender-affirming hormone therapy across the 7 years of follow-up. Within a given year, trans participants' electronic health records contained information related to their HIV serostatus, viral load (for those with HIV), gender-affirming hormone therapy prescription, sociodemographic characteristics, substance use, mental health, and other sexual health indicators.

Outcomes

Two binary outcomes were operationalised. Outcome 1 was HIV-positive serostatus (for all participants). Participants were considered to be living with HIV if they tested positive for HIV, or a clinician added an indicator for HIV-positive serostatus to the participant's electronic health record. HIV testing was done for participants who had clinical indications, as determined by their medical provider. Outcome 2 was viral non-suppression (for participants with HIV). Based on standards from the US Centers for Disease Control and Prevention (CDC),[14] HIV viral non-suppression was defined as having a viral load of 200 copies per mL of blood or greater. Individuals could not count toward both outcomes in one year, as each outcome was operationalised according to the calendar year.

The exposure variable of gender-affirming hormone therapy was coded as a binary variable of being prescribed gender-affirming hormone therapy (yes *vs* no) in electronic health record data. This variable was operationalised using the date of first gender-affirming hormone therapy prescription and the date of last gender-affirming hormone therapy prescription in each year of observation in the cohort. A participant was dichotomously coded as either having a gender-affirming hormone therapy prescription within the year versus having no gender-affirming hormone therapy prescription within the year. Hormone variable prescription types were pubertal blockers (eg, leuprolide), antiandrogens (eg, spironolactone), oestrogens (eg, estradiol), progesterone (eg, micronised progesterone), and testosterone (eg, testosterone cypionate).

Sociodemographics included age, continuously and grouped in years (18–24, 25–30, 31–40, 41–50, or ≥51). Gender identity was operationalised by cross-tabulating participants' self-reported gender identity and sex assigned at birth and coding as transgender woman, transgender man, non-binary assigned male at birth, non-binary assigned female at birth, or transgender, not specified. Racial identity was documented in the electronic health record as American Indian or Alaskan Native, Asian, Black or African American, multiracial, Native Hawaiian or Pacific Islander, White, or other race. Hispanic or Latinx ethnicity was indicated dichotomously (yes *vs* no). Type of medical insurance included private insurance, public insurance, and no insurance. The Ryan White HIV/AIDS program was counted as public health insurance in this analysis. A participant's individual income percentage of the federal poverty level was coded categorically as 0–99%, 100–199%, 200–299%, or 300% or more.[15] Study site was coded as Boston or New York City.

Alcohol use disorder was determined based on diagnosis per the Diagnostic and Statistical Manual of Mental Disorders (F10.10–21)[16] using documented ICD-10 coding, as captured in the electronic health record. Psychological distress was measured using the validated self-reported Patient Health Questionnaire 9-item (PHQ-9)[17] as part of routine care. A score of 10 or more was considered clinically elevated (hereafter, PHQ depression) consistent with validated cutoffs (88% sensitivity and 88% specificity for major depression).[17] When only a narrative, non-integer appraisal of a participant's PHQ-9 score was provided in the electronic health record, an a-priori decision was made by the investigative team that a rating of moderate depression, moderately severe depression, or severe depression was indicative of depression, whereas a rating of mild depression or no depression was not. Sexual health measures included whether a participant tested positive for anogenital gonorrhoea or chlamydia. A positive anogenital sexually transmitted infection diagnosis was defined as having had a positive urethral, cervical, or rectal test within the past year for either chlamydia or gonorrhoea (yes *vs* no). Pre-exposure prophylaxis (PrEP) for HIV prevention was defined as having a PrEP prescription within the past year (yes *vs* no). Years in the cohort (2013–19) was operationalised as a continuous variable of years retained in care, ranging from 1 to 7.

Statistical analysis

The study was powered (80% power, α=0·05) to detect a statistically significant association between gender-affirming hormone therapy and viral non-suppression (see published study protocol for sample size calculation).[12] Data analyses were done using R (version 4.3.1) and RStudio (version 2023.06.1). Descriptive statistics were generated for the full sample in 2019 and variable missingness was assessed descriptively. Missingness ranged from 0·0% for age to 24·1% for federal poverty level percentage. Test statistics and p values comparing trans participants with and without HIV were generated by χ^2 tests of independence with Monte Carlo-simulated p values (2000 replicates; categorical) and Wilcoxon rank sum tests with continuity corrections (continuous). A second longitudinal dataset was generated, restricted to participants with HIV. Analyses imputed 100 datasets for both the full cohort dataset and the restricted to participants living with HIV dataset, using multiple imputation with chained equations via the mice package in R (appendix p 1).[18] Cumulative HIV seropositivity and viral non-suppression rates were graphically visualised by race and ethnicity, and stratified by gender identity.

Bivariate and multivariable log-Poisson generalised estimating equation models with cluster-robust SEs were fitted with an exchangeable working correlation structure to the imputed datasets to produce risk ratios (RRs), adjusted RRs, and 95% CIs for a participant's risk of having HIV-positive serostatus (outcome 1, all participants) and being virally non-suppressed (outcome 2, participants with HIV) over time. For outcome 1, PrEP prescription was not included in the model as there were no new HIV cases among PrEP users. For stability in model estimands, non-binary assigned male at birth and non-binary assigned female at birth categories were combined for the viral non-suppression outcome due to small sample sizes. Generalised estimating equation models estimated the marginal or population-averaged effect of concurrent gender-affirming hormone therapy on HIV seropositivity or viral non-suppression, using robust SEs and adjusting for repeated measures. All variables were incorporated into a multivariable model for each outcome. p<0·05 was considered to indicate a statistically significant difference.

Interpretations of associations incorporated epidemiological guidance to reduce reliance solely on p values and consider the magnitude and direction of associations and 95% CIs, in addition to p values, when making inferences.

The effect of unmeasured confounders was evaluated in sensitivity analyses by estimating the E-value and corresponding 95% confidence limits.[19] The E-value is a measure of the minimum strength of the association that an unmeasured confounder (or set of confounders) would need to have, with both the exposure and the outcome, to fully explain the exposure–outcome association on the RR.[19]

Results

Among the 8109 trans participants in 2019, the median age was 29 years (IQR 24–37). Participants were diverse in gender identity with 2960 (36·5%) being transgender women, 2541 (31·3%) transgender men, 1507 (18·6%) non-binary, and 1101 (13·6%) another trans identity

(table 1). Participants were mostly White (4446 [54·8%]), followed by Black or African American (1323 [16·3%]), multiracial (498 [6·1%]), and Hispanic or Latinx (1663 [20·5%]). 1837 (22·6%) participants were living at 200% of the federal poverty level or greater; 2736 (33·7%) were publicly insured and 451 (5·6%) were uninsured. 210 (2·6%) had an alcohol use disorder diagnosis; 886 (10·9%) screened positive for depression via the PHQ-9. 340 (4·2%) had anogenital gonorrhoea or chlamydia diagnoses in the past 12 months. 3·1% of participants without HIV had a current PrEP prescription.

Most participants had a gender-affirming hormone therapy prescription (85·5% in 2013 and 89·4% in 2019; table 1). Rates of HIV seropositivity were 9·1% in 2013 and 6·9% in 2019, and viral non-suppression decreased across the 7 years of follow-up (61 [22·4%] of 272 participants with HIV in 2013 and 88 [15·7%] of 560 participants with HIV in 2019). In 2019, on average, participants with HIV were older than participants without HIV (median age 37 years [IQR 30–37] *vs* 28 years [24–36]; p<0·0001).

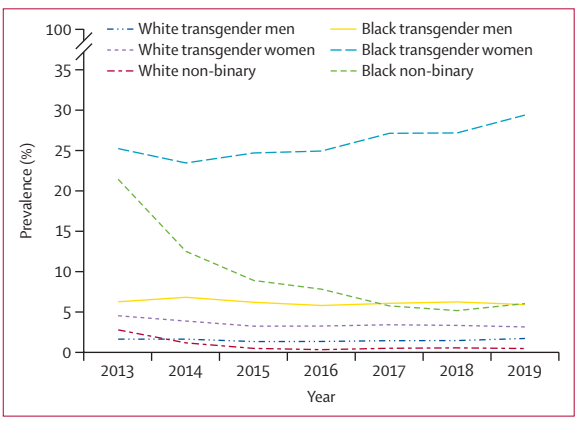

Figure 1: **HIV seropositivity rates among transgender, non-binary, and gender-diverse participants by race and year, stratified by gender identity (2013–19)**

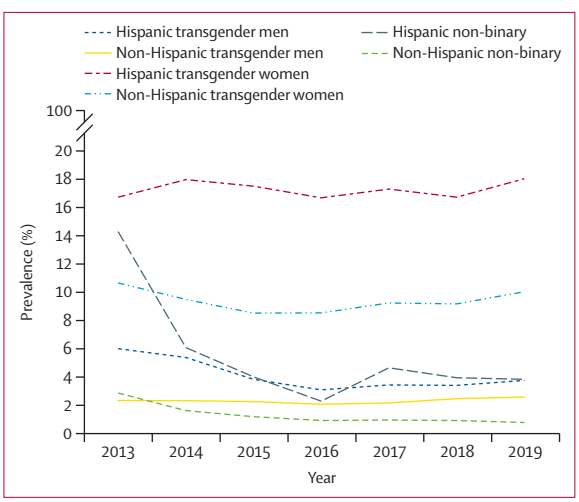

Figure 2: **HIV seropositivity rates among transgender, non-binary, and gender-diverse participants by ethnicity and year, stratified by gender identity (2013–19)**

Cumulative HIV seroprevalence rates stratified by gender identity are displayed by race (figure 1; appendix p 2) and ethnicity (figure 2; appendix p 3). In 2019, in terms of racial identity, the highest HIV seropositivity rates were in Black (164 [29·4%] of 558 participants), other race (19 [18·6%] of 102 participants), and multiracial (35 [17·8%] of 197 participants) transgender women, followed by other race (two [9·5%] of 21 participants) and Black (seven [6·0%] of 116 participants) non-binary participants. In terms of ethnicity, the highest HIV seropositivity rates were among Hispanic (129 [18·0%] of 716 participants) and non-Hispanic (225 [10·0%] of 2244 participants) transgender women, followed by Hispanic non-binary (six [3·8%] of 157 participants) and Hispanic transgender men (19 [3·7%] of 508 participants). HIV prevalence in transgender men ranged from one (0·8%) of 131 participants (multiracial transgender men) to 25 (5·9%) of 424 partcipants (Black transgender men). HIV seropositivity appeared stable for most subpopulations during follow-up, but increased for some groups (eg, Black transgender women; figure 1. In 2019, by racial identity, the highest rates of viral non-suppression were in Black non-binary participants (two [28·6%] of seven participants) and multiracial (ten [28·6%] of 35 participants), other race (four [21·1%] of 19 participants), and Black (33 [20·1%] of 164 participants) transgender women. In terms of ethnicity, in 2019, the highest rates of HIV viral non-suppression were among non-Hispanic transgender women (40 [17·8%] of 225 participants), followed by Hispanic non-binary participants (one [16·7%] of six participants) and Hispanic transgender men (three [15·8%] of 19 participants).

In a multivariable model, participants with a current gender-affirming hormone therapy prescription (adjusted RR 0·63, 95% CI 0·56–0·70) had a significantly lower risk of HIV seropositivity compared with participants without a gender-affirming hormone therapy prescription during follow-up (table 2). The E-value calculated was 2·55 (95% confidence limit 2·21–2·97) for the covariate-adjusted association between gender-affirming hormone therapy prescription and risk for HIV-positive serostatus.

In this model, factors associated with significantly higher risk of HIV positivity were as follows: being in an older age group compared with those aged 18–24 years; being a transgender woman or non-binary assigned male at birth compared with a transgender man; identifying as a racially or ethnically minoritised group compared with identifying as White; having public insurance and no insurance compared with having private insurance; having a positive anogenital gonorrhoea or chlamydia sexually transmitted infection diagnosis; and greater number of years in care (table 2). Variables associated with a significantly lower risk of living with HIV were being non-binary assigned female at birth compared with a transgender man and living at 100–199% of the federal poverty level or 300% or higher of the federal

poverty level compared with 0–99% of the federal poverty level.

In the multivariable model, participants with a gender-affirming hormone therapy prescription had significantly lower risk of viral non-suppression compared with those not on hormones during follow-up (adjusted RR 0·56, 95% CI 0·45–0·69, table 3). The E-value was 2·97 (95% confidence limit 2·26–3·87) for the covariate-adjusted association between gender-affirming hormone therapy prescription and viral non-suppression risk.

Factors associated with a significantly decreased risk of viral non-suppression were as follows: being in older age groups compared with the 18–24 years group; being a transgender woman compared with a transgender man; living at 100–199% of the federal poverty level and 200–299% of the federal poverty level versus 0–99% of the federal poverty level; and a greater number of years in care. Latinx participants living with HIV had a lower risk of viral non-suppression compared with White individuals (adjusted RR 0·84, 95% CI 0·69–1·01, table 3).

Discussion

This longitudinal study of trans participants receiving primary care at federally qualified health centres found that gender-affirming hormone therapy prescribed through informed consent protocols was associated with reduced rates of HIV seropositivity and viral non-suppression over time. The mechanisms by which gender-affirming hormone therapy affects HIV serostatus and viral suppression outcomes for trans participants in this study remain unclear. Gender-affirming hormone therapy is prospectively associated with reduced mental health distress and improved quality of life;[20] these effects might, in turn, facilitate improved health behaviours, such as condom use or antiretroviral medication adherence. Gender-affirming hormone therapy-related care might also increase trust with providers, thereby reducing barriers to discussing concerns about sexual health or adherence difficulties. Years retained in care predicted increased risk for HIV seropositivity and decreased risk for viral non-suppression, highlighting engagement in care as key to identifying new HIV infections and enhancing viral suppression. Future research is necessary to understand the pathways through which gender-affirming hormone therapy is associated with HIV clinical outcomes in this study.

Although overall HIV seropositivity declined across follow-up, rates increased among some subpopulations. We observed higher HIV seropositivity across several sociodemographic characteristics, mirroring national HIV epidemic statistics.[21–23] Ethnically and racially minoritised groups had a significantly increased risk for HIV seropositivity across the years we observed. Our findings highlight the urgent need for efforts to address the unique HIV prevention and care needs of trans participants of colour, mirroring national trends in cisgender populations. Transgender women and non-binary assigned male at

RR=risk ratio. PHQ-9=Patient Health Questionnaire 9-item. *Non-binary and transgender not specified, including participants assigned female at birth and assigned male at birth.

***Table 3*: Bivariate and multivariable longitudinal log-Poisson generalised estimating equation models for viral non-suppression in transgender, non-binary, and gender-diverse primary care participants living with HIV (≥200 copies per mL; 2955 observations)**

birth participants had the highest HIV rates, yet HIV seropositivity and viral non-suppression rates were also higher for transgender men and non-binary assigned female at birth participants than national HIV surveillance data. Consistent with previous research on socioeconomic marginalisation,[24] having public insurance or no insurance compared with private insurance and living in poverty significantly predicted HIV seropositivity. Furthermore, corroborating synergistic effects of HIV and sexually transmitted infections,[25] trans participants with a positive anogenital bacterial sexually transmitted infection diagnosis had an increased risk of HIV seropositivity over follow-up. The risk of HIV seropositivity was significantly increased in older age groups, highlighting the need for early HIV prevention. This finding contrasts with national HIV epidemiological surveillance data, wherein HIV infection rates are highest in those aged 18–24 years, and might be due to the large number of non-binary assigned female at birth participants aged 18–24 years not living with HIV in our cohort. Relatedly, the risk of viral non-suppression was lower for the 31–40 years, 41–50 years, and 50 years and older age groups compared with the 18–24 years group, underscoring the need for supportive interventions to enhance viral suppression in the youngest age group. Latinx participants living with HIV had a lower risk of viral non-suppression compared with White individuals, a finding with clinical relevance that highlights the potential heterogeneity in HIV seropositivity and viral non-suppression outcomes and the need to consider the unique needs of different racial and ethnic groups in health care. Our findings highlight the need for continued interventions in clinical settings to address HIV inequities.

Combination interventions that pair gender-affirming hormone therapy with other services, such as PrEP for HIV prevention and HIV care, might hold promise. The low uptake of PrEP observed in our study highlights the need for focused efforts to increase PrEP uptake for this population. Interventions are needed to address HIV inequities by race, ethnicity, gender identity, socioeconomic status, and age, including those culturally tailored to reach specific trans populations bearing disproportionate HIV burden. Examples of focused HIV-related efforts are Entre Nosotras, a peer-led PrEP project for trans Latina women,[26] and Project LifeSkills, a HIV status-neutral HIV prevention intervention for young transgender women.[27] Incorporating gender-affirming hormone therapy alongside these interventions represents an important future strategy. For example, HIV Prevention Trials 091 is currently testing the co-location of gender-affirming hormone therapy and PrEP delivery for transgender women across five sites (four in the USA and one in Brazil) to increase PrEP uptake and adherence. Additional interventional research to identify and test integrated strategies is warranted.

This study has several limitations. The federally qualified health centres in our study are specialised in providing gender-affirming hormone therapy through

an informed consent model, minimising gatekeeping and barriers to access. The association of gender-affirming hormone therapy with HIV outcomes might be confounded by the gender-affirming context in which clinical care occurred (eg, trained providers and affirming name or pronoun use policies). Second, participants were drawn from urban settings in the northeast USA, which might reduce generalisability to trans people in other regions. Furthermore, 33·7% of our participant population was publicly insured, higher than the national estimate of 23% found in a large community survey of more than 27 000 trans adults;[28] 5·6% of participants were uninsured, which is lower than the estimated 8% in a US representative study.[29] Future research examining the association between gender-affirming hormone therapy and HIV outcomes in samples with more publicly and uninsured individuals is recommended. Third, participants self-selected into gender-affirming hormone therapy treatment. Fourth, this study cannot rule out the possibility that participants received PrEP from other clinics or providers. Fifth, unmeasured confounding might be an issue, since some variables known to be associated with HIV outcomes (eg, housing instability) were not measured. However, the sensitivity analyses using E-values provide a sense of the magnitude of association that potential unmeasured confounders would need to fully explain the observed exposure–outcome associations, and the small E-value confidence intervals indicate that unmeasured confounding is unlikely. Sixth, the duration of hormone use or gender-affirming surgery was not assessed. A previous study of trans people in New York found gender-affirming surgery was associated with sustained viral suppression,[30] and a study of Black and Latina transgender women in Washington, DC and Baltimore found that the desire and unmet need for gender-affirming surgery was associated with increased odds of HIV treatment interruptions.[10] Thus, future research considering both gender-affirming hormone therapy duration and gender-affirming surgery is recommended. Additionally, the current study was 80% powered on the viral non-suppression outcome, but not on HIV seropositivity; additional research investigations of gender-affirming hormone therapy and HIV seropositivity are therefore needed. Finally, given that US HIV surveillance efforts do not have data about gender-affirming hormone therapy, we discuss adjusted parameter estimates for covariates and confounders to contextualise known HIV disparities (eg, by race and ethnicity) alongside gender-affirming hormone therapy, yet caution should be taken interpreting these estimates.[31]

Limitations notwithstanding, our study has strengths, including its primary care cohort (ie, not restricted to individuals presenting at gender clinics) and diversity in terms of HIV serostatus, gender identity, race, and ethnicity. The longitudinal design examined gender-affirming hormone therapy and HIV clinical outcome associations across 7 years of follow-up in real-world clinical settings. Data were reported for non-binary participants, a group for whom scarce HIV data exist. This research was informed by the priorities of trans people.[13] Our consideration of gender identity and gender-affirming hormone therapy in the context of HIV acquisition and viral suppression is novel, given that many HIV surveillance efforts do not routinely collect this trans-specific information.

In conclusion, in this federally qualified health centre-based study of a large sample of trans people in primary care, being prescribed gender-affirming hormone therapy was longitudinally associated with reduced rates of HIV seropositivity and viral non-suppression. Our findings contribute to the evidence base for the health-promoting role of gender-affirming hormone therapy, showing that gender-affirming hormone therapy is a medically necessary treatment that reduces HIV morbidity and improves HIV outcomes longitudinally for trans people. Our study found low rates of PrEP uptake in the cohort, representing another future intervention target to reduce HIV rates. Our results underscore the vital role of gender-affirming models of care and access to gender-affirming hormone therapy for trans people. Gender-affirming hormone therapy services were supported by the Health and Human Resources Administration and Ryan White HIV/AIDS Programs.[32] Integrated gender-affirming hormone therapy and HIV care is safe[33] and recommended for trans people.

Contributors

SLR wrote the first draft of the manuscript, was responsible for the decision to submit the manuscript for publication, and secured funding for the study. DRP conducted statistical analyses with support from SLR. All authors had full access to all the data in the study. SLR, DRP, and JC had verified the data. SLR, KHM, MBD, and AER co-designed the study. All authors critically reviewed, provided scientific input to the manuscript, and agreed with the decision to submit the manuscript.

Declaration of interests

SLR, JP, and ASK receive royalties from McGraw Hill for co-editing the textbook *Transgender and Gender Diverse Health Care: The Fenway Guide*. ASK reports royalties as editor of the American Psychiatric Association textbook *Gender-Affirming Psychiatric Care*. ALW receives separate research funding to her institute from ViiV Healthcare. All other authors declare no competing interests.

Data sharing

Data from this study are not publicly available for use. For data requests, please email the corresponding author. Data requests will be considered from investigators with funding support, after approval of a concept proposal by all study investigators, and with a signed data access agreement.

Acknowledgments

We wish to acknowledge the community advisory board, the scientific advisory board, and the LEGACY research team for their contributions. This research was supported by the Patient-Centered Research Outcomes Institute under award number AD-2017C1-6569 (principal investigator SLR) and the National Institutes of Health under award number R01MD013498 (principal investigator TP). HIV Response in U.S. EXPERIENCING RENEWED STRAIN

Emergency HIV Clinical Response Task Force
April 2026

KEY TAKEWAYS

- HIV service disruptions are occurring, especially for vulnerable populations. These disruptions affect clinical care, prevention and supportive services, and workforce capacity.
- Structural and social determinants of health – particularly unemployment, housing instability, food insecurity, and insurance loss – are emerging as drivers of disruption.
- Clinics are making operational adjustments to their services and staffing that may further limit access to HIV prevention, treatment, and care services.
- Vulnerable populations are falling out of care, notably transgender people, migrants and undocumented individuals, and people experiencing homelessness.
- Continuing to monitor service disruptions will be important as state AIDS Drug Assistance Programs (ADAPs) contract and the Medicaid expansion cuts take effect.

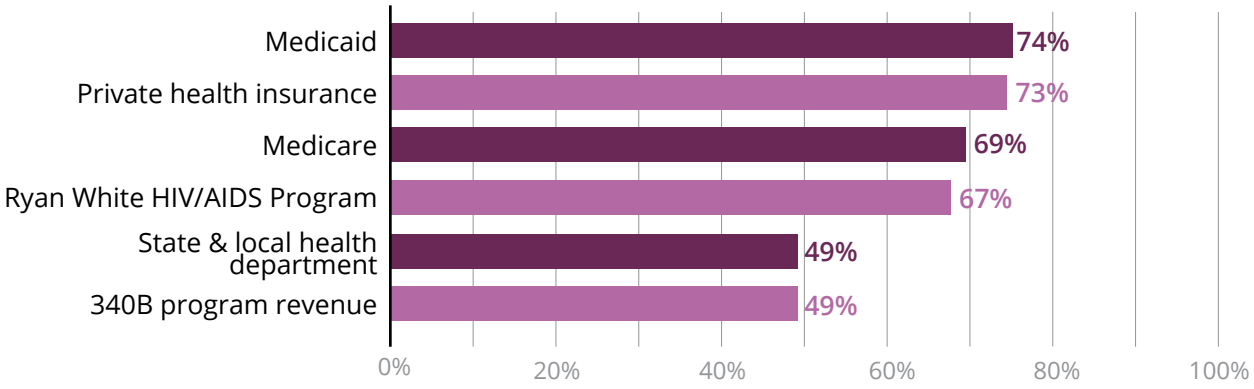
BACKGROUND

Despite decades of progress in HIV prevention and treatment, the HIV response in the United States is experiencing renewed strain. Funding uncertainty, workforce attrition, policy shifts, and rising social and economic precarity are reshaping the delivery of HIV services at the clinic and community levels. In response to reports of HIV clinical and supportive service disruptions, five U.S.-based professional medical and nursing associations – the American Academy of HIV Medicine, Association of Nurses in AIDS Care, Gay and Lesbian Medical Association, HIV Medicine Association, and International Association of Providers of AIDS Care – launched the Emergency HIV Clinical Response Task Force (Task Force) in June 2025.

The Task Force fielded an online Emergency HIV Clinical Response Survey in July 2025 to quantify the scope, nature, and equity dimensions of these disruptions as experienced by frontline HIV service providers across the U.S. A follow-up survey was fielded in November through December 2025 to map additional dimensions related to HIV service disruptions, including structural and social determinants of health, as well as operational austerity measures in the face of federal funding cuts.

METHODOLOGY

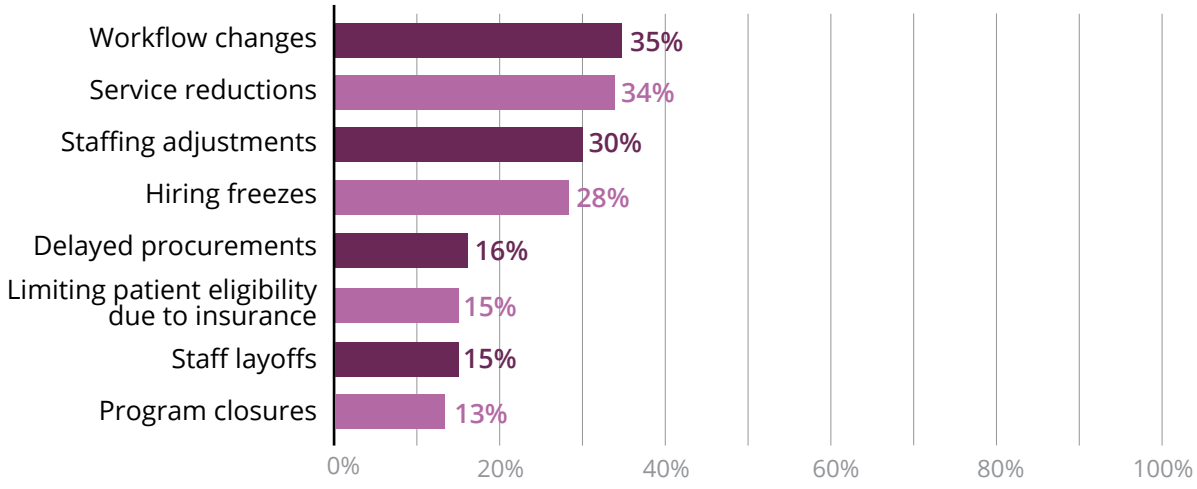
Between November 6, 2025, and December 11, 2025, a follow-up online Emergency HIV Clinical Response Survey was distributed to HIV service providers nationwide through the five members of the Emergency HIV Clinical Response Task Force. Analyses are based on 383 clinical provider respondents who completed the survey across 47 states and Puerto Rico. Respondents included physicians, nurses, pharmacists, case managers, social workers, and community-based providers working across academic medical centers, Federally Qualified Health Centers (FQHCs), hospitals, private practices, and outreach settings. Questions were intended to capture the breadth of disruptions and impacts experienced from July to October 2025.



RESPONDENT AND SITE PROFILES

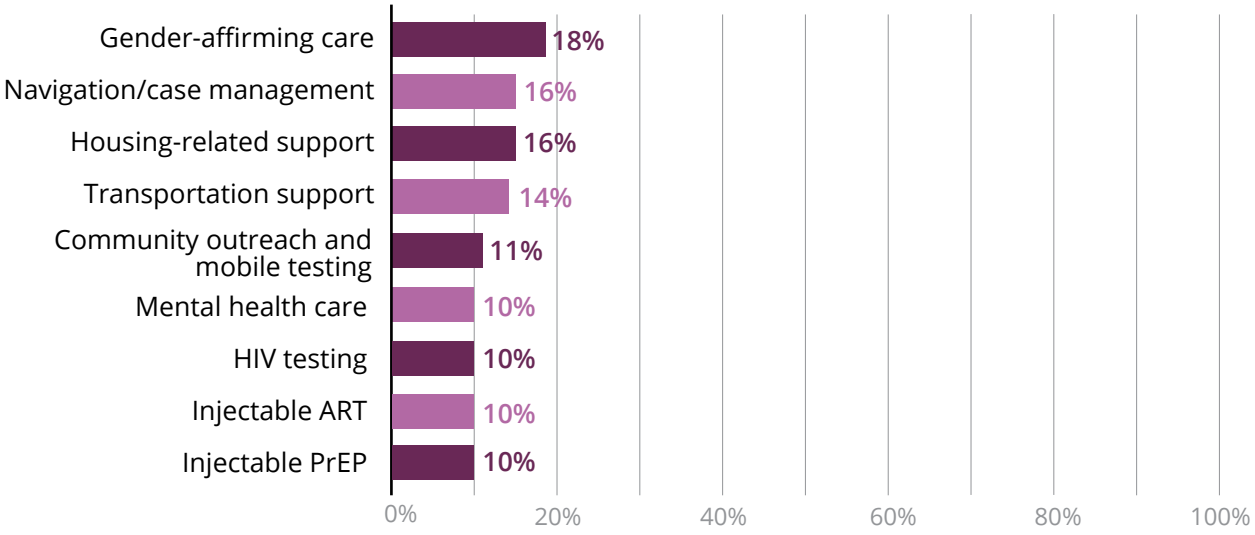
The perspectives captured reflect a cross-section of the HIV workforce and a diversity of clinical settings that deliver HIV care:

- Clinical roles dominated the sample, with physicians (30%), nurse practitioners (23%), and registered nurses (14%) comprising two-thirds of respondents.
- Over 65% of responses came from hospital-based clinics (33%) and community health centers and FQHCs (32%), underscoring impacts within core HIV care infrastructure.
- The South accounted for more than one-third of responses (36%), with responses from three other regions: Northeast (24%), West (23%), and Midwest (18%).



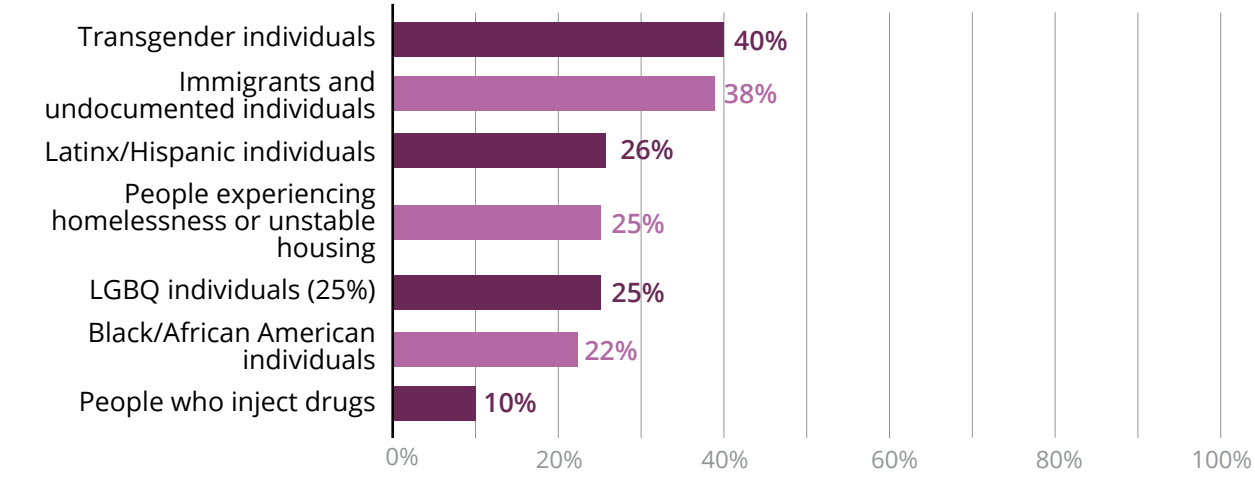
SOURCES OF FUNDING

Respondents reported a combination of funding sources for their clinical settings, including:



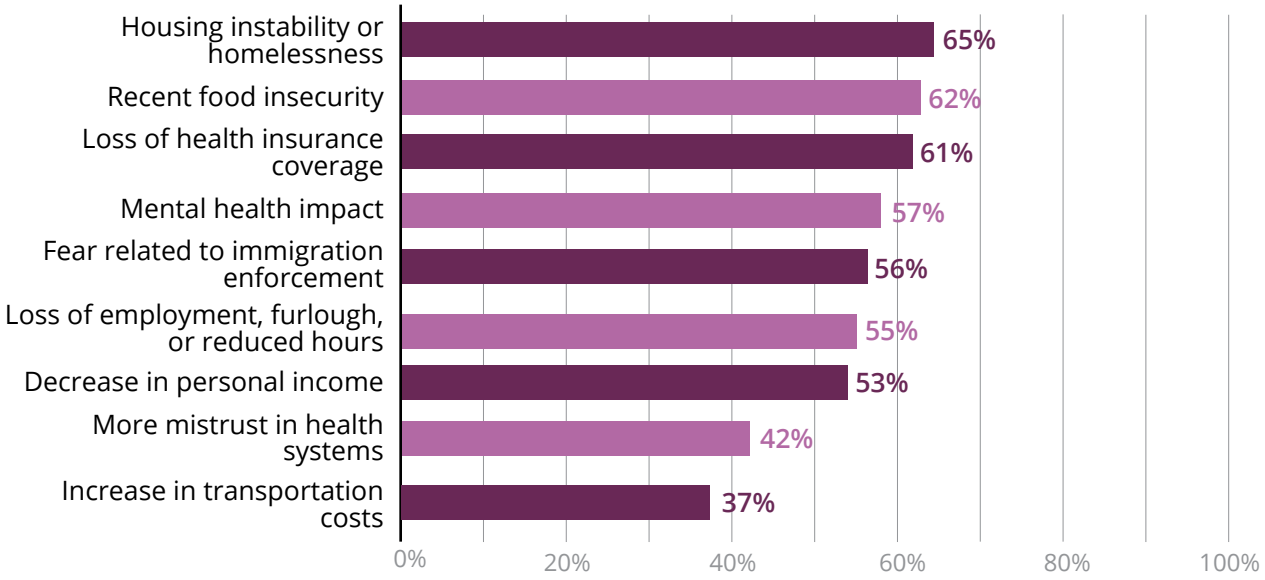
OPERATIONAL DISRUPTIONS

Sixty-eight percent of respondents reported one or more operational changes in their clinical settings due to changes in federal or state policies or funding cuts, including:



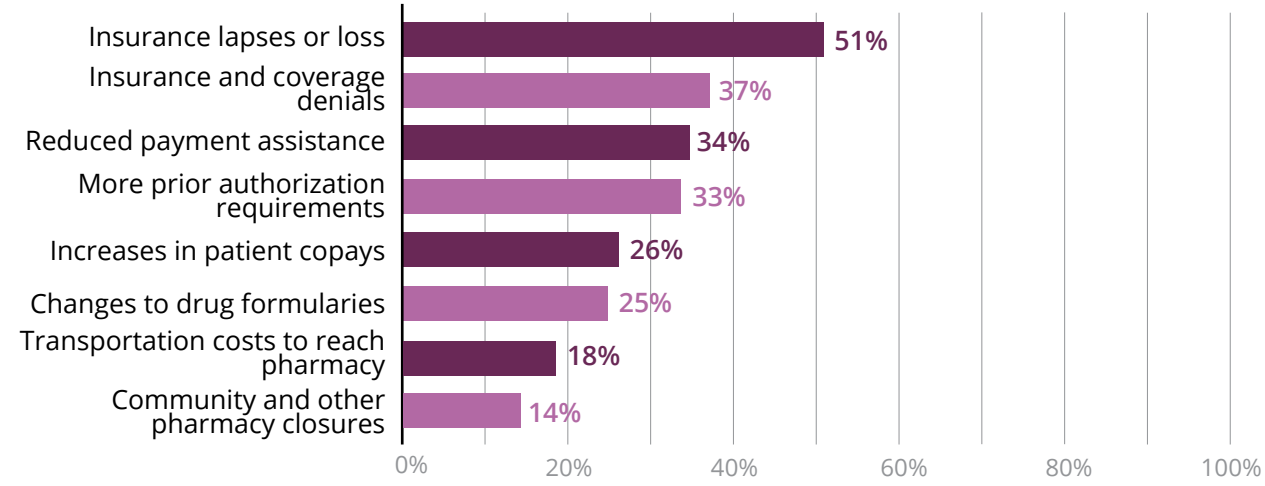
HIV AND OTHER HEALTH SERVICE DISRUPTIONS

Sixty-one percent of respondents reported at least one HIV service disruption in their clinical setting. Reported service disruptions spanned the HIV care continuum and beyond:



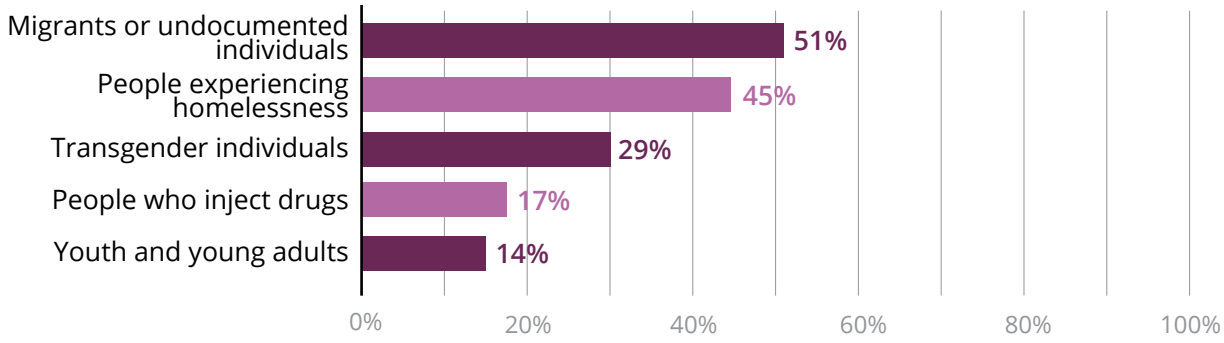
EQUITY IMPACTS: POPULATIONS MOST AFFECTED

Of the 69% of respondents who reported at least one population-level service disruption, the following key populations were cited as most affected:



PATIENT-REPORTED BARRIERS TO ENGAGEMENT IN CARE

Among the 92% of respondents who reported hearing from patients about specific barriers to remaining engaged in care, the following were the most cited:



MEDICATION ACCESS AND LOSS TO FOLLOW-UP

Of the 69% of respondents who reported their patients spoke with them about medication access, the following factors were most associated with medication access barriers:

Although 14% of respondents reported no significant population-specific effects on retention in HIV care, of the 86% of respondents who did report effects the following key populations were cited as the most affected:

INSIGHTS FROM OPEN-ENDED QUESTIONS

Forty-six percent of respondents provided additional insights through an open-ended survey question about the most urgent resources needed to safeguard continuity of HIV services:

- Funding concerns dominate the landscape, mentioned by 37% of respondents, with specific emphasis on Ryan White HIV/AIDS Program (20%) and 340B Drug Pricing Program (4%) sustainability.
- Health insurance coverage was reported as critical, with 27% of respondents citing Affordable Care Act/insurance concerns and 13% specifically mentioning Medicaid enrollment challenges.
- Social determinants of health, including housing (17%), transportation (13%), and food security (7%), were recognized as essential to maintaining HIV care continuity.

Forty-two percent of respondents answered a second open-ended question seeking insights into declines in clinic attendance by undocumented or migrant individuals observed in the respondents' clinical settings, with 83% of this subset of respondents citing fear of immigration enforcement and deportation as the primary contributing factor.

One survey response detailed a patient death directly attributed to this fear:

"Due to a fear of being detained by ICE, a patient with relapsed Hodgkin's lymphoma delayed care and then it became an emergency which resulted in his death."

CONCLUSION

The outcomes of the second Emergency HIV Clinical Response Survey document a clear warning signal that the Trump administration-led policy and funding actions taken over the last year are destabilizing the delivery of HIV services in the U.S.

Continued monitoring is critical in addition to locally-driven, novel, and nimble interventions to prevent disruptions in HIV testing, prevention, care, and treatment with a focus on key populations most affected by federal policy and budget shocks.

Addressing these disruptions is imperative to safeguarding lives and decades of progress in the U.S. HIV response.

IN THE UNITED STATES DISTRICT COURT
FOR THE DISTRICT OF MASSACHUSETTS

AMERICAN ACADEMY OF HIV MEDICINE; HIV MEDICINE ASSOCIATION, a division of the INFECTIOUS DISEASES SOCIETY OF AMERICA; INTERNATIONAL ASSOCIATION OF PROVIDERS OF AIDS CARE; JENNIFER K. BRODY, MD; and CHRISTOPHER B. FOX, NP, *Plaintiffs*, v. HEALTH RESOURCES AND SERVICES ADMINISTRATION; THOMAS J. ENGELS, in his official capacity as the Administrator of the Health Resources and Services Administration; U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES; and ROBERT F. KENNEDY, JR., in his official capacity as Secretary of the U.S. Department of Health and Human Services, *Defendants*.	Case No.

DECLARATION OF ANDREA WEDDLE, EXECUTIVE DIRECTOR OF THE HIV MEDICINE ASSOCIATION

I, Andrea Weddle, hereby declare and state as follows:

1. I am over 18 years of age, of sound mind, and in all respects competent to testify.

2. I have personal knowledge of the facts set forth in this declaration and would testify competently to those facts if called to do so.

3. I am the Executive Director of the HIV Medicine Association ("HIVMA"), which is an organizational component of the Infectious Diseases Society of America ("IDSA"), a 501(c)6

nonprofit organization. IDSA is bringing claims in this case on behalf of HIVMA's members and the transgender patients of its members.

4. I have been the executive director at HIVMA for 18 years and with the association since its inception 25 years ago. In my role, I oversee the strategy development for HIVMA. This includes the policy and programmatic agendas and activities that support our members to provide high-quality care to their patients, advance public health, and conduct HIV research. My work is informed by a postgraduate social work degree from the University of California, Berkeley, and expertise developed over the last two and a half decades on healthcare access and financing, with a focus on people with HIV and other complex, chronic conditions.

5. I submit this declaration in support of Plaintiffs' Motion for Preliminary Relief under 5 U.S.C. § 705 and for a Preliminary Injunction, which seeks to prevent Defendants from giving effect to certain conditions relating to transgender people and gender-affirming medical care set forth in Ryan White HIV/AIDS Program ("Ryan White Program" or "RWHAP") Notices of Funding Opportunity issued or forecasted to be issued in 2026 and the 2026 Updated HRSA General Terms and Conditions, issued on March 11, 2026 (collectively, "the Challenged Conditions").

6. In this declaration, I explain how the Ryan White Program protects public health by providing the majority of people diagnosed with HIV in the United States with comprehensive healthcare. I further describe how transgender people are disproportionately impacted by HIV, and that providing gender-affirming medical care under the Ryan White Program is an important strategy to administer effective HIV care to transgender people with HIV. By restricting their care, the Challenged Conditions are contrary to medical evidence and will likely result in a rise of HIV

transmissions. I conclude by explaining how the Challenged Conditions will cause significant patient and provider harm as well as negative economic impacts.

I. Background on HIVMA

7. IDSA established HIVMA in 2001.

8. HIVMA is a community of nearly 6,000 healthcare professionals who advance a comprehensive and humane response to the HIV pandemic, informed by science and social justice. HIVMA works to increase access to healthcare services and coverage for people with HIV and populations heavily impacted by HIV and to foster a robust, diverse, and culturally competent HIV workforce.

9. A majority of HIVMA members report patient care as their primary professional activity, and most manage the care of patients with HIV.

10. Many HIVMA members provide medical care to their HIV patients through the Ryan White Program, including through funding under Ryan White Parts A, B, C, D, F, and any supplementary funding under these parts. For their transgender HIV patients, this can include hormone therapy as treatment for their gender dysphoria (also known as "gender-affirming hormone therapy" or "gender-affirming medical care").

11. HIVMA develops national guidelines for HIV care, creates practice tools for HIV health care professionals, develops HIV continuing education programs, advocates for federal HIV policy, and leads the field towards ending the HIV epidemic.

12. For example, HIVMA has published *Primary Care Guidance for Providers Who Care for Persons with Human Immunodeficiency Virus*, last updated in 2024, and relied on by HIV medical providers since 2009. A copy of the Guidance is attached hereto as **Exhibit A**. The Guidance, which is published in the peer-reviewed journal *Clinical Infectious Diseases*, includes

a whole section on "Considerations for Transgender and Gender-Diverse Adults" that addresses the importance of gender-affirming hormone therapy as part of the primary care for transgender patients living with HIV. In addition, HIVMA has published a Gender-Affirming Care Resource Brief for its members.

13. HIVMA also created and has sponsored the Ryan White Medical Providers Coalition for twenty years. The Ryan White Medical Providers Coalition is a voice for Ryan White clinicians from across the nation who deliver quality HIV care to their patients using funding from the Ryan White Program. The coalition first convened in 2006 as a call to action led by physicians, advanced practice providers, and other healthcare professionals who work in Ryan White-funded clinics. The coalition evolved with the support of HIVMA and today is a respected and leading voice in federal advocacy related to Ryan White HIV/AIDS Program funding and policies.

II. Ryan White and HIV Care

14. Because so much of HIV care in the United States is affected and funded by the Ryan White Program, as executive director of HIVMA, I am aware of the contours of the program and how it affects HIVMA's members.

15. The Ryan White Program serves the majority of people diagnosed with HIV in the United States. In 1990, Congress passed the Ryan White legislation in response to the HIV/AIDS epidemic. Since then, healthcare providers, including current HIVMA members, have relied on Ryan White funding to serve their patients living with HIV, including transgender patients. Over half of all people diagnosed with HIV are served through the Ryan White Program, and many would not have access to necessary healthcare services and treatment without the program. Many HIVMA provider members would also not be able to meet the healthcare needs of their patients with HIV without Ryan White funding.

16. The goal of the Ryan White Program is to provide a safety net for people living with HIV by providing outpatient HIV care, treatment, and support services to those without health insurance, filling in gaps in coverage, and assisting with costs for those with insurance limitations. Funding is distributed to states/territories, cities, and clinics and community-based organizations in the form of grants.

17. Following its initial adoption and implementation, the Ryan White Program was expanded by Congress to address the unmet care and treatment needs of people living with HIV by focusing Ryan White funding on primary healthcare and support services important to enhancing access to and retention in care and adherence to daily treatment. This update to the Ryan White Program prioritized funding for core medical services, including services for co-occurring conditions for patients with HIV, as well as support services.

18. Medical advances in antiretroviral therapy ("ART") have made it possible for people living with HIV to have a lifespan that approaches that of people without HIV, without progressing to AIDS or transmitting HIV to others. Because of those advances, our members can now focus on maintaining health throughout the lifespan. Maintaining all aspects of HIV patient health is a necessary component of successful and effective HIV care and treatment. The Ryan White Program care model has proven to be highly successful at treating a complex patient population. As a result, demand for Ryan White services has steadily increased without an increase in resources, placing great strain on the HIV workforce and their ability to provide care.

19. As HIVMA's primary care guidance for people with HIV explains, to receive optimal medical care and achieve desired outcomes, persons with HIV must be consistently engaged in care and able to access uninterrupted treatment. Providing primary care for people with HIV is complex and involves management of multiple co-morbidities and the associated

challenges of polypharmacy—the concurrent use of multiple medications—while also attending to HIV-specific health concerns. HIV providers, such as our members, must address issues specific to preventive health, including cancer screening, reducing the risk of cardiovascular disease, providing recommended vaccinations, and promoting sexual health. Additionally, providers must address issues for specific populations, like those with childbearing potential, adolescents, and transgender people.

20. Creating a patient-centered care environment without stigma and discrimination, like that supported by the Ryan White Program, is essential for effectively treating people with HIV and sustaining care engagement, as evidenced by the higher viral suppression rates for Ryan White clients compared to the national average. To end the HIV epidemic by dramatically reducing HIV transmissions, barriers to care must be decreased at every level—societal, health system, clinic, and individual. Many populations with an increased likelihood of acquiring HIV disproportionately experience barriers to accessing care and treatment, including income inequality, unstable housing, food insecurity, joblessness, and poor access to transportation. These barriers emerge from a social framework replete with discrimination against those whose race, ethnicity, sexual orientation, or gender identity is in the minority. Increasingly, HIV care must acknowledge and address these issues in all affected populations to end the HIV epidemic. Ensuring that clinical settings are free of stigma and discrimination is a first and essential step.

III. Transgender Patients with HIV

21. Public health data show that between 55-78% of transgender people rely on public health coverage, such as Medicaid and Medicare.[1] And medical literature documents that

[1] Centers for Disease Control and Prevention. Individual-level Social Determinants of Health and Quality of Life Among Persons with Diagnosed HIV Infection—Medical Monitoring Project, United States, 2022 Data Cycle (June 2022–May 2023). HIV Surveillance Special Report 38, 45 tbl.3a. https://stacks.cdc.gov/view/cdc/168909. Published November 2024. (attached as **Exhibit B**).

transgender adults are more likely to be uninsured than their cisgender counterparts.[2] In addition, some states have prohibited state Medicaid funding for gender-affirming medical care. Given this landscape, Ryan White funding is essential to supplement the public health coverage of transgender people with HIV. Thus, for many transgender people with HIV, the Ryan White Program is the only way they can access the gender-affirming medical care that is medically indicated.

22. Of the more than half a million people served by the Ryan White Program, 2.1%, over 11,000, are transgender.[3]

23. It is well-understood that the HIV epidemic has disproportionately affected certain populations. Gay and bisexual men, other men who have sex with men, and transgender persons, particularly Black and Latina transgender women, are overrepresented among people living with HIV and represent the largest proportion of new HIV diagnoses every year in the United States.[4] As documented in HIVMA's primary care guidance for HIV patients, estimates show a pooled HIV prevalence of 19.9% among transgender women, with 66-fold higher odds of HIV prevalence than the general population, and an estimated HIV prevalence of 2.56% among transgender men.

In 2022, transgender people accounted to 2% of all HIV cases.[5] That is more than three times the proportion of transgender people in the United States (0.6%).[6]

24. Studies have found that access to gender-affirming hormone therapy is associated with reduced rates of HIV acquisition among transgender patients and, in transgender people with HIV, higher rates of viral suppression.[7]

25. Because of the presence of these health disparities and how they affect HIV care, HIVMA and its members need to be aware of the health needs and barriers affecting the populations most impacted by HIV.

26. Indeed, HIVMA's primary care guidance for HIV patients documents that stigma and discrimination are serious issues that threaten the quality of care for transgender persons, noting that "Nearly half of transgender persons face family rejection, 40% report a history of attempted suicide, 29% live in poverty, 30% have experienced homelessness, 33% have experienced discrimination within the healthcare system, and 23% avoid the healthcare system due to fear of discrimination."

27. The above is consistent with the medical literature, which documents that a significant number of transgender people experience negative interactions with their healthcare providers or avoid the healthcare system due to fear of being mistreated because they are transgender. For example, misinformation about transgender people and gender-affirming care is undermining trust in healthcare institutions, delaying or preventing them from accessing healthcare

[5] Centers for Disease Control and Prevention, Fast Facts: HIV in the United States (Apr. 22, 2024), https://tinyurl.com/3zactezx [https://perma.cc/LCE9-W2E5].

Reisner et al., *HIV seropositivity and viral non-suppression in transgender, non-binary, and gender-diverse people in primary care receiving gender-affirming hormone therapy in the USA between 2013 and 2019 (LEGACY): an observational, longitudinal, cohort study*,12 The Lancet HIVe283-e292 (2025).

services and contributing to the spread of diseases.[8] Based on literature cited in HIVMA's primary care guidance, this discrimination plays a dominant role in understanding why transgender women have 66-fold higher odds of HIV prevalence than the general population.[9] In an environment of misinformation and medical discrimination, providers play an important role in confronting misinformation while providing evidence-based care.

28. The U.S. Department of Health and Human Services, through the HHS Panel on Antiretroviral Guidelines for Adults and Adolescents, a working group of the NIH Office of AIDS Research Advisory Council, publishes and regularly updates the "Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV." Prior to 2025, including the September 2024 version, these guidelines contained a section titled "Transgender People with HIV."[10]

29. According to the 2024 HHS guidelines, of which HIVMA and its members keep regularly apprised, "Because transgender and nonbinary people bear a disproportionate burden of HIV, it is important for HIV care providers to be knowledgeable about the specific HIV care needs of these individuals." **Ex. F** at I-100.

30. The guidelines stated that:

> Individuals are more likely to engage in HIV care when gender affirmation needs are met. A national study of transgender people with HIV found that participants who work with HIV care providers who affirm their gender (e.g., providers who use their chosen name and pronoun) were more likely to be virologically suppressed. **Adherence to hormone therapy correlates with adherence to ART**.

> According to research with transgender youth and adults, **integrating HIV care with gender care facilitates treatment and is associated with higher rates of viral suppression**. In addition to minimizing the number of provider visits and potentially stressful clinical interactions, **care integration makes it easier to discuss concerns about drug–drug interactions between HIV treatment and gender-affirming medications**.
>
> …
>
> **HIV care services should be provided within a gender-affirmative care model to reduce potential barriers to ART adherence and to maximize the likelihood of achieving sustained viral suppression** … Clinicians should also ask people with HIV about their gender identity, chosen names, and pronouns, using developmentally appropriate language.
>
> …
>
> **Integrating hormone therapy with HIV services is the recommended practice; this requires HIV providers to become knowledgeable about hormone therapy and other aspects of gender-affirming services**.

Ex. F at I-102 – I-103 (emphases added).

31. The guidelines further documented,

> In 2022, the Ryan White HIV/AIDS Program (RWHAP) provided services for 11,085 transgender people, representing 2.8% of RWHAP clients. Of these transgender clients, 2.3% were transgender women, 0.3% transgender men, and 0.2% with another gender identity (e.g., nonbinary). Among RWHAP participants, retention in care (73.5%) and viral suppression (86.4%) for transgender adults and adolescents were lower than the national averages (77.5% and 89.6%, respectively).

Ex. F at I-101.

32. Unfortunately, the current administration eliminated the section on "Transgender People with HIV" and virtually every other mention of transgender people in the September 25, 2025 version of the guidelines.[11]

33. Nonetheless, as documented in HIVMA's guidance and the medical literature, in addition to reducing stigma and discrimination in order to facilitate patient empowerment, care

[11] U.S. Department of Health and Human Services, Panel on Antiretroviral Guidelines for Adults and Adolescents, Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV (updated September 25, 2025) (attached hereto as **Exhibit G**).

engagement, and viral suppression, it is crucial for HIV providers to monitor their patients' gender-affirming care for polypharmacy management. When pharmacokinetic interactions between medications are anticipated, providers should monitor clinical effects and adjust hormone doses as needed. It is important to provide patients with accurate information on drug–drug interactions between their ART and hormone therapy, including the lack of deleterious effects on hormone therapy, and to make dose adjustments as appropriate.

34. Our members use research, like that referenced in HIVMA's primary care guidance, to inform their care and educate their patients.[12] Such research shows how various HIV medications may decrease or increase hormone levels. Moreover, lack of communication around drug–drug interaction concerns may contribute to fear of drug–drug interactions and poor adherence to one therapy or the other. For these reasons, it is considered best practice for HIV care providers to also ensure their patients can obtain gender-affirming medical care when medically indicated.

35. In furtherance of the Ryan White Program's purpose and our shared goal to end the HIV epidemic, and based on the evidence as documented in the scientific and medical literature, HIVMA's primary care guidance included four primary recommendations for the care of transgender people with HIV. First, transgender people with HIV should have access to care that is gender-affirming, nondiscriminatory, non-stigmatizing, and culturally sensitive. Second, intake forms, medical records, and other documentation should include gender identity options in addition to sex assigned at birth, providers should address patients using their chosen name and

[12] *See*, *e.g.*, Lauren R. Cirrincione et al., *Drug interactions with gender-affirming hormone therapy: focus on antiretrovirals and direct acting antivirals*, 16 Expert Opin Drug Metab Toxicol 565–82 (2020) (attached as **Exhibit H**); Braun et al., *Transgender women living with HIV frequently take antiretroviral therapy and/or hormone therapy differently than prescribed due to drug-drug interaction concerns*, 4 LGBT Health 371–5 (2017) (attached as **Exhibit I**).

pronouns, and educational materials should reflect the experiences of transgender people. Third, transgender people should be offered medically necessary gender-affirming interventions in accordance with national guidelines. And fourth, HIV care providers should be familiar with gender-affirming hormone treatment and necessary clinical and laboratory monitoring, or work in concert with a provider or endocrinologist experienced in transgender care.

IV. Gender-Affirming Medical Care under the Ryan White Program

36. Given the above and Congress's instruction that the Ryan White Program shall be used to cover "outpatient and ambulatory health services" "including services regarding the co-occurring conditions" of HIV patients, HIVMA members who care for transgender patients with HIV have provided gender-affirming hormone therapy to these patients as part of their efforts to address the comprehensive healthcare needs of their patients.

37. As such, a Dear Colleague Letter issued by the Health Resources and Services Administration ("HRSA") issued on December 16, 2021, recognized that "RWHAP funds may be used to support gender affirming care across various HRSA RWHAP core medical and support service categories." A copy of the Dear Colleague Letter is attached hereto as **Exhibit J**. According to the Dear Colleague Letter, "Providing gender-affirming care is an important strategy to effectively address the health and medical needs of transgender people with HIV."

38. What is more, since 2010, HRSA, as the administrator of the Ryan White Program, has published a strategic plan to end the HIV epidemic. In 2024, HRSA introduced Ryan White Program 2030: Engaging People with HIV in Care to End the HIV Epidemic, which it updated on January 21, 2026. A copy of the 2024 Ryan White Program 2030 Briefer is attached hereto as **Exhibit K**, and a copy of the 2026 Ryan White Program 2030 Briefer is attached hereto as **Exhibit L**. This strategic plan recommends building off the lifesaving successes of the Ryan White

Program by "sustain[ing] high-quality care and treatment for people currently receiving services through the RWHAP while expanding efforts to identify and engage individuals with HIV who are undiagnosed or out-of-care." From 2010 to 2024, the Ryan White program successfully increased HIV viral suppression from 69.5% to 91.4%. Nationally, the average viral suppression rate is just 67%. Achieving viral suppression keeps people with HIV healthy and prevents HIV transmissions by stopping the sexual transmission of HIV, which also reduces long-term healthcare costs. The plan reiterates that Ryan White grantees, such as HIVMA's members, "play a critical role in advancing the goals of RWP 2030," "are responsible for employing sound planning and decision-making processes to determine which HIV-related services are prioritized," and "must continue to base service priorities and resource allocation decisions on the size, demographics, and needs of people with or affected by HIV." This plan concludes by reminding the HIV provider community to leverage the infrastructure and expertise of the Ryan White Program, along with its innovations and high-impact activities, to reach people with HIV who are out of care, "ensuring that no one is left behind in our efforts to end the HIV epidemic."

39. The Challenged Conditions seem to be at odds with the goals of the Ryan White Program 2030 plan. This plan recommends HIV providers advocate for and provide the best course of HIV care, while at the same time explicitly recommending that transgender patients' identities be disrespected and that their healthcare needs related to gender dysphoria, when such a co-occurring condition exists, be "left behind." This, in turn, has caused confusion and concern among HIVMA's members.

40. Leaving transgender patients behind by requiring that their identities be unacknowledged or disrespected and prohibiting the use of Ryan White funding for gender-affirming medical care is a turn of events that has led to deep concerns among HIVMA members.

Prohibiting the use of Ryan White funding for gender-affirming medical care is counter to the medical evidence and will cause harm to transgender people with HIV, likely leading to individuals falling out of care and, therefore, likely resulting in a rise in HIV transmissions. HIVMA has been educating HIV providers to provide person-centered, comprehensive, evidence-based care since it was established in 2001. And after the HRSA Dear Colleague letter was issued in 2021, there was an intentional push from the federal government and within the HIV care community to encourage Ryan White providers, to the degree they were not already doing so, to affirm their transgender patients and provide them with gender-affirming hormone therapy if medically indicated.

41. Understanding how the provision of gender-affirming medical care increases HIV care adherence and leads to viral suppression for transgender patients with HIV has been a central tenet of our HIVMA members providing effective HIV care to transgender patients, and is necessary to achieve our nation's goal to end the epidemic. Indeed, the entire national HIV care structure came to recognize that providing transgender patients with this necessary and helpful care ensures that such patients stay in HIV care. And that it is therefore necessary to achieve our goal to end the HIV epidemic.

42. Given this understanding, no one anticipated a future policy prohibiting the use of Ryan White funding for the necessary care of transgender patients with HIV. That is, until the Challenged Conditions and HRSA's actions under the current administration.

V. The Impact of the Challenged Conditions on HIVMA Members and their Patients

43. Given the current administration's stance towards transgender people and gender-affirming medical care, the Challenged Conditions, as well as the recent attacks on gender-affirming medical care, HIVMA has sought to better understand the funding challenges our

members face because of any restrictions on gender-affirming medical care, including the Challenged Conditions.

44. Concerns about restrictions on gender-affirming medical care services for people with HIV and the impact those restrictions would have on patient care are routinely raised in regular engagements with HIVMA members during open forums and Board, committee, and working group meetings, in addition to surveys. These concerns have also been a focus of discussion at HIVMA/Ryan White Medical Providers Coalition annual luncheons, which cumulatively have been attended by hundreds of providers. In response to the concerns raised, HIVMA created a gender-affirming care resource guide to support members.

45. Among HIVMA members, there is a lot of uncertainty and confusion around the Challenged Conditions and fears that some institutions may preemptively restrict gender-affirming care to protect Ryan White Program funding. Our members are also concerned that the Challenged Conditions will impact all their medical interactions with transgender patients, as the Challenged Conditions seem to suggest.

46. The Challenged Conditions place our members in an untenable position. If they choose to comply with the Challenged Conditions, they endanger the health and wellbeing of their transgender patients with HIV. If they follow their duty to their patients by providing their transgender patients with HIV the best care and the care they need, they risk losing essential federal funding for all their HIV patients, the vast majority of which is unrelated to gender-affirming care, and endanger the health and wellbeing of other HIV patients.

47. Our members also face difficult questions about navigating non-discrimination mandates when the use of Ryan White funds, which sometimes is the only source of funding for medical care, prohibits the provision of gender-affirming medical care. Or when, as the General

Terms and Conditions intimate, members must not acknowledge or respect their transgender patients' identities. By requiring our members to disrespect transgender patients and to deny them evidence-based care, it also puts them out of compliance with state and federal non-discrimination laws. Our members use Ryan White funding to provide comprehensive primary care services, addressing the full spectrum of co-occurring medical conditions for their non-transgender patients with HIV. But they cannot use Ryan White funding to provide their transgender patients with HIV with the same comprehensive primary care services, despite the fact that such care is often essential to maintaining engagement in HIV treatment and longitudinal care.

48. Beyond the unethical demands, HIVMA members are unsure how to navigate administrative and logistical challenges. HIVMA members have long relied on the Ryan White Program as an essential, stable, and comprehensive funding source that supports HIV medications as well as medically necessary healthcare that patients with HIV may need, like primary care and care for co-occurring conditions. This includes gender-affirming medical care for the transgender people living with HIV who need it. HIVMA members have structured integrated care programs on the understanding that Ryan White funds can, and are intended, to deliver such comprehensive primary care. This reliance is based on the structure and purpose of the Ryan White Program, as well as how the program has operated in the past.

49. The Ryan White Program often funds a clinic or a provider's salary, not just the individual care or medication that a patient needs. Even if alternative funding were available, which for many HIVMA members it is not, it remains unclear how providers could meaningfully separate or untangle Ryan White-funded services from the provision of medically necessary care for their transgender patients. Indeed, some Ryan White clinics have expressed concern that the restrictions could jeopardize their operations altogether.

50. The abrupt restrictions on care created by the Challenged Conditions would upend the settled expectations of HIV care providers participating in the Ryan White Program and those of their transgender patients; force providers to dismantle established care models, withdraw needed services from the transgender patients who depend on them; require them to discriminate against their transgender patients, which would cause these patients to fall out of care; and jeopardize both individual health outcomes and broader public health goals.

51. Our members fear that the Challenged Conditions will lead the HIV community to lose even more of its already depleted healthcare workforce, as they are morally depleted by being forced to deny evidence-based services to their patients.

52. If Ryan White healthcare providers are prohibited from providing gender-affirming care or required to discriminate against their transgender patients by refusing to acknowledge and respect their identities, the public health consequences would be serious and significant.

53. As noted, research shows that adherence to HIV care is negatively affected by stigma and discrimination. Transgender patients who are unable to receive gender-affirming medical care or receive care that is affirming and respectful of their identities lose trust in their providers, experience mental health declines, struggle to stay in stable housing, risk losing their jobs, and suffer from greater food insecurity. Ryan White funding addresses these issues because taking care of the whole person is *necessary* to prevent people from falling out of care. Falling out of care can lead to loss of viral suppression, leading to an increase in HIV transmission, and the development of viral resistance to medication, which then requires more intensive therapies. It also puts patients at risk of opportunistic infections that can be life-threatening and require intensive healthcare resource utilization, including inpatient hospitalizations. When people with HIV lose access to HIV treatment, the virus rebounds, impairing the immune system, potentially causing

irreparable harm depending on the length of the treatment disruption and other factors, and increasing the risk of transmitting HIV, leading to not only consequences for the individual, but the community-at-large.

54. Besides the human devastation, there is an economic cost. Lifetime HIV treatment costs for an individual range from $500,000 to $1.2 million. The more people with HIV, the more it costs to treat them and stop the spread. Denying access to services necessary to effectively treat HIV for transgender patients creates an exponential problem that compromises public health.

55. Before the COVID-19 pandemic, epidemiologists and public health experts warned about the system failures they were witnessing. HIVMA and its members fear that HIV care may be reaching a similar crisis point if the Challenged Conditions are allowed to take effect.

56. As the Executive Director of HIVMA, I see that the prohibition of Ryan White funding for gender-affirming medical care and the requirement that Ryan White healthcare providers refrain from respecting the identities of their transgender patients as a condition for funding are contributing to the funding uncertainty, undue workforce strain and attrition, policy shifts, and rising social and economic instability that predate system failure. HIVMA, along with the American Academy of HIV Medicine, Association of Nurses in AIDS Care, GLMA—Health Professionals Advancing LGBTQ+ Equality, and the International Association of Providers of AIDS Care, has joined together in the Emergency HIV Clinical Response Task Force to respond to these threats. The goal of this task force is to monitor and better understand how threats and restrictions on federal funding are impacting HIV care. Based on the 2025 surveys, gender-affirming medical care is the service area most at risk of disruption. By monitoring these threats, HIVMA can advocate for policies that respond to the needs of our members and their patients.

57. HIVMA members cannot achieve the goal of advancing a comprehensive and humane response to the HIV epidemic without addressing the needs of transgender people living with HIV.

I declare under penalty of perjury that the foregoing is true and correct.

Advances in antiretroviral therapy (ART) have made it possible for persons with human immunodeficiency virus (HIV) to have a lifespan that approaches that of people without HIV without progressing to AIDS or transmitting HIV to sexual partners or infants. There is, therefore, increasing emphasis on maintaining health throughout the lifespan. To receive optimal medical care and achieve desired outcomes, persons with HIV must be consistently engaged in care and able to access uninterrupted treatment, including ART. Comprehensive, evidence-based HIV primary care guidance is, therefore, more important than ever. Creating a patient-centered, stigma-free care environment is essential for care engagement. Barriers to care must be decreased at the societal, health system, clinic, and individual levels. As the population ages and noncommunicable diseases arise, providing comprehensive healthcare for persons with HIV becomes increasingly complex, including management of multiple comorbidities and the associated challenges of polypharmacy while also attending to HIV-specific health concerns. Clinicians must address issues specific to preventive health, including cancer screening, providing recommended vaccinations, and promoting sexual health, including sexually transmitted infection diagnosis, treatment, and prevention. Clinicians also must address issues for specific populations, including persons of childbearing potential during preconception and pregnancy, children, adolescents, and transgender and gender-diverse individuals. This guidance from an expert panel of the HIV Medicine Association of the Infectious Diseases Society of America updates the previous 2020 HIV Primary Care Guidance.

Keywords. HIV; primary care; immunizations; comorbidities; STIs.

Continuous access to antiretroviral therapy (ART) and engagement in a patient-centered, stigma-free, high-quality care environment are essential to assist people with human immunodeficiency virus (HIV) to achieve their health goals, improve their quality and length of life, and eliminate HIV transmission to sexual partners and infants through viral suppression. As effective ART has become simpler over time, HIV care and the care environment have become increasingly complex, and updated HIV primary care guidance is needed. As people with HIV live longer, clinicians must attend to preventing and managing comorbidities and coinfections that often occur earlier and more frequently in people with HIV than in people without HIV. This becomes increasingly important as individuals age. Likewise, screening for and addressing substance use and mental health conditions throughout the lifespan is essential to effective HIV care. At the same time, a strained HIV workforce struggles to provide care to an ever-increasing population of people with HIV and to do so with diminishing resources. Many people with HIV, including those at increased likelihood of acquiring HIV, disproportionately experience barriers to accessing care and treatment, including income inequality, unstable housing, food insecurity, joblessness, and poor access to transportation.

These barriers are embedded in a social framework interwoven with racism, sexism, and discrimination against those whose race, ethnicity, sexual orientation, or gender identity is in the minority. Increasingly, HIV care must acknowledge and address these issues to end the HIV epidemic in all populations. Ensuring that clinical settings are free of stigma and discrimination is a first and essential step. Unfortunately, the United States is still far below its goals for ending the epidemic. The most recent available data show that among all people estimated to be living with HIV (diagnosed or undiagnosed), only 57% had suppressed virus, with lower levels among Black, Hispanic/Latino, and Indigenous populations; people who inject drugs; and heterosexual cisgender men. Only 47% of all people with HIV met the definition for care retention, with even lower rates in many populations [1]. Such disparities highlight the fact that HIV care, as well as HIV prevention, must be person-centered, inclusive of attention to social determinants of health, and based on equity.

While this Guidance primarily addresses care for people with HIV, a patient-centered and individualized approach to HIV prevention and care is required to end the HIV epidemic. Substantial health disparities that are driven by societal inequities continue to be seen among those with new HIV diagnoses. Although pre-exposure prophylaxis (PrEP) is a highly effective tool for HIV prevention, its implementation is not yet equity-based or centered in the populations who would most benefit [2–4]. Some HIV care providers also provide PrEP, but expansion of both HIV testing and PrEP access is needed using novel service-delivery approaches that are beyond the traditional clinic visit to improve access. Similarly, the ongoing sexually transmitted infection (STI) epidemic disproportionately affects people with and vulnerable to HIV. STI screening, treatment, and prevention should be included in a syndemic approach to HIV prevention and care.

All of these factors contribute to the need for evolving HIV care recommendations in order to meet new and intensified challenges. This version of the Primary Care Guidance for Providers Who Care for Persons With Human Immunodeficiency Virus contains an expanded section devoted to patient-centered optimization of HIV care, including use of tools such as multidisciplinary care teams, telehealth, and street medicine. The Guidance has new sections devoted to immunizations, cancer screening, and STIs, including a focus on mpox (formerly monkeypox) and STI prevention using doxycycline postexposure prophylaxis (doxyPEP). An updated discussion of metabolic diseases addresses statin use in people with HIV as well as approaches to comorbidity screening and management. A section on children with HIV has been added, along with updated sections on care for adolescents, persons of childbearing potential, and transgender and gender-diverse populations, and on coronavirus disease 2019 (COVID-19) and people with HIV.

METHODS

Panel Composition

Participants on the panel are HIV Medicine Association (HIVMA) members who are experts in the care of persons with HIV and who volunteered to participate. Two co-chairs (M. A. H. and M. A. T.) with experience in developing guidelines led the expert panel.

Literature Review, Analysis, and Consensus Development of Evidence-based Recommendations

The expert panel, with the assistance from a consultant experienced in medical literature reviews, conducted a literature review to identify new contributions to the field from the date of the last guideline publication in 2020 to December 2023, except when noted in the literature cited. In particular, changes to key guidelines and recommendations and late-breaking data deemed to be practice-changing were included up to the time of manuscript submission. Panel members responsible for each section evaluated the evidence and developed recommendations accordingly. The entire panel reviewed all recommendations, and decisions on the final recommendations were made by consensus based on the evidence. The full panel participated in reviewing and editing the final document. A medical writer contributed to copy editing and formatting prior to submission.

Disclosure and Management of Potential Conflicts of Interest

All panel members complied with the Infectious Diseases Society of America (IDSA) policy on conflicts of interest, which requires disclosure of any financial or other interest that might be construed as constituting an actual, potential, or apparent conflict. Panel members were provided with IDSA's conflict of interest disclosure statement and asked to identify ties to companies that develop products that might be affected by promulgation of the guidance or any other potential conflicts. Information for panel members and spouses was requested regarding employment, consultancies, stock ownership, honoraria, research funding, expert testimony, and membership on company advisory committees. Disclosure of new conflicts of interest was solicited at the beginning of each panel meeting. The panel made decisions on a case-by-case basis as to whether an individual's role should be limited as a result of a conflict or potential conflict. No limiting conflicts were identified.

RECOMMENDATIONS FOR THE PRIMARY CARE OF PERSONS WITH HIV

The following recommendations are based on evidence available to the panel at the time of publication. Many of the recommendations refer to other guidelines and recommendations, including, but not limited to, those from the Department of Health and Human Services (HHS), Centers for Disease

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Control and Prevention (CDC), and the CDC Advisory Committee on Immunization Practices (ACIP), with the recognition that these sources evolve over time and that no single primary care guidance publication can fully anticipate these changes. In general, recommendations from the most current versions of guidelines and ACIP recommendations should be followed.

SECTION 1: OPTIMIZING CARE ENGAGEMENT, MEDICATION ADHERENCE, AND VIRAL SUPPRESSION

Recommendations

- All persons with HIV should be provided timely access to routine and urgent medical care via a patient-centered approach, beginning with Rapid ART at entry, if feasible.
- Longitudinal low-barrier models, such as extended or nontraditional business hours, walk-in acute or primary care, telehealth, and alternate care venues, including street medicine, should be incorporated as feasible.
- HIV care sites should provide linguistically and culturally appropriate care.
- HIV care sites should maximize diversity of the workforce to represent the patient population served in terms of gender identity, sexual orientation, race, ethnicity, primary language, and meaningful representation of persons with HIV.
- HIV care sites should implement programs that incorporate evidence-based and evidence-informed interventions shown to improve HIV care engagement and viral suppression, including providing gender-affirming and trauma-informed care, addressing structural and social determinants of health, and integrating mental health and substance use treatment with harm reduction and cultural humility at the core.
- HIV care sites should use a multidisciplinary team model but identify a primary clinician with experience and expertise in HIV for each patient and support the development of trusting long-term patient–clinician relationships.
- Because HIV-related stigma and misinformation remain highly prevalent within healthcare systems, HIV care site employees and clinicians should advocate for patients' rights throughout the healthcare system to ensure that people with HIV are appropriately considered for medical and surgical procedures.
- Surgical and dental decisions for people with HIV should be based on shared decision-making among the HIV specialist, surgeon, and patient while weighing all relevant factors and should not depend on the CD4 cell count or HIV RNA level alone.
- People with HIV should be considered as both solid organ recipients (regardless of donor HIV status) and solid organ donors to people with HIV.

Evidence Summary

Initiating ART on the day of or within 7 days of diagnosis is considered Rapid ART [5]. Rapid ART is a pillar of Ending the HIV Epidemic: A Plan for America and the National HIV/AIDS Strategy, while also being endorsed in each of the major clinical HIV treatment guidelines [6–9]. ART should be offered unless a clinical concern exists that warrants delaying ART initiation, such as cryptococcal or tuberculous meningitis, or if the patient expresses a desire to delay therapy. Structural, systemic, or programmatic barriers that would impede Rapid ART should be removed [10]. Elimination of barriers to the initial linkage to care leads to shorter times to viral suppression. Delay from diagnosis to the initial appointment for HIV care has been shown to be a predictor of failure to engage in care, which Rapid ART mitigates [11]. Persons engaged in Rapid ART programs may need enhanced support to achieve continuous care engagement and viral suppression [12].

The long-term effectiveness of ART is dependent on durable suppression of viral replication. Clinicians should emphasize that viral suppression not only improves the patient's health but prevents HIV transmission to others [13]. "Undetectable = Untransmittable" (U = U) messaging is welcomed and encouraged by communities with HIV and should be part of routine messaging in the clinic to mitigate stigma and encourage ART adherence. Pursuit of viral suppression should ensure that those individuals whose virus is not suppressed do not feel further stigmatized. Conversations should be conducted in a nonjudgmental fashion and should seek reasons and potential solutions for the adherence challenges that result in viremia. Stigma mitigation is important to optimizing adherence and viral suppression as stigma is a significant driver of care disengagement and adherence challenges [14].

Wherever persons with HIV are cared for, people-first language (such as "people with HIV" instead of "HIV-infected people") and gender-affirming language should be used, and appropriate pronouns and names should be used in electronic health records and when addressing patients directly [15]. Knowledge dissemination is critical to combating stigma in healthcare settings, while many myths about HIV remain [16, 17]. Clinicians should disseminate knowledge regarding scientific advances, including that HIV is a chronic illness in the setting of effective ART; that risk of transmission in healthcare settings is <1% with no reports of healthcare transmission in the modern ART and post-exposure prophylaxis (PEP) era; and that surgical and dental decisions should be based on shared decision-making among the HIV specialist, surgeon, and patient while weighing all relevant clinical factors. Decisions related to surgical and dental procedures should not depend on the CD4 cell count or HIV RNA level alone [18, 19]. Furthermore, people with HIV can be considered as both recipients and donors in solid organ transplantation, and HIV alone should not be an exclusionary factor [20–23]. People with HIV can receive

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

organs from all donors, while people with HIV can only donate organs to other people with HIV. The HIV Organ Policy Equity Act, enacted in 2013, reversed a federal ban on use of organs from people with HIV in recipients with HIV and set standards for research and clinical care in solid organ transplantation among people with HIV. It is important for clinicians to consider referrals for transplantation; updated lists of approved transplantation centers for people with HIV are accessible through the Health Resources and Services Administration Organ Transplantation and Procurement Network webpage [24].

The primary reason for treatment failure, particularly among patients on their first ART regimen, is suboptimal adherence to care or treatment regimens [25, 26]. Medication adherence is essential to achieving and maintaining viral suppression with modern ART, although 100% adherence may not always be necessary for optimal viral suppression outcomes [27]. Discussions and education around adherence to ART should use an empathetic lens with the goal of identifying barriers to adhering to regular medication use and brainstorming feasible solutions. Counseling about the importance of medication adherence should be provided carefully and thoughtfully so as not to perpetuate (or lead to) a sense of self-guilt or anxiety about missed doses. Further, inconsistent adherence may be linked to other important health outcomes, for example, cardiovascular disease and increased mortality, even in the setting of viral suppression [28].

There are many drivers of poor treatment adherence including inconsistent access to medications (including inability to afford medications, limited pharmacy hours, requirements to pick up prescription refills monthly); structural and societal-level barriers (including inadequate transportation; health system barriers to engagement; food or housing insecurity; stigma and discrimination based on HIV status, race, ethnicity, gender identity, sexual orientation, disability, or immigration status); clinic-level barriers (including stigmatizing/discriminatory language or practice by office staff or clinicians, restrictive hours, inaccessible location, lack of a mutually trusting and respectful, collaborative patient–clinician relationship); and patient-level barriers (mental health and substance use issues, pill fear, pill fatigue) [29–34]. Additionally, periods of transition (eg, postpartum, relocation, employment/insurance changes, incarceration) may lead to disengagement in care. Some populations may warrant dedicated programs and support to assist with care reengagement [35]. All of these factors must be considered when designing systems to improve care engagement.

Adherence to care means not only medication adherence but also medical visit attendance and continual engagement in care [36]. Low adherence to visits and poor engagement in care have been found to predict approximately 50% higher mortality among persons with HIV [37]. Thus, it is critically important that HIV care providers and clinics have evidence-based and evidence-informed strategies to effectively engage and assist patients in staying in care [38]. Interventions that improve care engagement or viral suppression generally achieve 1 of 3 things: care coordination through a multidisciplinary team of providers (both physical and behavioral health) and social supports, provision of an essential need such as housing or food assistance, or creation of an environment that elicits and acknowledges patients' goals, motivations, and care needs. Specific considerations may include physical location, clinic environment, and the individual's biopsychosocial situation. Inherent in each of these is a strengths-based approach that leverages a patient's strengths as a part of the solutions [39]. While many interventions have demonstrated some impact on care engagement and adherence to medication, none have a very large effect size [38]. Barriers to care are heterogeneous; therefore, programs to overcome these barriers will need to be similarly heterogeneous. Differentiated service delivery, whereby the location, intensity, frequency of the service, and who delivers that service are tailored to individual needs, is a model that factors in heterogeneous needs at a large scale [40].

Components that could provide a foundation for individual care engagement include social engagement programs, reminders around the clinic about the importance of attending appointments, patient navigation (including enhanced personal contacts), financial incentives, nutrition assistance, and mobile health platforms that leverage mobile devices to better engage patients [41–46]. Intake assessments and ongoing assessments of barriers to care should include social and economic factors such as stigma, violence, social support, food insecurity, unstable housing, and transportation challenges. Lack of adequate food or safe housing can impact the ability to remain adherent to a treatment regimen and even be associated with increased risk of death [47]. Early assessment by a qualified social worker or case manager is essential, and ongoing access to effective case management teams is necessary to overcome barriers to care [48].

At times, how and where care is delivered needs to shift entirely. Accordingly, there are several promising new care models that can help advance access and thus improve health outcomes. Telehealth is a technological innovation that was widely implemented during the COVID-19 public health emergency that allows clinicians to interface with patients via synchronous audio or video to overcome barriers and improve continuity of care [49]. Telehealth consultations can be leveraged to bring HIV care to a primary care clinic or resource-limited and rural settings or to address the shortage of HIV clinicians via peer mentoring [50–54]. The Centers for Medicare & Medicaid Services guidance issued in June 2023 requires audio-video technology for most nonbehavioral telehealth consultations and permits audio-only for mental health encounters [55]. A systematic review showed improved physician-defined outcomes with videoconferencing as opposed to audio-only.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

However, because patient outcomes were comparable between videoconference and audio-only, lack of videoconferencing capability should not be a barrier to telehealth encounters [56]. The benefits of a telehealthcare model include enhanced access to a multidisciplinary care team, on-demand care, and flexibility [57]. Despite these benefits, telehealth has the potential to introduce privacy and confidentiality concerns and potentially worsen disparities via the digital divide [58–60]. Telehealth also operates under ambiguous state-by-state piecemeal regulations that change in a dynamic environment. Laboratory and vaccination coordination are additional challenges. Telehealth can, however, bring evidence-based care to resource-limited populations such as incarcerated individuals and people who inject drugs. The Drug Enforcement Agency and Substance Abuse and Mental Health Services Administration rules have approved telehealth as an acceptable modality for medications for opioid use disorder and other co-occurring mental health disorders [61–63]. Further, telehealth provides an opportunity to optimize HIV care through low-barrier models such as harm reduction, an approach to healthcare that is guided by the philosophy of "meeting people where they are," both mentally and physically, and treating them with dignity and respect [64]. Syringe services programs and potential alternative care venues are the cornerstone of harm reduction, aimed at mitigating the harms associated with injection drug use [65]. Another low-barrier model is street medicine, a rapidly evolving form of harm reduction that sets the traditional healthcare system aside and enables providers to physically meet people from vulnerable communities (including persons who are unhoused) at sites accessible to them, such as walk-in clinics and other alternative care venues [66–71]. The incorporation of these innovative modalities into the practice of HIV medicine offers an opportunity to optimize care engagement in diverse and need-to-reach communities.

The quality of the patient–provider relationship is often cited as one of the most important factors in care engagement. Having a provider with whom the patient feels comfortable and can communicate effectively and honestly is key to developing this type of relationship [32, 72, 73]. The multidisciplinary care model for care coordination often helps patients remain in care, identifies unmet care needs, and improves adherence to medications [74–76]. Having an HIV team that includes a case manager, social worker, or staff with similar responsibilities and skills has been shown to enhance adherence to care and engagement [39]. Other team members may include physicians, HIV clinical pharmacists, nurses, nurse practitioners, physician assistants, mental health professionals, peers, health educators, patient navigators, and nutritionists. Culturally and linguistically competent care is critical to successful care engagement. Stigma mitigation is facilitated by diversifying the workforce to represent the patient population served in terms of gender identity, sexual orientation, race, ethnicity, and primary language and by ensuring meaningful representation of persons with HIV. A broad range of components, from having staff of the same race, culture, or lifestyle to having art and reading material in the clinic that reflects the culture of the local community, may be useful in facilitating this goal [77]. Tailored programs that facilitate care engagement are an essential component of effectively caring for persons with HIV. Ensuring the meaningful involvement of people with HIV in program design and implementation is critical to shaping clinical programs that prioritize access and care engagement.

Ongoing monitoring of care engagement and viral suppression is one element in a comprehensive package of quality and performance measures that can enhance care outcomes for persons with HIV. A national expert panel with participants from HIVMA and IDSA has developed HIV quality-of-care performance metrics [78]. These metrics are endorsed by the National Quality Forum and the CMS and have been adopted by many care organizations. Importantly, mortality decreases when performance measures are met [79].

SECTION 2: INITIAL EVALUATION AND IMMEDIATE FOLLOW-UP FOR PERSONS WITH HIV

Recommendations

- A comprehensive present and past medical history that includes HIV-related information, medication/social/family history (Tables 1 and 2), review of systems, and physical examination (Table 3) should be obtained for all patients upon initiation of care, ideally at the first visit or, if not feasible, as soon as possible after the first visit. In particular, in settings of Rapid ART initiation, clinicians may initially truncate parts of the comprehensive history and physical and provide a more targeted exam but with close follow-up to complete the essential and more comprehensive assessment.
- As many patients will not be able to recall details of prior treatments and laboratory results, medical records should be requested and reviewed, and the current medical record should be updated accordingly. Baseline laboratory assessments should be obtained at the initial visit (Table 4).

Evidence Summary

History of the Present Illness and HIV-Related and Other Medical and Surgical Histories

Table 1 outlines pertinent elements of the history of present illness (the reason that the patient presents to the clinic) and HIV-related information that should be obtained at the initial assessment. Table 2 outlines pertinent elements of current and past medical conditions, as well as other pertinent history to be addressed at the initial visit. Because of the high incidence of coinfections and comorbidities in people with HIV, special

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 1. Initial Assessment: History of the Present Illness and Human Immunodeficiency Virus–Specific History

History of the present illness
• Questions should focus on establishing rapport, putting the patient at ease, and determining the patient's primary reason for the visit, if not simply to establish the patient in HIV care
• Assess the patient's level of knowledge about HIV treatment and prevention, evaluate educational needs, and determine what ancillary and social support might be necessary (ideally in collaboration with effective case management)
• If not previously treated with ART, assess the patient's readiness to begin ART immediately, including on the day of the first visit if feasible
• If previously but not currently on ART, assess the patient's readiness to reinitiate ART immediately, including on the day of the first visit if feasible and if adequate information is available to choose an appropriate regimen
• Assess the need for assistance with social services such as housing, transportation, and food access, and involve support staff early if appropriate
HIV-specific history
• Approximate date of HIV diagnosis
• Approximate date of HIV acquisition and likely cause for HIV acquisition (including sexual trauma if appropriate), which can sometimes be determined on the basis of prior negative test results, occurrence of symptoms suggestive of acute retroviral infection, or timing of activities that may have resulted in exposure
• Prior HIV care
• Nadir CD4 cell count and highest viral load
• Current and past exposure to antiretroviral drugs
o Use of pre- or postexposure prophylaxis (including medications and date of last use)
o Use of antiretrovirals for prevention of perinatal transmission
o Prior antiretroviral treatment
• Drug regimens taken and HIV RNA level while on those regimens
• Duration of therapy
• Reasons for changing regimens (eg, virologic failure, tolerability, simplification) and adherence challenges
• Past medical record review (request records if not available)
o Results of all prior resistance testing
• Prior HIV-associated conditions
o Opportunistic infections and/or malignancies according to the Centers for Disease Control and Prevention stage 3 definition
o Other HIV-related conditions (eg, thrush)
History for people who currently inject drugs
• Current drug-use practices
• Source of needles and needle-sharing practices
• Access to naloxone

Abbreviations: ART, antiretroviral therapy; HIV, human immunodeficiency virus.

attention should be paid to this aspect of the history as well as any risk factors that may contribute to the development of comorbidities.

Family Medical History

A family medical history has become more important now that persons with HIV are living longer and are at increased risk for age- and sex-specific conditions in addition to HIV- and treatment-related complications. Clinicians should ask about any family history of conditions that might predispose the patient to malignancies, neurologic diseases, osteoporosis, and atherosclerotic disease and whether there is a family history of early coronary artery disease.

Social History

Clinicians should ask how the patient is adjusting to the diagnosis of HIV, who they have informed of their HIV status, and what support they receive from family and friends. If needed, patients should be offered assistance with the disclosure process. Work and educational histories should be discussed, including whether these have been affected by the diagnosis of HIV. Assessment of access to housing, food, transportation, and other primary social needs is essential. Other pertinent information includes insurance issues, financial status, relationship and family status, and plans for having children.

It is critical to obtain a sexual history in an open, nonjudgmental manner by using a sexual health framework and asking about the 5 "P's": past and current partners, practices, protection from STIs (including past PrEP use), past history of STIs, and pregnancy intention. Although targeted toward the general population, the CDC publishes an excellent step-by-step guide to taking a sexual history [80]. Important considerations for counseling and education are discussed in Section I of that document (Optimizing Care). Very few states require healthcare providers to notify sex partners of patients, but clinicians should be aware of laws in their own jurisdiction and advocate for repeal of laws that criminalize HIV status [81]. All clinicians should familiarize themselves with basic discussions about gender identity, including communication about appropriate pronouns, and fundamentals of care for transgender and gender-diverse individuals. See Section 11 for additional discussion of gender-affirming care.

As part of the initial evaluation and at periodic intervals thereafter, clinicians should assess for the presence of depression, anxiety, post-traumatic stress disorder (PTSD), and sexual or physical abuse, including domestic violence, using direct questions or validated screening tools (Patient Health Questionnaire-9 [PHQ-9] and Generalized Anxiety Disorder 2-item [GAD-2]) [82, 83]. Persons with HIV have high rates of adult sexual and physical abuse and childhood sexual abuse. A history of current and past psychoactive drug use, including

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 2. Other Medical and Surgical History

Comorbidities

Current or past chronic medical conditions that might affect the choice of therapy or response to therapy

- Prior and present gastrointestinal disease
- Liver disease including viral hepatitis A, B, and C; past treatment for hepatitis B and/or C
- Cardiovascular disease and risk factors, including hyperlipidemia, hypertension, diabetes mellitus, and smoking
- Osteopenia or osteoporosis
- Kidney disease
- History of receipt of blood products, organ transplant, or tattoos

Other past medical conditions that may have implications for persons with HIV

- Chickenpox or shingles, measles
- *Mycobacterium tuberculosis* illness, exposure, treatment; prior testing or treatment for latent tuberculosis
- STIs including syphilis, chlamydia, gonorrhea, herpes simplex, trichomoniasis, chancroid, HPV
- Abnormal anal cytology; past anorectal disease including warts, fissures

Gynecologic and obstetric history

- Past pregnancies and plans for future pregnancy, history of artificial insemination by an unidentified donor
- Birth control practices
- Last cervical Pap test, abnormal Pap test ever, colposcopy, loop electrosurgical excision procedure, biopsy (cone/knife)
- Menstrual history
- Other gynecologic conditions including pelvic inflammatory disease

Mental health history, current and past

- Previous or current psychotherapy and medication treatment
- Anxiety disorders, bipolar disorder, depression, violent behavior
- Suicidal, homicidal ideation; history of hospitalization due to mental health issues
- History of trauma, including sexual and physical abuse, intimate partner and other violence; post-traumatic stress disorder (with appreciation for the sensitive nature of these inquiries and the emotional responses they may elicit)
- History of substance use and treatments for substance use (if any, note which substances used)

Current or past use of psychoactive substances

- Tobacco including e-cigarettes; years of use and estimate of cumulative exposure
- Cannabis and cannabinoids (including vaping)
- Vaping (regardless of substance)
- Alcohol use: quantify daily/weekly/monthly use
- Stimulants, including methamphetamine, cocaine, crack cocaine
- Opioids
- Other nonprescription drugs
- Misuse or overuse of prescription drugs
- Other substances primarily used with sex (amyl nitrate [poppers], erectile dysfunction drugs)
- Past injection drug use (regardless of substance used); history of needle sharing; hospitalizations related to injection drug use

Past hospitalizations, surgical procedures, transfusions, or blood product receipt, especially during 1975–1985 or outside the United States and Canada

Immunization status (obtain from past medical records if possible)

- Childhood vaccination including for measles, mumps, rubella, rotavirus
- Coronavirus disease 2019
- Hepatitis A and B
- HPV
- Influenza
- Meningococcus
- Mpox
- Pneumococcus: with type of vaccine
- Varicella zoster
- Tetanus/diphtheria or tetanus/diphtheria/acellular pertussis
- Respiratory syncytial virus
- Travel vaccinations

Travel and residential history pertinent to endemic infectious diseases that may be reactivated, including histoplasmosis (Ohio and Mississippi River valleys), coccidioidomycosis (southwestern deserts), or tuberculosis

Pediatric medical history

- Maternal HIV, obstetric, and birth history
- Exposure to antiretroviral drugs perinatally
- Growth and development milestones
- Childhood vaccination history
- Caregiver environment and support
- Education history

Family medical history

- Diabetes
- Early heart disease: myocardial infarction in a first-degree relative before age 55 years in male relatives and before age 65 years in female relatives
- Hypertension

Table 2. Continued

• Hyperlipidemia • Cancer • Any other significant medical condition
Social history
• Race and ethnicity • Gender identity and sexual orientation; pronouns • Patient birthplace, residence, and travel history • Employment history • Incarceration history • Education history • Financial support • Children: ages, plans for having children in the future, HIV status of children • Pets • Diet and exercise • Sexual history: nonjudgmental inquiry about types of activity including partners (number, gender, whether met online) and practices (genital, anal, oral; use of drugs with partners; exchange of sex to meet needs such as money, housing, drugs; assessment of satisfaction with sexual performance); STI prevention including use of barrier protection such as condoms or dental dams, frequency of barrier use, and prior HIV preexposure prophylaxis or doxycycline postexposure prophylaxis use; past STIs and treatment (including mpox); sexual trauma, violence, and abuse also should be explored, recognizing the sensitivity of these issues • Marital/relationship status o Partner(s) health and HIV status o Partner(s) access to healthcare, including HIV testing (if appropriate) o Disclosure of HIV status to partner(s) • Social support and participation in support groups • Disclosure history: friends, family, work colleagues • Access to stable housing, food, transportation • For minors, review legal guardianship and consent/assent
Medications
• Current medications, including over-the-counter medications, supplements • Use of complementary or alternative therapy or treatment
Allergies and intolerance
• Dates and types of reactions, including hypersensitivity reactions to antiretroviral therapy
Healthcare maintenance and preventative health screenings (as appropriate) Dates of last:
• Cervical or anal Pap (and results, if known) • Mammogram • Bone density • Colonoscopy and/or anoscopy (and results, if known) • Abnormal aortic aneurysm screening • Dental visit • Dilated eye exam • Lung cancer screening (if applicable and results, if known)

Abbreviations: HIV, human immunodeficiency virus; HPV, human papillomavirus; STI, sexually transmitted infection.

alcohol and tobacco, and injection drug use should be taken. See Section 3 for more on screening and treatment for mental health and substance use issues.

Allergies and Medications

A discussion of allergies and intolerances should include questions about hypersensitivity reactions to antibiotics and ART. Clinicians should ask about all current medications, including dietary or herbal supplements, some of which have been shown to interact with ART. All prior ART regimens, including years of use, prior side effects, and reasons for switching, should be recorded. It is also important to assess prior adherence to medications and document viral loads while on each regimen.

Review of Systems

The review of systems should be comprehensive and include questioning about common HIV-related symptoms (see Table 3). Patients should be questioned about how their current weight compares with their past weights, and a dietary assessment should be performed. Given the high incidence of comorbidities in people with HIV, eliciting a history of comorbidities and their risk factors is essential. Depression, anxiety, and PTSD are common among people with HIV, especially cisgender women and lesbian, gay, bisexual, transgender, queer plus (LGBTQ+) populations, and the review of systems should include questions that focus on changes in mood, libido, sleeping patterns, appetite, concentration, and memory.

Physical Examination

A complete physical examination should be performed at the initial encounter or as soon afterward as possible. In addition to recording all vital signs (including height and weight), persons aged >50 years should be assessed for frailty. For all patients, the overall body habitus should be assessed, looking

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 3. Initial Assessment—Review of Systems and Physical Examination

Review of Systems	Physical Examination
A complete review of systems with special attention to the areas listed below: • Unexplained weight loss or gain, night sweats, fever, changes in body habitus • Skin: skin discoloration, rash, ulcers, or lesions • Lymph nodes: localized or generalized enlargement of lymph nodes • Eyes: vision change or loss • Mouth: gum disease, ulcers, oral lesions or pain, dental health and dentition for children • Cardiopulmonary: chest pain, palpitations, wheezing, dyspnea, orthopnea • Gastrointestinal: odynophagia, dysphagia, diarrhea, nausea, pain • Endocrinology: symptoms of hyperglycemia, thyroid disease, hypogonadism • Neurologic and psychiatric: persistent and severe headaches, memory loss, loss of concentration, depression, apathy, anxiety, mania, mood swings, lower-extremity paresthesias, pain or numbness, paralysis or weakness, cognitive difficulties, dizziness, seizures, sleep disorders • Genitourinary: dysuria, urethral or vaginal discharge or lesions, hematuria • Orthopedic: hip pain, joint pain, fractures, diagnosis of or risk factors for osteopenia/osteoporosis • Anorectal: anal discharge, rectal bleeding, rectal itching, pain or fullness in anal area • Developmental milestones: for infants and young children, assess for motor or speech delays • Growth delay and failure to thrive for infants and children	A complete physical examination should be performed, with special attention to the following areas: • Vital signs: including height and weight • General: including body habitus, evidence of obesity, wasting, lipodystrophy, assessment of frailty, ambulatory ability • Skin: seborrheic dermatitis, ecchymoses, purpura, petechiae, Kaposi sarcoma, herpes simplex or zoster, psoriasis, molluscum contagiosum, onychomycosis, folliculitis, condylomata, cutaneous fungal infections, acanthosis • Lymph nodes: generalized or localized lymphadenopathy • Eye: retinal exudates or cotton wool spots, hemorrhages, pallor, icterus • Oropharynx: oral hairy leukoplakia, candidiasis (thrush, palatal erythema, angular cheilitis), aphthous ulcers, gingivitis, periodontal disease, Kaposi sarcoma, tonsillar or parotid gland enlargement • Cardiovascular: heart exam, peripheral pulses, presence/absence of edema or bruits • Chest: lung exam • Breast: nodules, nipple discharge • Abdomen: hepatomegaly, splenomegaly, masses, tenderness • Genitourinary: ulcers, warts, chancres, rashes; gynecologic exam including bimanual exam, discharge (if male: testicular exam; evaluation for hernia) • Anorectal: ulcers, warts, fissures, internal or external hemorrhoids, masses, Kaposi sarcoma; prostate exam when appropriate • Neuropsychiatric: depression; mania; anxiety; signs of personality disorder; difficulties in concentration, attention, and memory; signs of dementia; speech problems; gait abnormalities; focal deficits (motor or sensory); lower-extremity vibratory sensation; deep tendon reflexes

for evidence of wasting, obesity, or, particularly in patients who have received older ART regimens, evidence of drug-related lipohypertrophy (including dorsocervical fat pad, gynecomastia, or visceral abdominal fat accumulation) and/or lipoatrophy (including loss of subcutaneous fat in the face, extremities, or buttocks). All adult patients with CD4 count <50 cells/μL, as well as infants and young children with profound immunodeficiency, should be referred to an ophthalmologist for a dilated funduscopic examination. Though persistent generalized lymphadenopathy is common among untreated persons with HIV, it does not correlate with prognosis or disease progression. However, focal or rapidly progressive lymphadenopathy may require further evaluation, including biopsy. Additionally, if lymphadenopathy does not quickly resolve with initiation of ART, diagnostic studies should be pursued. Neurology and/or neuropsychology referral for assessment of neurocognitive disorders, dementia, and focal neuropathies may be indicated [84, 85]. Cervical motion and uterine or adnexal tenderness on bimanual pelvic examination suggest pelvic inflammatory disease and should prompt STI testing. An anorectal examination is important to evaluate for anal warts, other STIs, and anal cancer, with age-appropriate screening for prostate abnormalities if assigned male at birth.

Baseline Laboratory Evaluation

A number of initial laboratory studies are indicated for persons who present with a new HIV diagnosis or for persons who reengage in care (see Table 4). Other tests may be indicated depending on the age and sex of the patient and/or symptoms. When rapid initiation of ART is possible, it is important to obtain baseline laboratory tests, including HIV RNA level, CD4 cell count, resistance testing, and viral hepatitis serology, and to assess for safety and general medical condition; however, ART initiation need not be delayed until results are received. The absence of results for HIV RNA level, HIV genotype, and hepatitis B surface antigen (HBsAg) will influence the choice of antiretrovirals (ARVs) for rapid initiation. If results of HIV screening are not available for review, an HIV diagnosis should be confirmed, preferably using a fourth-generation antigen/antibody test with rapid turnaround time.

Recommendations

HIV-Specific Tests for All Persons With HIV

- Patients who have no documentation of their HIV status or who were tested anonymously should have an HIV antigen/antibody screening test performed upon initiation of care. When HIV RNA is obtained, in addition to antigen/antibody for HIV screening, an isolated positive HIV RNA should be verified by repeat testing if HIV antibody is negative, especially in the setting of prior use of long-acting cabotegravir as PrEP.
- A CD4 cell count with percentage should be obtained upon initiation of care.
- Measurement of the CD8 cell count and the ratio of CD4 to CD8 cells is not considered necessary, as the results are not used in clinical decision-making.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 4. Recommended Initial Laboratory Screening and Other Studies in Persons With Human Immunodeficiency Virus

Test	Comment(s)
HIV-specific tests for all persons with HIV	In infants and children aged <18 years with perinatal HIV exposure, maternal antibodies can persist up to 24 months; therefore, HIV RNA nucleic acid tests are considered diagnostic; infants, children, and adolescents with HIV and history of initiating early ART may have negative antigen/antibody test
• HIV antigen/antibody testing	If written evidence of diagnosis not available or if viral load low or undetectable (an isolated positive HIV RNA with negative HIV antibody should be verified by repeat testing, especially in the setting of prior CAB-LA exposure as PrEP)
• CD4 cell count and percentage	CD4 cell count and percentage access are necessary to assess for immunosuppression and support decisions on OI prophylaxis and vaccinations
• Plasma HIV RNA polymerase chain reaction (HIV viral load)	Establish baseline and monitor viral suppression
• HIV resistance testing	• Baseline genotype for protease inhibitor, nonnucleoside reverse transcriptase inhibitor, nucleoside/nucleotide reverse transcriptase inhibitor, mutations for persons who have never initiated therapy or who are reengaging in care and not on therapy or with inconsistent access to therapy; INSTI genotype is recommended if clinical concern for transmitted INSTI resistance and/or acquired INSTI resistance, as in the setting of prior CAB-LA (as PrEP) exposure
HIV-related tests in selected patients	
• Coreceptor tropism assay	If use of C-C motif chemokine receptor 5 antagonist is being considered
• Human leukocyte antigen (HLA) B*5701	If use of abacavir is being considered
Other laboratory tests	
• Complete blood cell count with differential	Assess for anemia, neutropenia, thrombocytopenia
• Alanine aminotransferase, aspartate aminotransferase, total bilirubin, alkaline phosphatase	Assess for evidence of liver damage, hepatitis, or systemic infection (eg, elevated alkaline phosphatase with some OIs)
• Total protein and albumin	High total protein common with untreated HIV infection due to increased immunoglobulin fraction secondary to B-cell hyperplasia; low albumin may indicate nutritional deficiency or nephrotic syndrome
• Electrolytes, blood urea nitrogen, creatinine	Assess kidney function; use creatinine to calculate estimated glomerular filtration rate
• Lipid profile and blood glucose; hemoglobin A1c	Fasting not needed for initial lipid and glucose assessment; if abnormal, repeat fasting (hemoglobin A1c should be measured prior to ART initiation but is not used for diagnosis of diabetes in those on ART)
• Urinalysis	Assess for evidence of proteinuria, hematuria
Screening for coinfections	
• Gonorrhea, chlamydia	Nucleic acid amplification test (NAAT) with sites based on exposure history (eg, urine, vaginal, rectal, oropharyngeal; 3-site testing preferred for all patients)
• Trichomoniasis	In all persons who have vaginal sex
• Syphilis	Using local protocol (either rapid plasma reagin or treponemal-specific antibody tests)
• Latent *Mycobacterium tuberculosis*	Tuberculin skin test or IGRA; IGRA preferred if history of Bacillus Calmette-Guérin vaccination
• Varicella virus	Anti-varicella IgG if no known history of chickenpox or shingles
• Viral hepatitis A, B, C	Measure HBsAg, HBsAb, HBcAb, HCV Ab, HAV IgG antibody. If HBsAg-positive or HBcAb-positive, order HBV DNA level. If HCVAb-positive, known past HCV, or considering acute HCV, order HCV RNA level. HCV genotype should be collected unless a pan-genotypic treatment regimen will be used. Screen for hepatocellular carcinoma for all adult patients with cirrhosis and noncirrhotic patients with chronic HBV for an extended period
• Measles titer	Adequate evidence of immunity includes being born in the United States before 1957, written documentation of adequate vaccination, or serologic evidence of immunity [104]. Persons born in the 1960s may have been vaccinated with a vaccine other than MMR and may have waning immunity. Patients may opt to receive a booster MMR vaccine rather than check serology
• Cryptococcal antigen	Indicated for patients with CD4 count <100 cells/μL or symptoms consistent with infection
• Toxoplasma antibody	Indicated for patients with CD4 count <200 cells/μL or symptoms consistent with infection
Tests that may be performed under certain circumstances	
• Chest radiography	For patients with evidence of latent *Mycobacterium tuberculosis* infection; consider in patients with underlying lung disease for use as comparison in evaluation of future respiratory illness
• Cytology: cervical and/or anal Pap test	Cervical; anal if indicated. Abnormal results require follow-up with colposcopy or high-resolution anoscopy, respectively
• Glucose-6-phosphate dehydrogenase	Screen for deficiency in persons, especially those assigned male at birth, who are of African, Mediterranean, or Asian descent before prescribing oxidant drugs such as dapsone and primaquine in those with glucose-6-phosphate dehydrogenase deficiency. Sulfonamides should be used with caution without prior screening
• Pregnancy test in persons of childbearing potential	Pregnancy status is required to inform choice of ART and discussions about conception in persons of childbearing potential

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 4. Continued

Test	Comment(s)
• Serum testosterone level	In cisgender males with fatigue, weight loss, loss of libido, erectile dysfunction, or depression or who have evidence of reduced bone mineral density. Morning free testosterone is preferred. See Section 7 for management of hypogonadism
Tests that are not recommended for general screening purposes	
• HSV IgG, CMV IgG, biomarkers of inflammation	In asymptomatic persons, routine testing for all persons is not recommended for HSV, CMV. Biomarkers of inflammation are not recommended. CMV IgG may be considered if blood transfusion is contemplated in a person at low risk for CMV exposure. A negative CMV IgG may support use of CMV-free blood products

Abbreviations: ART, antiretroviral therapy; CAB-LA, long-acting cabotegravir, CMV, cytomegalovirus; HAV, hepatitis A virus; HBV, hepatitis B virus; HBcAb, hepatitis B core antibody; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IgG, immunoglobulin G; IGRA, interferon-γ release assay; INSTI, integrase strand transfer inhibitor; MMR, measles, mumps, rubella; OI, opportunistic infection; PrEP, preexposure prophylaxis.

- A quantitative HIV RNA level (HIV viral load) should be obtained upon initiation of care.
- Patients should be assessed for transmitted drug resistance with a genotype assay for protease and reverse transcriptase mutations upon initiation of care.
- If baseline integrase strand transfer inhibitor [INSTI] resistance is suspected (eg. transmitted mutations) or if HIV was acquired after receipt of long-acting cabotegravir for PrEP, regardless of the time since drug discontinuation due to the long half-life of injectable drug, genotypic testing for integrase resistance should be obtained.
- Resistance testing should be obtained for patients who reengage in care and who are currently not on ART or who have not had consistent ART access, recognizing that the absence of resistance mutations does not guarantee the absence of resistance when no selective pressure is present.
- Resistance testing, including for integrase mutations if appropriate, is indicated for patients who are experiencing virologic failure to guide modification of ART and should be performed while the patient is on the failing ART regimen or within 4 weeks of discontinuing the ART regimen.

Evidence Summary

Clinicians should be familiar with the current CDC HIV testing algorithms and interpretation of results based on the algorithms and assays used [86]. Confirming an HIV diagnosis is especially important in patients who are asymptomatic and have a normal CD4 cell count and an undetectable or very low viral load. In addition, patients may present to care with misinformation regarding previous test results. Delayed seroconversion may occur in persons who acquire HIV while taking oral PrEP or, especially, after exposure to cabotegravir as PrEP. If HIV infection is suspected within 3 months of taking oral PrEP or within 12 months following exposure to injectable long-acting cabotegravir (CAB-LA), HIV antibody testing and an HIV RNA level should be obtained. A positive HIV RNA result in the absence of a positive antibody should be verified by repeat testing because of the high rate of false-positive HIV RNA results reported in HIV Prevention Trials Network (HPTN) 083, especially if the last dose of CAB-LA was less than 6 months prior to screening [87, 88]. As new data emerge, CDC guidelines should be consulted for recommendations on screening for HIV in the setting of PrEP use [89].

The initial CD4 cell count is used to stage HIV infection, establish the risk of specific HIV-associated complications, and determine the need for prophylaxis against opportunistic infections (OIs). It is important that the clinician and patient be aware of the substantial variation in CD4 cell counts, especially during acute illness. Because CD4 cell counts may be affected by a variety of medications and intercurrent illnesses, caution should be taken when interpreting CD4 cell counts in these situations. Although the absolute CD4 cell count is the measure that is most often used in clinical practice, the CD4 cell percentage can also be used to assess immune function and is somewhat less variable than the absolute count. Total CD4 counts of 200 and 500 cells/μL generally correspond to CD4 cell percentages of 14% and 29%, respectively. In children aged <5 years, there is more variability in the absolute CD4 cell count; therefore, CD4 percentage is generally preferred for monitoring immune status [86, 90, 91].

The initial HIV RNA level defines the patient's baseline so that response to therapy can be measured. Clinicians should be aware of changes in the type of HIV RNA assay used, the associated variability, and differences in interpretation of results between assays. Thresholds for lower limits of detection for the most commonly used assays range from 20 to 50 copies/mL. Viral load should be measured during the initial evaluation of the untreated patient when establishing care or when a patient reengages in care. Viral suppression is defined as a viral load that is persistently below the level of quantification of the assay; however, the threshold for prevention of HIV sexual transmission is considered to be <200 copies/mL [7].

Drug-resistant HIV can be transmitted from one person to another. The purpose of baseline genotypic resistance testing is to assess for resistance (transmitted or acquired) that would

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

influence ART selection. Baseline genotypic resistance testing for protease and reverse transcriptase mutations should be performed for all persons beginning treatment [7]. Resources are available and frequently updated to assist clinicians in the interpretation of drug-resistance mutations [92, 93]. Because transmission of integrase mutations is currently uncommon, baseline integrase genotyping is recommended only when transmission of integrase resistance is suspected, such as when HIV is suspected to have been acquired from an individual known to have been taking a regimen that contains an integrase inhibitor [94]. All persons who acquired HIV after using cabotegravir for HIV PrEP should have integrase resistance testing performed due to the long half-life of this drug and the risk of selecting integrase resistance when fully inhibitory drug levels are no longer present. These individuals should not receive INSTI therapy until an integrase genotype test is performed and sensitivity is demonstrated [7]. Lack of genotypic testing limits the regimens that may be prescribed, including 2-drug regimens such as dolutegravir/lamivudine fixed-dose combination, and other combinations in which resistance to one drug would result in functional monotherapy [7]. In persons who reengage in care and who have been off therapy for 4 or more weeks, resistance mutations may be absent due to lack of selective pressure rather than absence of resistance, and results should be interpreted with this in mind.

Patients who are taking a failing ARV regimen (HIV RNA level >200 copies/mL) should undergo resistance testing to guide interventions and improve viral control. In those with HIV RNA levels between 201 and 500 copies/mL, testing may not be successful but should be considered.

HIV-Related Tests in Select Patients

Recommendations

- Co-receptor tropism testing should be performed if the use of a chemokine receptor 5 (CCR5) antagonist is being considered.
- Human leucocyte antigen (HLA) B*5701 testing should be performed before initiation of abacavir therapy.
- Patients who are positive for the HLA B*5701 haplotype are at high risk for abacavir hypersensitivity reaction and should never be treated with abacavir (this should be noted appropriately in the medical record).

Evidence Summary

Co-receptor tropism testing is needed to determine which patients are appropriate candidates for initiation or continuation of a CCR5 antagonist [7]. CCR5 antagonists are not effective for patients with X4 or dual/mixed-tropic (D/M) virus. The use of a CCR5 antagonist under these circumstances could increase the risk of virologic failure and the development of resistance to the other drugs in the regimen. Tropism screening may fail to detect X4 or D/M virus if it is present at very low levels, and patients may experience treatment failure with CCR5 antagonists because of the presence of pre-existing X4 or D/M virus not detected by the tropism assay. Patients who exhibit virologic failure while taking a CCR5 antagonist may also be considered for tropism testing. Routine tropism testing is not recommended prior to initiation of regimens that do not contain a CCR5 antagonist. Repeat tropism testing is recommended when considering the use of a CCR5 antagonist as part of the ART regimen, even if previously done in the past, unless the previous tropism was X4 or D/M. Tropism may shift from R5 to X4 or D/M during the course of infection, especially with more advanced immunodeficiency (CD4 count <100 cells/μL). A proviral DNA tropism assay can be used in patients with undetectable HIV RNA when considering the use of a CCR5 antagonist in a new regimen [7].

Screening for the HLA B*5701 haplotype is essential in patients being considered for abacavir therapy in order to identify those who are at high risk for the abacavir hypersensitivity reaction [7]. A negative test result does not rule out the possibility of a hypersensitivity reaction but indicates that it is extremely unlikely. Patients who have negative test results should still be counseled about a hypersensitivity reaction before being treated with abacavir [7].

Laboratory Tests to Assess Safety and General Health

Recommendations

- A complete blood count with differential white blood cell count and chemistry panel with electrolytes, glucose, creatinine, calculated creatinine clearance (or estimated glomerular filtration rate [eGFR]), blood urea nitrogen, total protein, albumin, total bilirubin, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and urinalysis should be obtained upon initiation of care.
- Because many ARV drugs, the HIV infection, and host factors are associated with abnormal cholesterol and triglyceride levels, a lipid profile should be obtained upon initiation of care and repeated fasting, if appropriate.

Evidence Summary

Anemia, leukopenia, and thrombocytopenia are common among persons with untreated HIV. The complete blood count is also used to calculate the absolute CD4 cell count. A chemistry panel (including electrolytes, glucose, creatinine, eGFR, blood urea nitrogen, total protein, albumin, total bilirubin, AST, and ALT) is an important tool to assess renal and hepatic function and to look for evidence of pre-existing liver injury or hepatitis.

Kidney function is abnormal in up to 30% of persons with untreated HIV, and HIV-associated nephropathy is a relatively

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

common cause of end-stage renal disease, especially in Black persons with HIV, although both rates and mortality have declined with more effective ART [95, 96]. A calculated creatinine clearance or eGFR should be obtained to further assess baseline renal function. The eGFR assists in prescribing ARV agents and other commonly used medications that require renal dosing. Clinicians should be aware that some medications such as cobicistat, dolutegravir, bictegravir (BIC), and trimethoprim may affect creatinine secretion and elevate serum creatinine without affecting renal function [97]. A screening urinalysis for proteinuria should be considered at initiation of care and annually thereafter, especially in patients who are at increased risk for developing kidney disease (including those with CD4 counts <200 cells/μL or HIV RNA >4000 copies/mL and those with diabetes mellitus, hypertension, or hepatitis C virus [HCV] coinfection) [7]. Patients with proteinuria of grade ≥1 by dipstick analysis or reduced kidney function can be referred to a nephrologist for consultation and should undergo additional studies, including quantification of proteinuria, renal ultrasound, and possible renal biopsy. As discussed in Section 7, screening for glucose intolerance and diabetes mellitus is recommended because of the increased prevalence in this population. Among adults and children with HIV, fasting blood studies are more problematic because of feeding schedules in children and work schedules in adults, and clinicians should obtain fasting levels when nonfasting levels are abnormal [7]. The lipid profile is important because of high rates of cardiovascular disease in this population and the importance of managing risk factors. Additionally, several ARVs affect lipid levels or have drug interactions with statins (see Section 7).

Screening for Coinfections

Recommendations

- Upon initiation of care, persons with HIV without a history of tuberculosis or a prior positive tuberculosis screening test should be screened for *Mycobacterium tuberculosis* infection using either a tuberculin skin test (TST) or an interferon-gamma release assay (IGRA). Those with positive test results should be treated for latent *M. tuberculosis* infection after active tuberculosis has been excluded.
- Persons with HIV who have close contact with persons with infectious tuberculosis should be treated for latent *M. tuberculosis* infection regardless of their TST or IGRA results, age, or prior courses of tuberculosis treatment; active tuberculosis should be excluded first.
- Persons with HIV should be screened for evidence of hepatitis B virus (HBV) infection upon initiation of care by detection of HBsAg, hepatitis B surface antibody (HBsAb), and antibody to hepatitis B total core antigen (anti-HBc or HBcAb). If HBsAg is positive, HBV viral load should be ordered.
- Persons with HIV should be screened for evidence of immunity to hepatitis A virus (HAV) with HAV immunoglobulin G (IgG).
- Persons with HIV should be screened for HCV antibody upon initiation of care. If positive, HCV RNA should be ordered to assess for active HCV infection. Curative therapy should be offered to all who are diagnosed with active HCV. HCV RNA testing is indicated ≥12 weeks post-completion of anti-HCV treatment to check for successful and sustained treatment. HCV RNA should be used for screening if HCV infection within the last 6 months is suspected or there is a history of prior HCV infection that has cleared due to spontaneous resolution or curative treatment. HCV RNA testing should be considered in persons with advanced immunosuppression (CD4 cell count <200 cells/μL).
- Infants born to persons with HBV and/or HCV should be tested for HBV and HCV transmission.
- Persons who are not immune to HAV and HBV should be immunized according to current national guidelines.
- All persons with HIV born in 1957 or after should be tested for immunity to measles, mumps, and rubella (MMR) by measuring antibodies.
- MMR vaccine should be given to protect against measles, mumps, and rubella if persons were born in 1957 or after and have not received this vaccine or do not have immunity to these infections.
- Serologic screening for varicella zoster virus (VZV) may be considered for persons who have not had chickenpox or shingles and who have not been previously vaccinated (see Section 4).
- Screening for toxoplasma IgG is recommended for asymptomatic persons with CD4 count <200 cells/μL and for those with symptoms suggestive of toxoplasmosis.
- Testing for serum cryptococcal antigen is indicated in persons with CD4 count <100 cells/μL and in symptomatic patients but is not routinely recommended in asymptomatic persons if CD4 count is ≥100 cells/μL.
- Screening for syphilis, chlamydia, gonorrhea, and, for persons having vaginal sex, trichomonas should be performed at entry to care (Please refer to Section 6).

Evidence Summary

All persons with HIV should be tested for *M. tuberculosis* infection using TST or IGRA upon initiation of care [7, 98, 99]. A TST or IGRA should be performed any time there is concern about a recent exposure. For those with CD4 count ≤200 cells/μL, testing should be repeated after the CD4 count increases to >200 cells/μL following initiation of ART. For a person with HIV, induration of >5 mm by TST is considered a positive result and should prompt chest radiography and other evaluation, as warranted, to rule out active tuberculosis [100]. Annual testing should be considered for those who have

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

negative results by TST or IGRA but are at ongoing risk for exposure [7, 101]. Routine cutaneous anergy testing is not recommended because of lack of standardization of reagents and poor predictive value and because prophylaxis provided to anergic persons has been shown to prevent few cases of tuberculosis [102]. The QuantiFERON-TB Gold in-tube test (Cellestis Limited) and the T-SPOT TB test (Oxford Immunotech) are approved by the US Food and Drug Administration (FDA) as aids for detecting latent *M. tuberculosis* infection.

A large meta-analysis suggests that IGRAs perform similarly to TSTs when identifying persons with HIV with latent tuberculosis infection [103]. However, prior vaccination with Bacillus Calmette-Guérin (BCG) vaccine may result in a positive TST result, whereas there is less cross-reactivity with the IGRA. IGRAs that are reported as indeterminant should be repeated, as follow-up testing may be negative. The CDC states that use of an IGRA is preferred over the TST in patients with a history of BCG vaccination and in patients with a low likelihood of returning to have their skin test read. Advanced immunosuppression may be associated with false-negative results in all types of immunologically based tests used for detection of *M. tuberculosis* infection. The routine use of the IGRA in children, especially those aged <5 years, is currently not recommended due to limited data and some evidence of lower sensitivity.

Screening for and prevention of HAV, HBV, and HCV are critical in the management of people with HIV. Those who have HBV and/or HCV coinfection should be managed according to the most current published guidelines [98, 104–106]. Hepatitis A vaccination is especially important for persons with unstable housing, for persons who inject drugs (PWID), and for those with chronic liver disease due to recent outbreaks in certain communities [107]. Prevaccination screening for HAV infection is cost-effective when there is a seroprevalence of >30% in the patient population [108]. Because of worse outcomes for persons with HIV and HBV coinfection, persons with HIV who also have HBV should be adequately treated for HBV [7]. Because many persons with HIV may be treated with tenofovir-based ART that also suppresses HBV, stopping tenofovir-based ART may result in a flare of HBV, especially when changing ART to a 2-drug regimen that does not contain tenofovir. Persons with HBV are at higher risk for hepatocellular carcinoma (HCC) even in the absence of cirrhosis. Screening for HCC in persons with HBV should be conducted according to the American Association for the Study of Liver Diseases guidelines [104]. Persons not immune to HAV and HBV should be immunized according to applicable guidelines (see Section 4).

Persons with HIV should be screened for HCV antibody upon initiation of care. If positive, HCV RNA should be ordered to assess for active HCV infection. HCV RNA should be used in persons with a negative HCV antibody if infection within the last 6 months is expected and in persons with a history of prior HCV infection that has cleared due to spontaneous resolution or curative treatment. HCV RNA should be considered in persons with advanced immunosuppression (CD4 count <200 cells/μL), especially in persons who are HCV-seronegative with a history of injection drug use or with unexplained increased serum transaminases because approximately 2%–4% of persons with HIV–HCV coinfection have false-negative HCV antibody results; this occurs primarily among those with advanced immunosuppression [98]. According to multiple studies, the rate of mother-to-infant HCV transmission is up to 3-fold higher among women with HIV, and pregnant people with HIV should be tested for HCV with each pregnancy [106, 109]. Infants can be tested for HCV RNA after age 2 months or for HCV antibody after age 18 months [110]. All persons diagnosed with chronic HCV should be offered curative treatment. Eradication of HCV reduces, but does not eliminate, the risk of HCC in persons with cirrhosis; therefore, ongoing HCC screening in this group is warranted. Screening for HCC is recommended in all patients with cirrhosis due to hepatitis B or C or other nonviral etiologies (including alcohol use and fatty liver disease) [111].

Acceptable evidence of immunity against measles includes at least 1 of the following: written documentation of adequate vaccination, laboratory evidence of immunity, laboratory confirmation of measles, or birth in the United States before 1957 [112, 113]. It is advisable to determine anti-varicella IgG levels for patients who are unable to verify a history of chickenpox or shingles [114, 115]. STI screening should be obtained as part of the initial assessment. See Section 6.

In spite of a high prevalence of toxoplasma IgG in the population, toxoplasma encephalitis occurs among those with advanced immune deficiency. Screening for toxoplasma IgG, therefore, is indicated for asymptomatic persons with CD4 count <200 cells/μL and for those with a clinical presentation suggestive of toxoplasmosis. Testing for serum cryptococcal antigen is indicated in persons with CD4 count <200 cells/μL or in symptomatic individuals [98].

Tests That May Be Performed Under Certain Circumstances

Recommendations

- A baseline chest radiograph should be obtained in all persons with HIV who have a positive tuberculosis screening test result in order to rule out active tuberculosis. It may also be useful in other patients who are likely to have pre-existing lung abnormalities, including those who smoke or have a history of injecting drugs.
- Before starting therapy with oxidant drugs such as dapsone and primaquine, screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency is recommended, particularly

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

for individuals assigned male at birth of African, Mediterranean, or Asian descent. Sulfonamides should be used with caution without prior screening.
- Persons of childbearing potential should have a pregnancy test upon initiation of care or reengagement in care.
- In general, routine testosterone testing is not recommended among cisgender males with HIV. However, morning serum testosterone levels are recommended in adult cisgender men with decreased libido, erectile dysfunction, reduced bone mineral density (BMD) or low trauma fractures, hot flashes, or sweats.
- Obtaining testosterone levels in cisgender women at baseline in non-research settings is not recommended.

Evidence Summary

In general, all persons with HIV do not require a baseline chest X ray. However, persons with HIV are susceptible to a variety of pulmonary complications. A radiograph obtained at baseline in these individuals, as well as in persons with a history of pulmonary disease or smoking, may be useful for comparison in the evaluation of future respiratory complaints. Because people who inject drugs are especially likely to have radiographic abnormalities that may be mistaken for infiltrates, careful clinical history and physical assessment are warranted to guide subsequent medical decision-making. For discussion of cancer screening in persons who smoke, see Section 5. G6PD deficiency is a genetic condition that may result in hemolysis after exposure to oxidant drugs. Persons assigned male at birth and individuals of African, Mediterranean, and Asian descent have higher likelihood of these genetic variants. Dapsone and primaquine are often used to treat persons with HIV and can lead to hemolysis in the presence of G6PD deficiency. Sulfonamides should be used with caution without prior screening [116, 117].

The pregnancy status of all persons of childbearing potential should be assessed at the initial visit. In addition, the intent to have children, intent or ability to use consistent birth control, and timing of potential conception should be discussed. Although preliminary data suggested that neural tube defects were associated with dolutegravir use during conception, updated data showed no statistical significance, and dolutegravir is now a recommended drug for treatment during conception as well as pregnancy [118, 119]. The HHS perinatal guidelines provide ART recommendations for pregnant individuals [120]. The HHS ART guidelines provide recommendations for individuals who are planning to conceive and those unable to use reliable contraception [7] (see Sections 8 and 9).

Cisgender men with HIV, especially those with advanced disease, are at risk for hypogonadism. Interpretation of testosterone values must be made in clinical context, as all currently available assays (including measures of total, free, and bioavailable testosterone) are associated with technical issues that may result in significant variability. Testing should be performed on a specimen obtained in the morning (ideally before 10 AM) and confirmed with repeat testing if the result is below the lower limit of normal. Recommendations differ regarding the optimal assay to use for initial testing in the setting of HIV. Testosterone circulates primarily bound to plasma proteins (including sex hormone–binding globulin and albumin). If total testosterone is used for initial testing, a determination of sex hormone–binding globulin and/or free testosterone is strongly recommended when alterations of binding proteins are suspected (including patients with cirrhosis and hepatitis, hyper- or hypothyroidism, or nephrotic syndrome). Free testosterone may be determined by equilibrium dialysis (most reliable but most expensive) or using the free online testosterone calculator developed by the Hormonology Department, University Hospital of Ghent, Belgium [121]. So-called direct free testosterone (analogue) assays are unreliable and should not be used. If a diagnosis of hypogonadism is established, measurement of luteinizing hormone and follicle-stimulating hormone is recommended to determine whether the source of dysfunction is primary (testicular) or central (pituitary or hypothalamic) in origin. Hypogonadism should be treated by clinicians who are familiar with monitoring patients on androgen replacement therapy (see Section 4). For recommendations pertaining to age-appropriate cancer screening, see Section 5.

Tests Not Recommended for General Screening Purposes

Recommendations

- Routine testing for herpes simplex virus (HSV) IgG, cytomegalovirus (CMV) IgG, and biomarkers of inflammation is not recommended.

Evidence Summary

Routine screening for HSV is not recommended [122]. Routine screening for CMV IgG is not generally useful because CMV seroprevalence is extremely high and generally not actionable [98]. Testing for CMV IgG may be considered, however, if blood transfusion is contemplated in a person at low risk for CMV exposure. The identification of seronegativity would prompt the use of CMV-negative or leukocyte-reduced blood products when transfusions are needed, thus reducing the risk of iatrogenic infection. There are no data supporting the use of inflammatory biomarkers for risk assessment of comorbidities [123].

SECTION 3: ROUTINE HEALTHCARE MAINTENANCE CONSIDERATIONS FOR PEOPLE WITH HIV

Effective HIV primary care requires regular health maintenance, including HIV-related lab monitoring, mental health and substance use screenings, oral health examination, and patient education and counseling. Health assessments that are

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

recommended for the general population (age- and gender-guided) as well as those specific for people with HIV should be reviewed and addressed at least annually with patients with HIV, whether performed at 1 or more visits (Table 5).

HIV-Specific Monitoring Following the Initial Assessment

Recommendations

- After initiation of ART, HIV RNA should be rechecked after 2–4 weeks but no later than 8 weeks and then every 4–8 weeks until suppression is achieved. Afterward, viral load should be monitored every 3–4 months to confirm maintenance of suppression below the limit of assay detection. This interval may be prolonged to every 6 months for patients whose viral load has been suppressed for more than 1 year and whose clinical and immunologic status is stable. Viral load should be monitored more frequently after reinitiating or changing ART, preferably within 2–4 weeks, with repeat testing every 4–8 weeks until viral load becomes undetectable. More frequent testing may be considered in other clinical scenarios, such as pregnancy and/or breastfeeding.
- If HIV RNA results are above the limit of assay detection but <200 copies/mL, referred to as "blips," assessing and addressing medication adherence, tolerability, and drug–drug interactions are warranted with an earlier repeat of HIV RNA testing.
- CD4 cell count should be monitored to determine the need for prophylaxis against OIs and to aid in generating appropriate differential diagnoses. CD4 cell counts should generally be monitored every 3–6 months for the first 2 years or if the virus is not suppressed. After 2 years, for patients on suppressive ART regimens with CD4 counts of 300–500 cells/μL, CD4 cell count can be monitored every 12 months unless there are changes in the patient's clinical or virologic status. If the CD4 count rises above 500 cells/μL, CD4 monitoring is optional.
- Repeat HIV genotypic resistance testing for mutations in the reverse transcriptase and protease genes, including in the integrase genes, when there is history of INSTI use, should be performed if virologic failure occurs and when clinically indicated. If ART initiation has been delayed, repeat genotype testing prior to ART initiation should be considered.

Evidence Summary

Frequency of HIV RNA monitoring depends on the response to therapy and duration and consistency of viral suppression. Once ART has been initiated, HIV RNA is monitored to confirm response to therapy and attainment and maintenance of viral suppression. After HIV RNA becomes undetectable, monitoring is approximately quarterly but can be every 6 months for persons with at least 1 year of continuous suppression and stable clinical and immune status [7]. More frequent testing may be warranted during pregnancy and/or breastfeeding, and the HHS Perinatal Antiretroviral Guidelines should be followed [120].

After virologic suppression has been achieved, if a viral load blip (isolated increase in HIV RNA above the limit of assay detection but <200 copies/mL that is followed by spontaneous suppression) or persistent low-level viremia with HIV RNA <200 copies/mL occurs, medication adherence should be assessed, and any identified barriers should be addressed. Medication tolerability should be reviewed, and side effects should be managed. Potential drug–drug interactions, including with over-the-counter medications and supplements, should also be reviewed. Earlier HIV RNA testing, for example, after 2–4 weeks, to ensure that no virologic failure (2 consecutive HIV RNA levels >200 copies/mL) has occurred is recommended [6]. If low-level viremia occurs, HIV viral load should be checked at least every 3 months to ensure that virologic failure has not occurred. As discussed in Section 1, assessing adherence regularly, ideally through a multidisciplinary team approach, is essential for identifying and addressing barriers, with a goal of preventing loss of virologic suppression and promoting improved adherence after such loss. Once ART is initiated and sustained virologic suppression is achieved, CD4 cell count can be monitored less frequently. Once the virus is suppressed for at least 2 years and CD4 cell count rises above the level associated with risk for opportunistic diseases, monitoring can occur annually or not at all if the CD4 count is >500 cells/μL [7].

The recommended frequency of HIV RNA and CD4 monitoring is not the only determinant of how frequently patients should be seen for overall healthcare needs. Patients with concurrent medical conditions may need to be seen more frequently, as well as patients who need ancillary services, such as treatment adherence counseling, mental health and substance use treatment services, STI screening, HIV education, case management services, or harm-reduction counseling.

If virologic failure occurs, genotypic resistance testing for mutations in reverse transcriptase, protease, and integrase (if indicated) genes should be performed to guide the choice of the next treatment regimen. If ART initiation has been substantially delayed, repeat resistance testing may be considered prior to initiating ART [7].

Other Lab Monitoring

Recommendations

- Complete blood count should be monitored every 12 months or when clinically indicated.
- A chemistry panel including glucose, creatinine, eGFR, electrolytes, AST/ALT, and total bilirubin should be done 1–2 months after ART initiation or change. Otherwise, it should be done every 6 months and when clinically indicated. If the

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 5. Routine Health Care Maintenance for People With Human Immunodeficiency Virus After Initial Assessment

Type of Intervention	Intervention	Recommendation	Comments
-specific monitoring	HIV RNA	Assess every 4–8 weeks after initiation of ART until undetectable and then every 3–4 months. In patients with consistent viral suppression and stable CD4 cell count for more than 1 year, measure every 6 months. If viral blip occurs (HIV RNA detectable but <200 copies/mL), assess adherence and barriers and repeat after 2–4 weeks.	
	CD4 cell count	Assess every 3–6 months for the first 2 years after starting ART or if viremia is present or if CD4 <300 cells/μL. If CD4 300–500 cells/μL and HIV RNA suppressed for 2 years, measure every 12 months. If CD4 >500 cells/μL and HIV RNA suppressed for 2 years, measurement is optional.	
	HIV genotype	Repeat if virologic failure occurs and when clinically indicated. Genotypic testing should include mutations in protease PR/reverse transcriptase genes as well as integrase genes when there is a history of integrase strand transfer inhibitor use, including use of cabotegravir PrEP.	
	Human leucocyte antigen B*5701 testing	No need to repeat this test if done in past. A negative test result is required prior to use of abacavir.	
	Tropism testing	Should be done prior to use of CCR5 antagonist regardless if tropism was done in past. If result is ever X4 or dual-mixed, no need to repeat again as CCR5 antagonist can never be used.	
Other labs	Complete blood count	Perform once a year or when clinically indicated.	
	Chemistry panel	Perform 1–2 months after antiretroviral start or change. Then, every 6 months and when clinically indicated. If not on ART, every 6–12 months.	Including creatinine, estimated glomerular filtration rate, electrolytes, and aspartate aminotransferase/ alanine aminotransferase/total bilirubin.
	Urinalysis	Perform annually if at risk of kidney disease and when clinically indicated. Perform before and during use of tenofovir disoproxil fumarate/tenofovir alafenamide.	
	Pregnancy test	Perform in persons of childbearing potential prior to ART start or change and when clinically indicated.	
Screening for mental health and substance use issues	Depression screening	Perform using a validated tool such as Patient Health Questionnaire (PHQ)-2 or -9 at least annually if resources available and when clinically appropriate.	
	Anxiety screening	Perform using a validated tool such as General Anxiety Disorder -2 or -7 in patients aged <65 years at least annually, if resources available and when clinically indicated.	
	Tobacco use screening	Perform for every adolescent and adult at every visit and offer smoking cessation options if current smokers.	
	Substance and alcohol use screening	Perform using validated tools such as alcohol use disorders identification test and drug abuse screening test at least annually when clinically indicated. Refer to treatment if substance or alcohol use disorder is diagnosed.	

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Case 1:26-cv-12638-WGY Document 12-1 Filed 06/10/26 Page 18 of 58

Table 5. Continued

Type of Intervention	Intervention	Recommendation	Comments
Screening for and monitoring of metabolic disorders	Blood pressure screening	Perform at every visit.	
	Weight measurement	Perform at every visit.	
	Screening for hyperlipidemia	Lipid profile: perform every 5 years if normal; more frequently if abnormal or other cardiovascular risk factors present (every 6–12 months); if abnormal, repeat fasting.	Follow atherosclerotic cardiovascular disease risk calculator. Consider testing 1–3 months after starting or changing ART. See Section 7 for further discussion.
	Screening for diabetes mellitus and glucose intolerance	Serum glucose: perform annually; if abnormal, obtain fasting glucose. Hemoglobin A1C should be obtained prior to initiation of ART, if possible. In persons with diabetes, repeat at least every 6 months (more frequently if clinically indicated). Urine microalbumin or urine protein/creatinine ratio: in patients with diabetes, repeat at least every 6 months (more frequently if clinically indicated).	Consider testing 1–3 months after starting or changing antiretroviral medications. Hemoglobin A1c is not used to diagnose diabetes in persons on ART. It may be used for screening and monitoring. Consider threshold cutoff of 5.8%. See Section 7 for further discussion.
	Screening for bone mineral density	Baseline bone densitometry by dual-energy X-ray absorptiometry should be performed in all postmenopausal women and men aged ≥50 years.	See Section 7 for further discussion.
Screening for infectious diseases	Syphilis screening	Perform at least annually in asymptomatic persons; repeat every 3–6 months in asymptomatic persons if risk of acquisition is high, regardless of doxyPEP use.	Acquisition risk depends on sexual activities, use of barrier protection, and local prevalence.
	Gonorrhea and chlamydia screening	Perform at least annually in asymptomatic persons; can repeat every 3–6 months in asymptomatic persons if risk of acquisition is high, regardless of doxyPEP use.	Screening by NAAT at all sites of sexual contact (rectal, oropharyngeal, vaginal, urine/urethral) is recommended for all sexually active persons with HIV. Acquisition risk depends on sexual activities, use of barrier protection, and local prevalence.
	Trichomoniasis screening	Perform annually for persons having vaginal sex.	Screen using NAAT testing.
	Hepatitis A, B, and C screening	Hepatitis C: in sexually active cisgender men and transgender women who have sex with cisgender men and people who inject drugs, screen annually. Hepatitis B: repeat HBV serology (HBsAg, HBsAb, and HBcAb total) in persons without known HBV infection or immunity prior to switching to ART without tenofovir and when clinically indicated, including prior to HCV treatment with direct-acting antivirals.	In those with new abnormal liver function tests, check for acute HAV, HBV, and HCV. Use HCV RNA and HBV DNA testing when clinically appropriate, including for HCV screening in persons with past HCV or those suspected of recent infection within the past 6 months.
	Tuberculosis screening	Perform annually in patients at risk for tuberculosis.	Perform either tuberculin skin test or interferon-γ release assay.
Screening for and prevention of cancer	Smoking	Screen at every visit and for smokers, advise about benefits of cessation and offer pharmacotherapy and referral to behavioral interventions.	Provide resources per local guidelines, including classes, agents that facilitate smoking cessation.
	Low-dose chest computed tomography scan	Those aged between ages 50 and 80 years who have ≥20 pack-years of smoking and are current or former smokers should have an annual low-dose computed tomography scan of the lungs.	
	Prostate cancer screening	Digital rectal exam: considered primary evaluation before PSA screening; consider for patients aged 55–69 years. PSA screening: Age 50–69 years: discuss risks and potential benefits with patient. Age ≥70 years: PSA screening is not recommended.	The impact of HIV on prostate cancer risk is not yet known. African Americans and people with a relative with prostate cancer have a higher burden of prostate cancer. Clinicians should follow US Preventative Services Task Force or American Cancer Society guidelines and consider patient wishes.

Case 1:26-cv-12638-WGY Document 12-1 Filed 06/10/26 Page 19 of 58

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 5. Continued

Type of Intervention	Intervention	Recommendation	Comments
	Colon cancer screening	Perform for those aged 45–75 years if average risk (including personal and family history). Age 76–85 years: individualize screening based on overall health and prior screening. Consider screening earlier if first-degree relatives diagnosed with colon cancer prior to age 50 years.	Screening tests include: stool-based screening (guaiac fecal occult blood test, FIT, FIT-DNA) every year (or up to 3 years for FIT-DNA) or colonoscopy every 10 years if normal, or more frequently if polyps are identified.
	Breast cancer screening	Age 50–75 years: mammography performed at least every 2 years.	Age 40–49 years: inform of the potential risks and benefits of screening and offer screening every 2 years.
	Cervical cancer screening	Age <21 years: Pap test within 1 year of sexual activity, no later than age 21 years. Age 21–29 years: Pap test at diagnosis of HIV, repeat yearly × 3, then if all normal, Pap test every 3 years. Age <30 years: no HPV testing unless abnormalities are found on Pap test. Age ≥30 years: Pap test only, same as age 21–29 years. Or Pap test with HPV testing, if both negative, then Pap test with HPV every 3 years.	Abnormal Pap test and/or HPV follow-up similar to general population. Note: In general, continue screening past age 65 years.
	Anal cancer screening	Digital anorectal exam: perform at least annually if asymptomatic. Anal Pap: screen transgender women and men aged >35 years who have sex with men and all other people with HIV aged >45 years, with anal Pap smears if there is access to or ability to refer for high-resolution anoscopy and treatment.	Abnormal anal Pap tests should prompt referral for high-resolution anoscopy.
	Hepatocellular carcinoma screening	Perform alpha-fetoprotein and liver ultrasound every 6 months.	For patients with cirrhosis from any cause or chronic hepatitis B, as well as fibrosis levels F3 or F4 among patients with hepatitis C.
Other healthcare maintenance	Reproductive desires	All persons with HIV regardless of sexual orientation and gender identity should be asked about their reproductive desires. Persons of childbearing potential should be routinely asked about their plans and desires regarding pregnancy.	ART, hormone therapy, and other treatments may affect pregnancy and pregnancy plans.
	Oral health examination	All persons with HIV should have oral health examinations biannually.	
	Patient education	Tailor education at every visit to patient's current needs. Regularly address with all patients the importance of medication adherence and viral suppression for personal health and preventing sexual transmission (undetectable equals untransmittable) and provide information on sexual health and harm-reduction practices including PrEP, PEP, safer injection practices, syringe services programs, and naloxone.	Brief counseling and tailored interventions should be offered to patients who may benefit from them to reduce risk. Refer patients to programs that offer interventions not accessible locally, such as medication for opioid use disorder, mental health services, sexually transmitted infection testing, viral hepatitis treatment, PrEP, PEP.

Abbreviations: ART, antiretroviral therapy; CCR5, C-C motif chemokine receptor 5; doxyPEP, doxycycline postexposure prophylaxis; FIT, fecal immunochemical test; HAV, hepatitis A virus; HBcAb, hepatitis B core antibody; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; NAAT, nucleic acid amplification test; PEP, postexposure prophylaxis; PrEP, preexposure prophylaxis; PSA, prostate-specific antigen.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Case 1:26-cv-12638-WGY Document 12-1 Filed 06/10/26 Page 20 of 58

patient is not on ART, a chemistry panel should be done every 6–12 months.
- Urinalysis should be monitored annually for those at risk for kidney disease and when clinically indicated. Urinalysis should be monitored before and during treatment with tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide (TAF).
- Tuberculosis screening should be performed annually for persons at risk for infection. Repeat testing is recommended in patients with advanced HIV disease who initially had negative TST or IGRA results but subsequently experienced an increase in CD4 cell count to >200 cells/μL on ART and who may thus have developed sufficient immune competence to mount a positive reaction.
- HCV screening with HCV antibody should be repeated every 12 months for persons at increased likelihood of exposure or when clinically indicated. Screening with HCV RNA rather than HCV antibody is indicated for persons with suspected HCV infection within the past 6 months and previous HCV infection that has cleared due to spontaneous resolution or curative treatment. Screening with HCV RNA instead of HCV antibody should be considered for persons with severe immunodeficiency (CD4 count <200 cells/μL).
- Consider repeating hepatitis B serology, including HBsAb, HBsAg, and HBcAb, in persons not infected with or immune to HBV who are switching to an ART regimen that does not contain tenofovir and when clinically indicated, including before starting HCV treatment with direct-acting antiviral (DAA) medication.
- Pregnancy testing in people with HIV of childbearing potential should be performed prior to ART initiation or modification and when clinically indicated.
- Screening for sexually transmitted infections should be performed periodically, as discussed in Section 6.

Evidence Summary

Complete blood count and chemistry panels should be monitored regularly to assess medication toxicity and to monitor potential for existing comorbid conditions (eg, chronic kidney disease, hepatitis). Monitoring frequency depends on the presence of underlying medical conditions and the need to monitor for ART toxicities, depending on the regimens chosen [6, 7, 124]. Persons with co-occurring diabetes, hypertension, HCV, nephrotoxic medication such as tenofovir, genetic predisposition, or advanced HIV disease are at increased likelihood of kidney disease and should be monitored for renal function at least every 6 months, and urinalysis should be performed at least annually. Urinalysis should be monitored before and during treatment with tenofovir-containing compounds [6, 7, 124].

Annual tuberculosis screening should be considered for those who have negative results for latent tuberculosis but are at ongoing risk for exposure, such as through incarceration, congregate settings, homelessness, and travel to countries with high tuberculosis incidence [98, 101]. A TST or IGRA should be performed any time there is concern of a recent exposure or after a CD4 count increase to >200 cells/μL following initiation of ART. Routine cutaneous anergy testing is not recommended.

HCV screening should be repeated at least annually in persons who are at increased likelihood of exposure, such as persons who inject drugs, cisgender men who have sex with cisgender men, and transgender women [98, 125–128]. HCV RNA testing is indicated for screening when HCV infection within the past 6 months is suspected and in people who had previous HCV infection that cleared spontaneously or through treatment. HCV RNA testing should be considered when a person has severe immunodeficiency with CD4 count <200 cells/μL, especially if the person has a history of injection drug use or an ALT level above the upper limits of normal [7, 129]. Repeating HCV RNA after confirmed curative therapy (undetectable HCV RNA at least 12 weeks post-completion of treatment) is not necessary unless there is a clinical indication, such as evidence of unexplained liver injury or ongoing exposure [106].

Persons who have negative hepatitis B serology should be vaccinated (see Section 4). Persons who test positive for HBV infection (with the presence of HBsAg or HBV DNA) should have TDF or TAF and emtricitabine (FTC) or lamuvidine (3TC) included in the ART regimen. People who test positive only with HBcAb may have resolved HBV infection with loss of HBsAb, and HBV DNA testing can be performed to confirm. If the HBV DNA test is negative, the person should then be vaccinated. HBV reactivation can occur in patients during and after treatment with HCV DAA medication, and repeat hepatitis B screening (including with HBV DNA testing if indicated) should be considered in patients not infected with or immune to HBV, especially those with isolated HBcAb, prior to treatment with HCV DAAs [7, 130–132].

A pregnancy test should be performed in persons of childbearing potential prior to initiating or modifying ART. Clinicians should discuss the benefits of ART with the patient as well as regimens that are recommended during pregnancy and their potential toxicities. Shared decision-making with the patient should occur regarding the choice of ART for initiation, continuation, or modification.

Screening and Treatment for Mental Health and Substance Use Issues

Recommendations

- Screening for depression using a validated screening tool should be conducted on every adult patient at least once, with screening frequency based on risk. Annual screening is reasonable, given the elevated risk of depression in people with HIV.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

- Screening for anxiety using a validated screening tool should be conducted on every adult patient aged <65 years, with screening frequency based on risk. Annual screening is reasonable, given the elevated risk of anxiety in people with HIV.
- Screening for tobacco use should be conducted for every person with HIV at every visit. Current smokers should be advised of the benefits of quitting and offered options to assist with smoking cessation, including pharmacotherapy and connection to behavioral interventions.
- Screening for unhealthy alcohol use and substance use using validated screening tools should be conducted on every adult patient at least once, with screening frequency based on need. Annual screening is reasonable given the elevated risk of unhealthy alcohol and substance use in people with HIV. Individuals diagnosed with an alcohol or substance use disorder should be offered treatment, including pharmacotherapy (such as methadone or buprenorphine for opiate use disorder) and connection to behavioral health interventions.
- Individuals who inject drugs should be counseled on safer injection and substance use practices to prevent viral hepatitis and other infectious diseases and injection-related conditions such as endocarditis, osteomyelitis, cellulitis, and abscesses. They should be educated on PrEP and PEP for injection partners and provided information on syringe services programs, where available.
- All individuals with substance misuse or use disorders should be provided with life-saving medications such as naloxone for overdose prevention.

Evidence Summary

People with HIV have high rates of depression; anxiety; and tobacco, alcohol, and substance use disorders. After initial screening, optimal screening intervals for mental health and substance use disorders are not known. Repeat screening on a regular basis, such as annually, is reasonable because of the high prevalence of these conditions among people with HIV [133–136]. Screening for depression and anxiety should include the use of validated screening tools such as Patient Health Questionnaire-2 (PHQ-2), PHQ-9, and GAD-2 [82, 83, 137, 138]. People with HIV should be screened for drug and alcohol use with validated screening tools such as the Alcohol Use Disorders Identification Test and the Drug Abuse Screening Test [134, 136, 139]. Self-reported substance use screening tools can be incorporated into electronic health records [140]. Patients who are found to have alcohol or substance misuse or use disorders should be offered or referred for pharmacotherapy, such as buprenorphine or methadone for opioid use disorder and naltrexone for alcohol or opioid use disorder, and/or behavioral health treatment provided within a harm-reduction model of care. Education on safer injecting practices and drug use, syringe services programs, and overdose prevention provides people with choices on how to minimize health risks such as injection-related infections and where to access services if and when they are ready. Naloxone should be provided for overdose prevention. Co-location of substance use treatment with HIV care is ideal [141]. Brief interventions that include use of motivational interviewing can be provided by trained healthcare personnel [142].

Tobacco use is a major cause of decreased life expectancy and poor health outcomes, including cardiovascular disease and lung cancer, in people with HIV [143–146]. People with HIV should be asked about tobacco use at every visit [147–149]. This can be accomplished when taking the patient's vital signs. People who smoke tobacco should be counseled on the benefits of quitting, offered pharmacotherapy, especially varenicline, and connected to behavioral health interventions [150, 151]. See Section 5 for cancer screening in smokers.

Other Health Maintenance Considerations

Recommendations

- All persons with HIV, regardless of sexual orientation and gender identity, should be asked about their pregnancy intentions. Persons of childbearing potential should be routinely asked about their pregnancy intentions, especially prior to treatments that may affect the ability to have children or the outcome of pregnancy.
- Patient education should be tailored at every visit based on the patient's current needs. In particular, the clinician should evaluate the need for education on the following:
  - The importance of medication adherence in achieving viral load suppression to maximize personal health and eliminate HIV transmission to sexual partners (U = U);
  - Optimizing sexual health of the patient and their sexual partners by informing patients about PrEP, PEP, barrier methods, and other strategies for HIV and STI prevention; and
  - Safer use of recreational drugs and their potential side effects and known drug interactions.
- All persons with HIV should have regular oral health examinations at least every 6–12 months.

Evidence Summary

It is important to discuss pregnancy intention and family planning with every patient, especially prior to prescribing medication or treatments that may affect pregnancy or fertility, such as ART or hormone therapy for gender-affirming care. Education should include U = U and the ability to become pregnant without risk of HIV transmission, as well as available options for preserving sperm/ova for future family planning prior to certain treatments. Every patient should also be informed of the possibility of becoming or getting their partner pregnant; if

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

desired, options for birth control should be reviewed and offered (see Section 8).

Barriers to adherence and care engagement should be repeatedly assessed. Clinicians should engage in effective patient education in a respectful and nonjudgmental manner for maintenance of physical, emotional, spiritual, and sexual health. Providing information on medication adherence, sexual health, and recreational drug use is critical for engaging and retaining patients in care (see Section 1).

People with HIV have frequent oral health complications, especially if the CD4 cell count is low [152]. Any identified oral health complication should be addressed immediately. In addition, every patient should have regular oral health exams. Given the risks for oral complications, a biannual oral health examination for people with HIV is reasonable.

SECTION 4: IMMUNIZATIONS FOR PERSONS WITH HIV

Vaccinations are routinely provided as part of primary care visits, and HIV primary care providers play a unique and trusted role in providing counseling and guidance on recommended immunization strategies. However, due to the time required for counseling, it is advisable to use standing orders and delegate routine vaccinations, which do not require shared decision-making, to other members of the healthcare team, such as qualified nursing or pharmacy staff. Shared decision-making is a collaborative process often used when there is uncertainty regarding the benefits of a specific treatment for a particular population [153, 154]. The healthcare provider shares clear and understandable information about a health condition, explains the necessary decisions and available options, and allows the patient to express their preferences and values. Together, the patient and provider discuss the pros and cons, including risks, which results in a collaborative decision that respects the patient's autonomy. Studies have shown that when shared decision-making is not required, computerized standing orders are more effective than computerized reminders, especially for offering influenza and pneumococcal vaccinations [153, 155]. Vaccination receipt is increasingly regarded as a measure of healthcare quality, and all members of the healthcare team can collectively contribute to achieving these quality metrics. Current immunization recommendations are included in Table 6. However, recommendations change frequently, and HHS OI guidelines and ACIP recommendations should be checked frequently [98, 110, 156].

Pneumococcus, Influenza, Meningococcus, Tetanus-Diphtheria-Pertussis

Recommendation

- Vaccination against infection with pneumococcus, influenza, meningococcus, and tetanus-diphtheria-pertussis should be offered to all people with HIV.

Evidence Summary

Evidence of increased invasive disease due to 7 serotypes not covered in the pneumococcal conjugate vaccine (PCV) 13 (Prevnar13) and the approval of new vaccines with broader coverage have led to revised recommendations for pneumococcal vaccination. The use of PCV20 (Prevnar 20; Vaxneuvance) alone or a combination with PCV15 plus 23-valent pneumococcal polysaccharide vaccine (PPSV23; Pneumovax23) given at least 8 weeks later is now recommended for all individuals aged ≥65 years and for those aged between 19 and 64 years with underlying conditions (such as HIV) who are unvaccinated or whose vaccination status is unknown (see Figure 1). Although there are no clinical outcome data for people with HIV, no additional PPSV23 doses are needed when PCV20 is used, making this a simple and preferred regimen [157, 158]. For those who have received both PCV13 and PPSV23 and are aged <65 years, 1 dose of PCV20 can be administered at least 5 years after the last dose of PPSV23 to complete the series or a second dose of PPSV23 can be administered at least 5 years after the prior dose, with a third and final dose administered at age 65 years or later but at least 5 years after the last PPSV23 dose. For persons aged at least 65 years at the time of a PPSV23 dose, no additional doses are needed. Those who have received only PPSV23 can be given PCV20 with no additional vaccinations or they can be given PCV15 followed by PPSV23 after 8 weeks. Those who have received only PCV13 can be given PCV20 at least 1 year later to complete the series or be given PPSV23 at least 8 weeks later with subsequent PPSV23 doses to complete the series. When there is no access to PCV15, PPSV23, or PCV20, patients should receive whatever is available to receive protection. For those who are aged <65 years and have received PCV20 or PCV15 with PPSV23 at least 8 weeks later, no additional pneumococcal vaccine is needed at age 65. Shared decision-making is recommended when considering PCV20 for adults aged ≥65 years who completed their series with other vaccines. If the decision to administer is made, it should be administered at least 5 years after the last PPSV23 dose. PCV21 (Capvaxive) has also been approved by the FDA and could be substituted for PCV20 in adults for whom a dose of PCV20 is currently recommended [159]. At the time of publication of this guidance, no specific data are available for PCV21 in people with HIV.

All people with HIV should receive an annual influenza vaccination, but they should not receive live vaccination via nasal spray (LAIV4 Flumist). Patients aged >65 years should receive 1 of 3 high-dose, adjuvanted, or recombinant influenza vaccines: HD-IIV4 (Fluzone), aIIV4 (Fluad), or RIV4 (Flublok) [160, 161]. Recommendations for tetanus toxoid, reduced diphtheria toxoid, and reduced acellular pertussis (Tdap; Adacel, Boostrix) are the same as for the general population. Pregnant individuals should receive Tdap during each pregnancy between 26 and 37 weeks' gestation [162]. Adults with

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Table 6. Immunizations for People With Human Immunodeficiency Virus

Vaccination	Dose	Revaccination	Comment
Influenza, standard dose: IIV4 (Afluria, Fluarix, FluLaval, Fluzone), ccIV4 (Flucelvax), aIIV4 (Fluad), RIV4 (Flublok); high dose: HD-IIV4 (Fluzone)	1	Yearly	Age >65 years high dose (HD-IIV4, aIIV4, RIV4). LAIV4 (FluMist) is contraindicated for people with HIV; for people with egg allergy, use IIV or RIV.
Tetanus, diphtheria, and acellular pertussis: TdaP (Adacel, Boostrix); tetanus, diphtheria (Tenivac, Tdvax);	1	10 years	Td can be given every 10 years; give TdaP with each pregnancy, give Td if contaminated wound and none received in 5 years.
Meningococcus (MenACWY-TT vaccine; MenQuadfi or Menveo)	2 doses, 2 months apart	5 years	MenACWY-TT: every 5 years after primary series. MenACWY-D is no longer available. Vaccination against meningococcus B not routinely recommended for all individuals. Two MenB vaccines are available, MenB-4C (Bexsero) and MenB-FhBp (Trumenba). A pentavalent meningococcal is available from serogroups ACWY and B (Penvrava) if both vaccines are indicated.
Measles, mumps, rubella	2 doses, 1 month apart	…	CD4 >200 cells/μL and no immunity; if pregnant and not immune, administer after delivery if CD4 >200 cells/μL.
Hepatitis A (Havrix, Vaqta)	2 doses, 6 months apart	…	Check for evidence of immunity post-vaccination, 1–2 months post-vaccination series complete.
Hepatitis B	…	Nonresponders to primary series: repeat full primary series of recombinant, adjuvanted vaccine 0, 1 months (can give third dose at 6 months if HBsAb not seroprotective). Alternatives for revaccination due to nonresponse: double dose recombinant vaccines (Engerix-B, Recombivax HB) at 0, 1, 6 months.	Vaccinate those who do *not* have chronic hepatitis B virus. Check for evidence of immunity postvaccination (HBsAb titer >10 mIU/mL).
• Hepatitis B–naive to vaccination, primary series: recombinant, adjuvanted vaccine (HepB- CpG, Heplisav-B)	2 doses, 0, 1 month	…	Primary series: HepB-CpG (Heplisav-B): after 2 doses, check antibody levels at 1–2 months (and if not immune [titer is not >10 mIU/mL] may consider third dose).
• Alternatives to HepB-CpG: recombinant vaccine double dose (Engerix-B, Recombivax-HB)	3 doses, 0, 1, and 6 months (double dose)	…	Alternatives to HepB-CpG: Engerix-B (20 μg; double dose = 40 μg); Recombivax HB (10 μg; double dose = 20 mcg); check HBsAb titer 1–2 months after complete series.
• Alternatives to HepB-CpG and needing hepatitis A vaccination: combined hepatitis A and recombinant hepatitis B vaccine (Twinrix)	0, 1, and 6 months	…	…
Human papillomavirus (Gardisil)	3 doses (0, 1–2, 6 months)	…	Recombinant 9-valent can be offered to people with HIV up to age 45 years with shared decision-making; vaccination should not be given during pregnancy.
Mpox (Jynneos)	2 doses, 4 weeks apart (subcutaneous or intradermal)	…	Jynneos live nonreplicating vaccinia vaccine requires both doses for maximal immunity (subcutaneous preferred); ACAM 2000 vaccine contraindicated with HIV.
RSV (Arexvy, Abrysvo)	1 dose	…	Those aged ≥75 years should receive a dose; those aged 60–74 years with likelihood of severe RSV should receive a dose (2 different vaccines available); limited data in people with HIV.
VZV (Varivax)	2 doses, 3 months apart		Contraindicated if CD4 <200 cells/μL.
Recombinant zoster vaccine (Shingrix for prevention of recurrence)	2 doses, 0, 2–6 months apart		Can be given to those aged ≥18 years to prevent recurrence of herpes zoster (if prior VZV).
Severe acute respiratory syndrome coronavirus 2 (COVID-19); primary series in persons who are moderately to severely immunocompromised	Because of the changing nature of COVID-19 vaccine policy, see the Centers for Disease Control and Prevention COVID-19 vaccine recommendations for details (https://www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html)		
• Unvaccinated	3 doses (mRNA; Pfizer-BioNTech or Moderna); 2 doses Novavax	…	Pfizer-BioNTech: second dose 3 weeks from first dose, third dose 4 weeks from second dose. Moderna: each dose 4 weeks apart; Novavax: 3 weeks apart.

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Case 1:26-cv-12638-WGY Document 12-1 Filed 06/10/26 Page 24 of 58

Table 6. Continued

Vaccination	Dose	Revaccination	Comment
• Received 1 dose prior mRNA	2 doses		Moderna: each dose at least 4 weeks apart. Pfizer-BioNTech: 3 weeks from last dose; 4 weeks from first and second updated.
• Received 2 doses prior mRNA	1 dose	…	Moderna or Pfizer-BioNTech at least 4 weeks after last dose.
• Received 1 or more Novavax or Janssen	1 dose	…	Moderna, Pfizer-BioNTech, or Novavax: at least 8 weeks after last dose.
Vaccination following primary series completion: Please check ACIP recommendations for updates			
• Received complete series not including 2023–2024 vaccine	1 dose 2023–2024 vaccine	…	…
• Received complete series including 2023–2024 vaccine	Age ≥65 years: 1 additional dose 2023–2024 vaccine; age 19–64 years: may give 1 additional 2023–2024 vaccine based on risk		
• Subsequent revaccination	Please check ACIP recommendations.		
Pneumococcus (please see Figure 1 for illustration)			
• PCV20 (Prevnar20) • PCV21 (Capvaxive may be substituted for PCV20)	1 dose	No further doses of PCV20 or PCV21 are needed after first dose. At any time, if PCV20 or PCV21 is substituted for PPSV23, the pneumococcal vaccination series is complete. …	• If no pneumococcal vaccine given or unknown, 1 dose of PCV20 completes pneumococcal vaccination (preferred due to simplicity). PCV21 could be substituted for PCV20 in adults in whom a dose of PCV20 is currently recommended. • If previous PPSV23 or PCV13 alone, can give 1 dose of PCV20 at least 1 year later to complete the series. • If previous PCV13 and PPSV23 received before age 65 years, may give 1 dose PCV20 at least 5 years later to complete series. • If previous PCV13 and 1 dose of PPSV23 received at age ≥65 years, no further vaccine needed, but may receive 1 dose PCV20 at least 5 years later with shared decision-making.
• PCV15 (Vaxneuvance)	1 dose	Give PPSV23 8 weeks after PCV15 to complete the series.	• If no pneumonia vaccine given or unknown, may give 1 dose, followed by PPSV23 8 weeks later (alternative). • If previous PPSV23 alone, give 1 dose PCV15 at least 1 year later to complete series. • If previous PCV13 alone, no PCV15 needed; give PPSV23 at least 8 weeks later or PCV20 at least 1 year later.
• PPSV23 (Pneumovax23)	Do not give as initial vaccine	If only received PPSV23, give PCV20 or PCV15 at least 1 year later to complete series.	If received PCV13 and PPSV23: • If received PPSV23 at age <65 years, may give third and final PPSV23 dose at least 5 years after second PPSV23 dose; OR may receive 1 dose PCV20 at least 5 years after last PPSV23. • If received PPSV23 at age ≥65 years, no further PPSV23 needed (may receive 1 dose of PCV20 with shared decision-making).
Travel Vaccines			
• Vibrio cholera (CVD103-HGR; Vaxchora)	1 dose, oral	…	CVD103-HgR live attenuated; give 10 days prior to exposure; lasts for 3 months; do not give if CD4 <200 cells/μL.
• Polio (Ipol)	3 doses (0, 1–2, 6–12 months)	…	IM, inactivated vaccine for those at high risk for exposure to poliovirus.
• Typhoid (Thyphim Vi)	1 dose	…	Thyphim Vi polysaccharide vaccine (IM), administer 1 week prior to exposure; note: do not give oral vaccine; avoid in pregnancy.

Abbreviations: ACIP, Advisory Committee on Immunization Practices; COVID-19, coronavirus disease 2019; CpG, cytidine monophosphate guanosine; HBsAb, hepatitis B surface antibody; HIV, human immunodeficiency virus; IM, intramuscular; mRNA, messenger ribonucleic acid; PCV. pneumococcal conjugate vaccine; PPSV, pneumococcal polysaccharide vaccine; RSV, respiratory syncytial virus; VZV, varicella zoster virus.

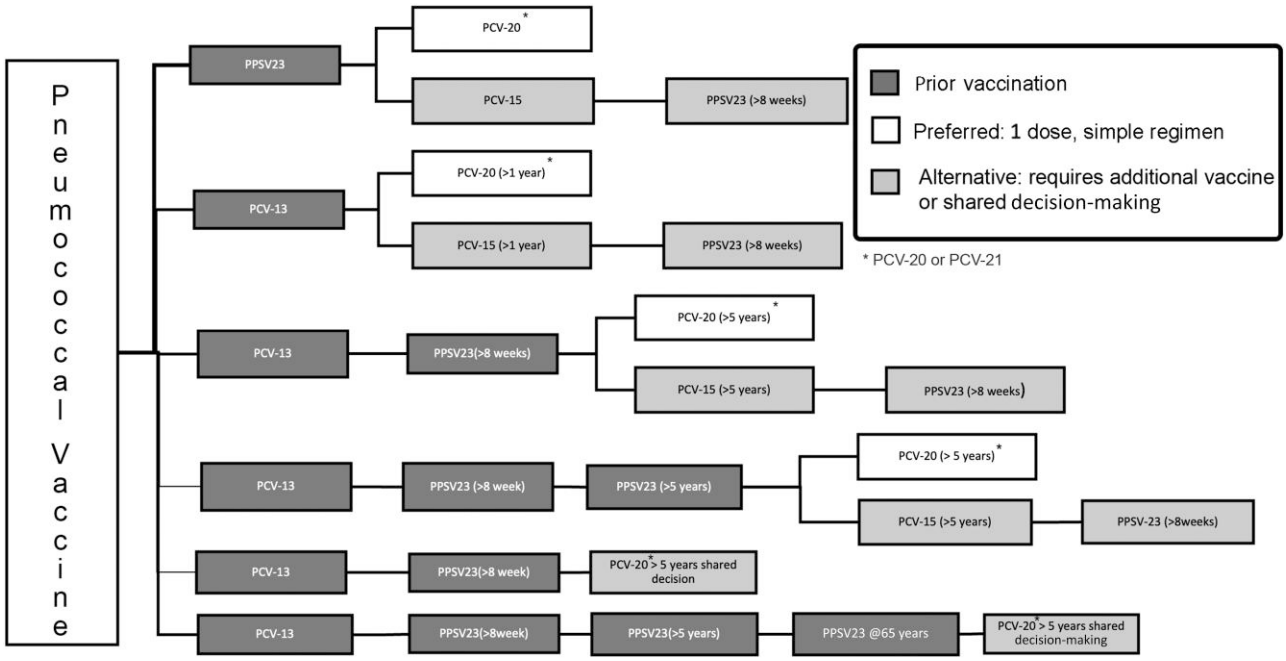

Figure 1. Vaccinations to prevent pneumococcus infection. Abbreviations: PCV, pneumococcal conjugate vaccine; PPSV, pneumococcal polysaccharide vaccine.

HIV should receive a 2-dose quadrivalent meningococcal conjugate vaccine primary series of serogroup A, C, W, and Y (Menveo, MenQuadfi) at least 2 months apart if not previously vaccinated. After the primary series, revaccination should occur every 5 years. Serogroup B meningococcal vaccine (Bexsero, Trumenba) is not routinely recommended but may be given to persons aged 16–23 years and under certain circumstances [163]. Although there are no specific data for people with HIV, a new pentavalent meningococcal vaccine that contains antigens from serogroups ACWY and B (Penbraya) may be given when both vaccines are indicated at the same time [156].

HAV and HBV

Recommendations

- Vaccination for HAV is recommended for all nonimmune individuals with HIV, especially those with indications for hepatitis A vaccine (including PWID, those unstably housed, those with current or prior incarceration, gay and bisexual men or transgender persons with chronic liver disease, travelers to countries with high endemicity, and persons who have hepatitis B and/or C).
- HAV IgG antibody testing should be repeated 1–2 months or at the next scheduled visit after the second vaccine to assess for immunogenicity. A repeat vaccine series is recommended in those who remain seronegative.
- Individuals susceptible to infection should be vaccinated against HBV.
  - The adjuvant recombinant vaccine (HepB-CpG; Heplisav-B) 2 doses at 0, 1 month is preferred.
  - Alternative regimens can be used if HepB-CpG is not available, including double doses of the recombinant hepatitis B vaccines Engerix-B 40 µg (two 20-µg doses) or Recombivax-HB 20 µg (two 10-µg doses) or standard doses of the combined hepatitis A and recombinant hepatitis B vaccine (Twinrix) given at 0, 1, and 6 months.
- HBsAb levels should be checked 1–2 months after completion of the primary immunization series. If HBsAb is <10 mIU/mL, revaccination with a full vaccine series is necessary. Three doses of HepB-CpG may be considered.
- Vaccination should be recommended for nonimmune sexual partners of persons who are positive for HBsAg.
- Persons who are negative for HBsAg and HBsAb but positive for HBcAb should receive vaccination.

Evidence Summary

Responses to both HAV and HBV vaccines are reduced in patients with a CD4 count <200 cells/µL and those with quantifiable HIV RNA levels. An interim analysis of AIDS Clinical Trial Group (ACTG) study A5379 of adjuvanted recombinant HepB-CpG (Heplisav-B) given at 0, 1, and 6 months to unvaccinated people with HIV who had viral suppression and a median CD4 count of 625 cells/µL (range, 149–1562) showed that 100% developed seroprotective titers of HBsAb >10 mIU/mL

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

at 28 weeks (4 weeks after a 3-dose vaccine series). At 24 weeks (after 2 doses and prior to the third dose), 98.5% had seroprotective titers. In addition, at 28 weeks (4 weeks after the third dose), 83.8% had titers >1000 mIU/mL [164]. These data are promising, but durability of such high titers is unknown and will be assessed in the ongoing A5379 study [164]. In a person with a high CD4 cell count, a 2-dose HepB-CpG series is seroprotective, but the high titers achieved after a third dose in persons with high CD4 cell counts and suppressed virus, as well as improved responses after a third dose in persons without HIV but who had chronic kidney disease, suggest that those with low CD4 cell counts might achieve a more robust response with 3 doses. Until additional data are available, if a titer >10 mIU/mL is not achieved, consider the patient to be a nonresponder, and a full revaccination series is recommended [98].

Vaccines that can be used if HepB-CpG is not available include 2 recombinant hepatitis B vaccines (Engerix-B or Recombivax-HB) using a double dose at 0, 1, and 6 months or combined hepatitis A and hepatitis B recombinant vaccine at 0, 1, and 6 months. PreHevbrio® is a third recombinant vaccine for which insufficient data exist for people with HIV. Patients who fail to respond to an initial series can be revaccinated with a full series of double-dose Engerix-B or Recombivax-HB (at 0, 1, and 6 months) or a complete 2-dose series of HepB-CpG. Initial data from ACTG 5379 look promising for 2 or 3 doses of HepB-CpG for people with HIV who did not achieve seroprotection from an initial vaccination series. In these individuals, either 2 or 3 doses of HepB-CpG was superior to 3 single-strength doses of Engerix-B, with seroprotective responses of 93.1%, 99.4%, and 80.6%, respectively [165]. Although few people with low CD4 counts were included in the study, these preliminary data suggest that 3 doses of HepB-CpG might be an effective strategy for revaccination in these individuals. A 2-dose strategy is likely to achieve seroprotection for many, and checking HBsAb levels 2 months after the second dose can inform if a third dose should be given at 6 months, as both strategies were superior to 3-dose single-strength recombinant vaccine. However, ACTG 5379 is ongoing, and the durability of seroprotection is still unknown. No safety data on HepB-CpG are available in pregnancy; therefore, HepB-CpG should be avoided in this population. For those initially vaccinated when the CD4 count was <200 cells/μL, an improved response may be observed after virologic suppression on ART and a CD4 count >200 cells/μL are achieved. One dose of vaccine should be administered to patients who have a positive anti-HBc with a negative HBsAg and HBsAb. If the HBsAb titer is not >100 mIU/mL, a full series should be administered [166]. Prior to administration of any HBV vaccine, it is necessary to confirm that the patient does not have chronic HBV.

Those who have been incompletely vaccinated should receive 1 dose of hepatitis B vaccine following exposure to HBV. Those who have not been vaccinated should receive hepatitis B immune globulin (IG) within 24 hours to 7 days for percutaneous exposure to HBV and up to 14 days for sexual exposure to HBV. All infants born to HBsAg-positive persons should receive hepatitis B IG and hepatitis B immunization, preferably in the first 12 hours of life. Routine vaccination for HAV and HBV is recommended for all infants [120, 167]. Serologic testing for viral hepatitis should be repeated if suspected exposure occurs or if there are newly elevated transaminase levels.

MMR, Papillomavirus, and VZV

Recommendations

- MMR vaccine should be administered to people with CD4 count ≥200 cells/μL to protect against measles, mumps, and rubella if they were born in the United States in 1957 or after and have not received this vaccine or do not have immunity to these infections.
- Persons aged between 9 and 26 years should be vaccinated against human papillomavirus (HPV), and those aged 27–45 years who are unvaccinated or inadequately vaccinated should be offered the vaccination series, if appropriate, through shared decision-making.
- Persons who are susceptible to VZV (those who have not been vaccinated, have no history of varicella or herpes zoster, or are seronegative for VZV) should receive PEP with varicella zoster IG as soon as possible (but within 10 days) after exposure to a person with varicella or shingles.
- Varicella primary vaccination should be considered in VZV-seronegative persons aged >8 years with CD4 count >200 cells/μL and in children with HIV aged 1–8 years with CD4 cell percentages >15%. Primary varicella vaccination is contraindicated for persons with CD4 count <200 cells/μL.
- Recombinant zoster vaccine (RZV), 2-dose series, should be given to those aged ≥18 years to prevent reactivation. Response may be better if suppressed on ART and the CD4 count is >200 cells/μL.

Evidence Summary

In 2019, there were 1274 individual cases of measles in 31 states, the highest number reported in the United States since 1992 [168]. The majority of cases occurred in individuals who had not received measles vaccination. The MMR vaccine is administered in a 2-dose series with at least 1 month between doses. MMR should not be given if CD4 is <200 cells/μL. Acceptable evidence of immunity against measles includes written documentation of adequate vaccination, laboratory evidence of immunity, laboratory confirmation of measles, or birth in the United States before 1957 [113].

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

A preventive 9-valent HPV vaccine (9vHPV; Gardisil) is routinely recommended in a 3-dose schedule for all persons with HIV aged 9–26 years. Catch-up vaccination can be offered to those aged 27–45 years based on shared decision-making [156, 169]. The vaccine is safe and highly effective in preventing infection with the HPV subtypes associated with genital warts and those responsible for approximately 70% of cervical cancers and most anal cancers. Evidence shows a vaccine-associated decrease in the prevalence of HPV infections, anogenital lesions, and precancerous cervical neoplasia [169]. Studies show the safety of HPV vaccine in women, men, and children [170]; however, the efficacy data for people with HIV are limited, with mixed results [171–174]. Furthermore, little is known about the efficacy of HPV vaccination in older age groups. One study reported that when HPV vaccination was given to those with HIV at an older age but <45 years anal dysplasia was reduced [175]. The vaccine is not expected to impact the development of cancer in those who already harbor oncogenic subtypes. All persons with HIV should receive 3, rather than 2, doses of vaccine, regardless of age [176].

Varicella vaccination (Varivax) should be considered (2 doses of single-antigen varicella vaccine, not measles/mumps/rubella/varicella, administered 3 months apart) for adults and adolescents with HIV with a CD4 count >200 cells/μL on suppressive ART who do not have prior evidence of immunity to varicella (including documented prior infection) [177, 178]. Children should also receive the vaccine if aged >8 years and with a CD4 cell percentage ≥15%. Persons without evidence of immunity who have no history of varicella or shingles and no history of vaccination against VZV and who are at risk of developing severe disease or complications should receive varicella zoster IG within 10 days after exposure to persons with varicella or shingles [110, 177, 178]. Varicella zoster IG is not indicated for persons who received 2 doses of varicella vaccine and became immunocompromised later in life [110, 177]. RZV (Shingrix) should be administered to adults aged ≥18 years using 2 doses 2–6 months apart for the prevention of herpes zoster [98]. Those whose virus is suppressed on ART with CD4 count >200 cells/μL may respond better, but the vaccine can be safely given regardless of CD4 cell count. Those who have not had varicella exposure (either infection or vaccination) should not be offered this vaccine. Data indicate that 99% of those born prior to 1980 have had varicella, even if they do not recall receiving the vaccination [179]. Studies in HIV have found the vaccine to be safe and immunogenic after 2 doses.

COVID-19, Mpox, and Respiratory Syncytial Virus

Recommendations

- All people with HIV should receive updated COVID-19 vaccines as recommended by the CDC. Due to rapid changes in recommendations, the CDC guidance should be checked for the most current information.
- The following should be counseled about transmission of mpox and offered vaccination with the live-nonreplicating modified vaccinia Ankara-Bavarian Nordic (MVA-BN) vaccine. The full 2-dose series is required for optimum protection.
  - Persons without mpox lesions who have known or suspected exposure to someone with mpox or with a sex partner in the past 2 weeks who was diagnosed with mpox;
  - Cisgender men who have sex with cisgender men or transgender, nonbinary, or gender-diverse persons who, in the last 6 months, have had a new diagnosis of an STI or more than 1 sexual partner;
  - Persons who, in the last 6 months, have had sex at a commercial sex venue or sex related to a large commercial event or in a geographic area where mpox transmission is occurring;
  - Persons who have a sex partner with any of the above risks or persons who anticipate experiencing any of the above scenarios.
- Persons aged ≥75 years should receive 1 dose of a respiratory syncytial virus (RSV) vaccine. Those aged 60–74 years who are at increased likelihood of severe RSV should receive 1 dose of an RSV vaccine.

Evidence Summary

Vaccination against severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has had a dramatic impact in reducing severe illness, hospitalization, and mortality. People with HIV are at increased likelihood of reinfection with SARS-CoV-2 [180] and for post-COVID-19 conditions (PCCs, formerly postacute symptoms of COVID-19 or PASC); vaccination protects against development of PCCs [181]. Those who are previously unvaccinated or who received a monovalent COVID-19 vaccine in the past should receive an updated COVID-19 vaccine at least 2 months after the last dose [182]. Note that these recommendations continue to change, and all clinicians should check the CDC website for the most current information [183].

The CDC recommends vaccination against mpox for cisgender gay, bisexual, and other men who have sex with cisgender men and those who are transgender, gender-diverse, or nonbinary and who, in the past 6 months, have had a new diagnosis of at least 1 STI or more than 1 sex partner. Additionally, persons who, in the last 6 months, have had sex at a commercial sex venue or sex in association with a large public event or in a geographic area where mpox transmission is occurring should be offered vaccination. Vaccination is recommended for sexual partners of persons described above and persons who anticipate experiencing any of the above [156]. A live nonreplicating vaccinia virus vaccine for smallpox and mpox (MVA-BN; Jynneos) is safe to administer to those with

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

immunocompromising conditions, including HIV, although the immune response may be diminished in this population, particularly those with low CD4 cell counts or unsuppressed virus. There are insufficient data during pregnancy and breastfeeding. The peak antibody response is achieved 2 weeks after the second dose [184]. Data from an electronic record review suggest that the Jynneos vaccine was effective in preventing mpox disease [185]. It is crucial that both doses are received for optimal immunity. Those who are unvaccinated and have had exposure should receive the complete series with the first dose within 4–14 days of exposure [98]. The duration of protection remains uncertain, but there is evidence that suggests that severity of disease is reduced in individuals who develop mpox after vaccination, including those with HIV [186–188]. The live attenuated ACAM 2000 smallpox vaccine should not be given to people with HIV (see Section 6).

RSV is a highly contagious virus that can cause severe lower respiratory infections in young children and older adults. Recently, the FDA approved 2 vaccines for those aged ≥60 years, based on risk for severe RSV disease. The RSVPreF3 is a single-dose adjuvanted recombinant prefusion F protein (preF) vaccine, and the RSVPreF is a single-dose recombinant stabilized preF vaccine (Arexvy, Abrysvo). In clinical trials, the efficacy of preventing RSV-associated lower respiratory infection varied from 77% to 81% [189]. Of 38 177 participants who received the vaccines, 6 cases of inflammatory neurologic events after RSV vaccination occurred [189]. Persons aged 60–74 years who have heart or lung disease or weakened immune systems, who are frail, or who live in a group setting are at increased likelihood of severe RSV and should receive 1 dose of an RSV vaccine. Persons aged ≥75 years should receive 1 dose of an RSV vaccine. Data regarding RSV vaccine in people with HIV are limited. Risks and benefits should be assessed based on shared decision-making [190].

Travel Vaccination

Recommendation

- Individuals who travel should be advised to follow CDC guidelines, with particular attention to CD4 cell count, based on their travel activities and destinations.

Evidence Summary

Cholera is a toxin-mediated bacterial infection that results from ingestion of contaminated food or water, leading to severe watery diarrhea. Cholera is likely to occur in areas with inadequate sanitation. CVD103-HgR (Vaxchora) is a single-dose live attenuated oral cholera vaccine recommended for travel to high-risk areas in which *Vibrio cholera* transmission can occur. The duration of protection is approximately 3 months, and vaccine efficacy may be lower in people with HIV. CVD103-HgR should be given at least 10 days prior to potential exposure among those aged 18–64 years [191]. Before 2022, poliovirus cases had not been seen in the United States for more than 30 years, and only a limited number of cases had been reported in Afghanistan and Pakistan. In 2022, there was a 23% increase globally in polio cases caused by circulating vaccine-derived poliovirus and decreased polio vaccination rates, including a paralytic case in New York City, accompanied by local wastewater surveillance for poliovirus [192]. The risk of acquiring vaccine-derived polio is low and can be mitigated by vaccination. Those who may have high-risk exposure can receive a 3-dose vaccine (Ipol) if CD4 is >200 cells/μL and if the benefits outweigh the risks [193]. Typhoid fever can cause life-threatening illness due to *Salmonella* Typhi. Individuals who travel to high-incidence areas should consider vaccination to reduce the risk for typhoid fever. Typhoid vaccine Thyphim Vi covers *Salmonella enterica* serotype paratype A, B, and C. The intramuscular vaccine should be administered 1 week prior to travel. People with HIV should avoid the live-attenuated oral vaccine (Vivotif) [194].

SECTION 5: SCREENING FOR AND PREVENTING CANCER

Because of an increased likelihood of both first and second primary cancers among people with HIV, enhanced cancer prevention, screening, and treatment efforts are needed for people with HIV both before and after an initial cancer diagnosis. It is recommended that clinicians who are treating patients with cancer inquire and screen for HIV if serostatus is not established [195, 196]. Clinicians treating HIV should regularly inquire about cancer risks and ensure recommended screenings [195]. Although persons with HIV have increased rates of certain cancers, recommendations for screening (prostate, breast, colon, lung) are not different from those for the general population, and providers should follow US Preventive Services Task Force (USPSTF) and American Cancer Society guidelines. However, AIDS-defining cancers and non–AIDS-defining cancers, especially virally based cancers, occur more frequently in people with HIV and merit increased attention [197–199]. Higher CD4 count (≥350 cells/μL) and maximal viral suppression are associated with lower 5-year mortality among patients with HIV and any cancer diagnosis [200]. While most cancers are not diagnosed at younger ages in people with HIV, lung cancer, anal cancer, and myelomas may occur at younger ages among people with HIV compared with those without HIV. People with HIV are at greater risk for oral/pharyngeal and kidney cancers [198, 201]. Viral suppression is especially associated with lower risk of virally associated and non–AIDS-defining cancers among those on ART [201]. As such, as with most comorbidities, viral suppression is urged for people with HIV who have cancer. Because people with HIV have

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

higher mortality rates after they develop cancer, increased observation, vigilance, and screening are required [202].

Recommendations

Prevention

- All patients should be asked about tobacco use at every healthcare encounter, and those who smoke should be strongly encouraged to stop smoking and offered smoking cessation assistance, including pharmacotherapy and behavioral interventions.
- Because alcohol increases risk of certain cancers, moderation in alcohol consumption should be recommended.
- Vaccinations against HPV and HBV are essential to reduce the risk of cervical, anal, head, and neck cancers and hepatocellular carcinoma.

Screening and Detection

- Providers should be vigilant for cancer, especially human oncogenic viral-based cancers, associated with Epstein-Barr virus (EBV), HPV, HCV, and HBV, even if no specific screening is recommended.
- Screening for prostate, breast, lung, and colon cancer should be conducted according to USPSTF and American Cancer Society guidelines for the general population.
- Biennial mammogram screening is recommended for persons aged 40–74 years, per USPSTF guidelines.
- A digital anal rectal exam should be performed annually, whether or not high-resolution anoscopy (HRA) is available.
- Transgender women, cisgender men aged >35 years who have sex with cisgender men, and all other people with HIV aged >45 years should be screened with an anal Papanicolaou (Pap) test if there is access to or ability to refer for HRA (preferred) and treatment. The IDSA recommends HPV testing with cytology only and not just HPV testing alone.
  - For low-grade squamous intraepithelial lesions or worse, the patient should be referred for HRA and HPV testing if aged <45 years. Patients aged at least 45 years should be referred for HRA and HPV testing.
  - All high-grade squamous intraepithelial lesions (HSILs) should be treated, ideally with hyfrecation, and monitored routinely among people with HIV and aged >35 years.
  - All patients with anal cancers should be referred to surgical oncology for treatment.
- Persons with HIV aged between 21 and 29 years should have a cervical Pap test annually. If the results of 3 consecutive cervical Pap tests are normal, follow-up Pap screening should be in 3 years.
  - Abnormal Pap test results require either follow-up colposcopy by a qualified practitioner or repeat Pap test in 6–12 months.
  - For persons aged ≥30 years, cervical Pap tests should be done annually. If the results of 3 consecutive Pap tests without an HPV test are normal, a follow-up Pap should be performed in 3 years. If the Pap test is done with HPV testing and both the cytology and HPV testing are negative, follow-up cervical cancer screening can be done in 3 years after a single Pap smear.
  - Unlike for people without HIV, there is no age limit for Pap screening.
  - If HPV testing reveals HPV16 or HPV16/18, referral for colposcopy is recommended.
- Providers should follow USPSTF screening recommendations for prostate cancer.
  - Shared decision-making for prostate-specific antigen (PSA) testing is recommended for patients aged 50–69 years with at least a 10-year life expectancy.
  - PSA-based prostate cancer screening should be considered for persons of Black or African descent, people with prostates aged 45–49 years with at least a 10-year life expectancy, and persons who have at least 1 first-degree relative with prostate cancer.
- Screening for hepatocellular carcinoma every 6 months by ultrasound with or without alpha-fetoprotein is recommended for those with cirrhosis from any cause, those with chronic hepatitis B, and those with a history of chronic hepatitis C (treated or untreated) and stage F3 or F4 fibrosis.

Special Populations

- After vaginoplasty, patients should be reminded that screening for conditions related to remaining organs, such as prostate cancer, is still necessary.
- Cancer screening for transgender and gender-diverse persons should be conducted based on guidelines for the organs and tissues present in the individual.
- Among transgender people with prostates, PSA is unreliable for those on androgen blockers and those who have undergone orchiectomy. For those with a neovagina, a neovaginal and rectal exam should be used to examine the prostate.

Evidence Summary

Acquired immunodeficiency, as encountered among people with HIV, is associated with an increased risk for cancer [203]. As such, interventions that may prevent cancer are essential to HIV care. Healthcare systems should maintain a record of patients' current smoking status. All clinicians should advise patients to stop smoking and document this message at least yearly in the health record. Pharmacotherapy such as varenicline should be offered, as well as referrals for behavioral

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

interventions to assist with smoking cessation [146, 150, 204]. The CMS, American Cancer Society, and USPSTF recommend that adults aged between 50 and 80 years with a ≥ 20 pack-year smoking history and who currently smoke or have quit within the past 15 years receive screening noncontrast low-dose computed tomography (LDCT) scan of the chest to detect lung cancer [205]. Persons with HIV may receive the same mortality benefit from LDCT screening as those not living with HIV if the CD4 count is >500 cells/μL and the patient is ART-adherent [206].

Heavy alcohol use can negatively impact most cancer treatments and may put people at greater risk for esophageal, stomach, and liver cancers [207]. As such, reduced alcohol use is advised. Further, vaccination against HBV and HPV is also strongly recommended to prevent liver cancer and HPV-associated cancers, including anal, cervical, and head and neck cancers. Although persons with HIV have increased rates of certain cancers, recommendations for screening (prostate, breast, colon, lung) are not different from those for the general population. Because people with HIV are at increased risk of both primary and additional cancers, screening for cancer is needed, and enhanced secondary cancer prevention is essential [196].

While screening for most cancers in adults with HIV is not different from that of the general population, including breast cancer screening, providers who treat adults with HIV should have high suspicion for cancers, even if no regular screening is recommended. Providers should be especially vigilant for human oncogenic virally based cancers, including cancers that are due to EBV, HPV, HBV, and HCV [203]. Higher CD4 count (≥350 cells/μL) and maximal viral suppression are associated with lower 5-year mortality among patients with HIV and any cancer diagnosis. Maximal viral suppression should be encouraged, especially if people with HIV and cancer are undergoing chemotherapy or radiation therapy [200]. Genital, oral, cervical, and anal warts should be treated to prevent development of cancer [208].

Screening for hepatocellular carcinoma every 6 months by ultrasound with or without alpha-fetoprotein is recommended for those with cirrhosis from any cause [209]. This recommendation applies to people with HIV and chronic HBV and those with treated or untreated HCV and fibrosis stage F3 or F4. Breast cancer is the second leading cause of cancer-related deaths in women in the United States after lung cancer [210]. It does not appear to be increased in prevalence among people with HIV, although unusual clinical presentations and rapid progression have been reported, suggesting that breast cancer may behave more aggressively in this setting (bilateral disease, poorly differentiated carcinoma, and early metastasis) [210]. At present, screening mammography in persons with HIV should follow USPSTF and American Cancer Society guidelines for the general population, which are not always concordant [211, 212].

Anal cancer incidence (as well as oral cancers that are of HPV origin) is greatly elevated among people with HIV, especially among cisgender men who have sex with cisgender men, older people with HIV, people with CD4 count <200 cells/μL, and African Americans [208, 213]. There are national screening guidelines for the use of anal Pap tests in healthcare maintenance, especially among people with HIV [214]. For all people with HIV who have a prostate, a digital rectal exam is recommended to detect masses, blood, or prostate size and smoothness. Data published in 2022 demonstrate the benefit of anal cancer screening and treatment among cisgender men with HIV aged >35 years who have sex with cisgender men and all other people with HIV aged >45 years if there is access to or ability to refer to HRA (preferred) and treatment. If an anal Pap test or HRA is done, all HSILs should be treated, preferably using hyfrecation, and monitored regularly for clearance or recurrence. The exact timing of follow-up monitoring is still undetermined [215, 216]. Additional data are needed to determine whether persons with a history of receptive anal intercourse and all persons with genital warts should have periodic anal Pap tests if access to appropriate referral for follow-up, including HRA, is available [217]. If anal cancer is diagnosed, referral should be made to oncology or surgical oncology for appropriate treatment [208]. Data are needed to generate recommendations for anal cancer screening and prevention in cisgender women.

Prostate cancer screening that follows USPSTF guidelines is generally recommended. There is increasing evidence, however, that prostate cancers among people with prostates aged 50–69 years who have a 10-year life expectancy should have shared decision-making about PSA testing. Among Black adults with a prostate, the lower age limit for PSA screening is 45 years. PSA screening is not recommended at this time for adults with a prostate aged ≥70 years [218–220].

For persons aged between 21 and 29 years, cervical cancer screening should be performed within 1 year of sexual debut but not later than age 21 years or at the diagnosis of HIV. If the initial Pap test is negative, some experts recommend that a repeat Pap test be performed within 6–12 months. If the results of 3 consecutive Pap tests are normal, a follow-up Pap test should be performed at 3 years. The use of HPV co-testing in this age group is not recommended. For persons aged >30 years, cervical cancer screening should commence at diagnosis and be continued throughout a patient's lifetime and not stopped at age 65 years as recommended for the general population. In this age group, Pap testing can be done with cytology alone or with the addition of HPV co-testing. Some experts recommend that a repeat Pap test be done 6 months after the initial Pap test. If the results of 3 consecutive Pap tests are normal, a follow-up Pap test should be done in 3 years. If testing is done with Pap and HPV co-testing and if the results of both tests are normal, the next screening can occur in 3 years [221, 222].

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

Special considerations are needed for transgender adults with HIV in regard to cancer. While likely multifactorial, transgender persons have a greater risk of being diagnosed with cancer later than the general population, lower odds of receiving appropriate oncologic treatment, and worse odds of survival than other people with cancer. Thus, greater vigilance is needed for transgender individuals at risk of cancer [223]. Further, even after vaginoplasty, there needs to be lifelong follow-up for prostate cancer and other cancers found among people born with male sex organs that are not removed. It also should be noted that among transgender individuals with prostates, PSA testing may be unreliable if they are taking androgen blockers or are status post-orchiectomy. For those with a neovagina, a neovaginal exam of the prostate should be performed [224].

SECTION 6: STI SCREENING, TREATMENT, AND PREVENTION

In 2022, the United States experienced extremely high rates of chlamydia, gonorrhea, and syphilis, with continuing and striking disparities by race/ethnicity, gender, sexual orientation, age, and geography. People with HIV accounted for 36.4% of cases of primary and secondary syphilis among gay and bisexual men [225]. Trichomonas is common among persons who have vaginal sex, although most cases are asymptomatic. Beginning in 2022, global outbreaks of mpox disproportionately affected people with HIV and have been particularly frequent and more severe among those with advanced immune suppression [226]. Evidence is evolving to support prevention of some STIs using doxyPEP, although the risk of antimicrobial resistance is an ongoing concern. It is essential that STI screening, treatment, and prevention efforts be centered on equity-based strategies.

Screening and Treatment for STIs

Chlamydia, Gonorrhea, Syphilis, and Trichomonas

Recommendations

- Services for STI (including mpox) screening, treatment, and prevention should be convenient and affordable, delivered in a stigma-free environment, and made accessible to populations with the highest prevalence of infection using equity-based strategies.
- All patients should be screened for gonorrhea, chlamydia, and syphilis upon entry into care. Persons who have receptive vaginal sex should be screened for trichomonas using the vaginal or cervical nucleic acid amplification test (NAAT). Screening for gonorrhea and chlamydia should be by NAAT at all sites of sexual contact (oral, anal, urethral/urine, vaginal/neovaginal). Done correctly, self-collected NAAT swabs may be used to enhance acceptability.
- In asymptomatic sexually active persons, screening for gonorrhea, chlamydia, and syphilis should be repeated at least annually. Persons who have receptive vaginal sex should be screened for trichomonas at least annually.
- In persons with multiple or anonymous sex partners, screening should be conducted every 3–6 months depending on sexual activities, presence of recent STIs in the patient or their partner(s), and local community STI prevalence. Those found to have gonorrhea, chlamydia, syphilis, or trichomonas on initial screening should be treated and rescreened in 3 months because of high reinfection rates.
- For those diagnosed with pharyngeal gonorrhea, a test of cure should be performed at 7–14 days with an NAAT or culture, although testing at 7 days is associated with a higher rate of false-positive results. If an NAAT obtained for test of cure is positive, a culture should be obtained, and positive cultures should undergo antimicrobial susceptibility testing.
- For gonorrhea that is unresponsive to treatment, regardless of site, culture should be obtained, and positive cultures should undergo antimicrobial susceptibility testing.
- All persons with syphilis should be screened for ocular and otic involvement as well as neurologic symptoms and signs. However, a lumbar puncture is not indicated in individuals with isolated ocular or otic symptoms. A lumbar puncture should be performed in those with neurologic findings.
- Retreatment after treatment failure should be implemented according to CDC STI guidelines. Following a diagnosis of syphilis, nontreponemal titers should be followed and a lumbar puncture performed if titers increase by 4-fold (sustained by at least 2 weeks) without evidence of reinfection after treatment. Cerebrospinal fluid (CSF) examination and retreatment may be considered if titers do not decrease 4-fold by 24 months.
- Pregnant individuals should be screened for chlamydia, gonorrhea, and syphilis at the first prenatal visit, 28 weeks, and also, for syphilis, at delivery. Screening for trichomonas should be offered at the first prenatal visit. Screening should be more frequent depending on past STI incidence in the patient or partner(s) and community STI prevalence. Partners of pregnant persons with STIs should be offered screening and treatment.
- Because of increasing antibiotic resistance, especially with gonorrhea, CDC STI treatment guidelines should be consulted frequently, and treatment should follow these recommendations.
- In cisgender women, trichomonas should be treated using metronidazole 500 mg twice daily for 7 days, while a single 2-g dose may be used in cisgender men.

Evidence Summary

Between 2018 and 2022, gonorrhea diagnoses increased by 11% overall but were lower than in 2021, with 40% occurring among

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

gay, bisexual, and other cisgender men who have sex with men. Syphilis diagnoses increased a striking 78.9%; this includes 3755 cases of congenital syphilis, a 183% increase since 2018. Cases of chlamydia were level compared with 2018 but at a high incidence of 1 649 716 cases. Chlamydia, gonorrhea, and syphilis continued to disproportionately affect racial and ethnic minorities, with 31% of these cases occurring in non-Hispanic African Americans and half of diagnosed STIs occurring among persons aged 15–24 years [225].

Screening

Nucleic acid amplification testing is the most sensitive screening method for chlamydia and gonorrhea and should be obtained from all sites of sexual exposure. For persons with a vagina/neovagina, swabs from that area are more sensitive than urine, while urine is acceptable for persons with a penis. Self-collected vaginal/neovaginal and anal swabs are as sensitive as those collected by care providers and may be more acceptable and adaptable to at-home testing. The COVID-19 pandemic accelerated interest in home-testing for STIs, sometimes paired with telemedicine or online ordering of test kits, particularly for gonorrhea and chlamydia [227]. In a pilot study in Washington, DC, in which self-tests for HIV, chlamydia, and gonorrhea were sent to users by mail, positivity rates for chlamydia and gonorrhea (especially in extragenital areas) were high in returned samples [228]. Clinicians should be familiar with CDC's updated laboratory testing guidelines for syphilis [229]. Diagnosis of syphilis generally relies on serologic testing that consists of a nontreponemal test (with positives expressed in titers) and a treponemal test. However, self-testing has relied on treponemal antibody testing, which may be falsely negative in early infection or positive long after an initial infection has been treated. Clinicians should be familiar with considerations regarding point-of-care testing for syphilis from the National Syphilis and Congenital Syphilis Syndemic Federal Task Force [230]. The development of nontreponemal tests suitable for self-testing remains a research gap of high interest.

All persons with syphilis should be screened for ocular and otic syphilis and for neurologic signs and symptoms. Persons with syphilis and ocular or otic symptoms should receive treatment immediately to preserve vision and hearing. However, a lumbar puncture is not required unless neurologic signs or symptoms are present. A lumbar puncture is indicated in those with neurologic findings and those whose nontreponemal titer has increased 4-fold (sustained for more than 2 weeks) without evidence of reinfection. Persons whose nontreponemal titers have not decreased 4-fold by 24 months should be examined clinically; a CSF examination and retreatment may be considered. CDC STI guidelines should be consulted when treatment fails [213]. Pregnant persons are at high risk for STIs and should be screened for gonorrhea, chlamydia, syphilis, and trichomonas at the first prenatal visit, 28 weeks, and also at delivery for syphilis [120, 225]. Congenital syphilis is preventable and can be eliminated by diligent screening and treatment during pregnancy, including at delivery. Note that treponemal antibody tests (such as fluorescent treponemal antibody absorption (FTA-ABS) or microhemagglutination assay for *Treponema pallidum* (MHA-TP)) often remain positive for life despite effective treatment [231].

Trichomoniasis is the most common STI among those who have vaginal sex, with disproportionately high rates among Blacks and cisgender women with HIV [231]. It is associated with increased HIV shedding in those without viral suppression, with pelvic inflammatory disease, and with adverse pregnancy outcomes. Screening should be conducted using an NAAT or an FDA-approved rapid test and repeated in 3 months for those who test positive, as reinfection rates are high. During pregnancy, screening should occur at the first prenatal visit and during the third trimester, at minimum, with treatment delivered as needed.

Treatment

Antibiotic resistance is of high concern, especially for gonorrhea, although most strains have remained sensitive to ceftriaxone to date. In 2020, CDC recommended gonorrhea treatment with a single dose of intramuscular ceftriaxone 500 mg (or 1000 mg for those who weigh ≥150 kg) without concurrent azithromycin [232]. Test of cure with an NAAT or culture is recommended for pharyngeal gonorrhea at 7–14 days after treatment, although testing at 7 days is associated with a higher rate of false-positive results. Culture should be obtained for all gonorrhea treatment failures so that antimicrobial susceptibility testing can be performed [231]. The preferred treatment for early, secondary, latent, and late-latent syphilis continues to be benzathine penicillin G. However, doxycycline can be used for 14–28 days, depending on the stage of the disease in the event of true penicillin allergy or penicillin shortage. If neurosyphilis is present or the patient is pregnant, intravenous aqueous crystalline penicillin G should be used, even if desensitization is required. The high price of commercially obtained benzathine penicillin and intermittent shortages of this drug are barriers to ending the syphilis epidemic, particularly among pregnant women for whom no other viable regimens are recommended. In cisgender women with HIV, treatment of trichomonas using metronidazole 500 mg twice daily for 7 days was more effective than a single 2-g dose of metronidazole; cisgender men can be treated using the single-dose regimen [231]. In most cases, chlamydia is treated with doxycycline 100 mg twice daily for 7 days. However, rectal chlamydia associated with inguinal lymphadenopathy or symptoms of proctocolitis (such as bloody discharge, tenesmus, ulcers) raises suspicion of lymphogranuloma venereum (LGV). Although LGV and non-LGV chlamydia can be distinguished by molecular testing, LGV is usually diagnosed clinically and treated with 21 days of doxycycline 100 mg twice daily. Close monitoring of and referral

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

to the CDC STI treatment guidelines are essential, as susceptibilities and recommendations change over time [231].

Mycoplasma Genitalium

Recommendations

- Persons with recurrent urethritis or cervicitis should be screened with an NAAT for *Mycoplasma genitalium* (Mgen). Screening should be considered for those with pelvic inflammatory disease.
- Screening for Mgen in asymptomatic persons or screening of extragenital sites is not recommended.

Evidence Summary

Mgen is a cause of nongonococcal/nonchlamydial penile urethritis and can cause persistent or recurrent urethritis. It has been associated with cervicitis, endometritis, and pelvic inflammatory disease in cross-sectional studies. Case-control and cross-sectional studies suggest that urogenital Mgen is more common among people with HIV and may be associated with HIV shedding among people not taking ART [231]. Resistance to azithromycin is widespread, and fluoroquinolone resistance is increasing. Multidrug resistance to azithromycin, fluoroquinolones, and doxycycline has been identified [233]. Resistance testing for refractory or recurrent infections should be performed where available, but molecular tests are not yet widely available outside of research settings. There are insufficient data on clinical outcomes associated with asymptomatic Mgen, and antibiotic use in this setting could increase the prevalence of resistant organisms. Therefore, screening of asymptomatic persons for Mgen is not recommended. The efficacy of doxyPEP for prevention of symptomatic Mgen is an area of active investigation, as is the risk of Mgen resistance in this setting [234].

Mpox

Screening and Treatment

Recommendations

- Persons exposed to mpox through sexual activity or close contact should be advised to monitor for symptoms for 21 days, consider vaccination if asymptomatic and within 14 days of exposure, and seek medical care immediately if symptoms develop.
- Persons with cutaneous, oropharyngeal, or anorectal lesions suspected to be due to mpox should receive polymerase chain reaction (PCR) testing of lesions for orthopoxvirus (mpox) and should isolate as recommended in the CDC guidelines.
- Persons with suspected mpox should be offered screening for HIV (if not known to have HIV) and STIs, especially chlamydia, gonorrhea, and syphilis.
- ART initiation should not be delayed when HIV is diagnosed concurrent with mpox, and therapy should be adjusted as soon as possible for those on ART with virologic failure in the setting of mpox.
- Treatment with tecovirimat should be offered to people with HIV whose virus is not suppressed or whose CD4 count is <350 cells/μL, those who are pregnant, and those who have other immunocompromising conditions; severe disease; oropharyngeal, anorectal, genital lesions; bacterial superinfection, especially requiring debridement; or other conditions that put them at high risk of poor outcomes, as designated by the CDC.

Evidence Summary

Compared with previous mpox outbreaks, the global outbreak that began in 2022 occurred predominantly among cisgender men and transgender women who have sex with cisgender men and has been associated with more mucosal and anorectal disease and delayed prodromal symptoms compared with previous outbreaks in endemic countries. A global systematic review of 52 studies that included 6345 persons with mpox found that 40% of persons also had HIV [235]. A global series of mpox among 382 people with HIV and CD4 count <350 cells/μL found high prevalence of serious outcomes, including necrotizing skin lesions, lung involvement, secondary infections, and sepsis, particularly in those with CD4 count <100 cells/μL. In the group as a whole, 28% were hospitalized and 7% died. Among those who died, all had CD4 count <200 cells/μL, and mortality was especially high (57%) among 21 persons who developed mpox immune-related inflammatory syndrome (IRIS) after initiation or reinitiation of ART. In this series, only 16% received tecovirimat (TPOXX) [226]. Initiation of ART, however, should not be delayed because of concern about IRIS, as viral suppression can be lifesaving in this population. As of March 2023, the CDC reported that 94% of deaths associated with mpox in the United States were among people with HIV. In those with CD4 count data available, 96% of deaths were among people with CD4 counts <50 cells/μL. Among those with treatment data available, only 9.1% were receiving ART prior to their mpox diagnosis. Of all mpox deaths, 90% occurred among Black men [236]. An equity-based approach to mpox screening, treatment, and prevention is essential, prioritizing people with HIV, especially those with low CD4 counts or uncontrolled virus and racial and ethnic groups that bear a disproportionate burden of severe mpox.

PCR testing of mpox lesions is associated with the highest diagnostic yield [237], although virus can often be recovered from the anorectal and oropharyngeal regions. Other STIs often occur concurrently with mpox, and STI (and HIV if status is unknown) screening is imperative in persons who present with suspicion of mpox. People with suspected or confirmed mpox who are at risk of serious outcomes should receive TPOXX under an expanded access investigational new drug submission administered by the CDC [238]. This includes people with unsuppressed virus or CD4 count <350 cells/μL; other immunocompromising conditions; severe disease;

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

oropharyngeal, anorectal, or genital lesions; or bacterial superinfection, especially requiring debridement. People without severe disease may consider enrolling remotely in the Study of Tecovirimat for Human Mpox Virus (STOMP) trial, a National Institutes of Health–sponsored study to determine the effectiveness of TPOXX [239].

Although the 2022 mpox outbreak peaked in the summer of 2022 and was curtailed by vaccination, education, and behavior change among persons at highest likelihood of acquisition, clusters of resurgence continued to occur in 2023 and increased in early 2024 [188, 240]. A health alert from the CDC in December 2023 notified health professionals of the human-to-human transmission of clade I mpox within the Democratic Republic of Congo (DRC), with concern for international spread. Mpox infections in the United States have been with the clade II virus, while clade I is associated with increased transmissibility and more severe outcomes than with clade II. Clinicians should be aware of the possibility of clade I infection in persons returning from the DRC and other affected nations who develop symptoms within 21 days of travel. Both Jynneos vaccination and TPOXX treatment are thought to be effective against the clade I virus [241]. Vaccination efforts are of ongoing importance, including ensuring that both doses of vaccine are received. As of November 2023, only 61% of people who received an initial MVA-BN smallpox vaccine (Jynneos) received the full series [242]. A global case series of 37 persons with mpox reinfection or mpox that occurred after adequate vaccination found that cases were mild, with few lesions and little mucosal involvement, no deaths, and only 1 hospitalization in spite of only 2 individuals receiving TPOXX [187]. Therefore, while a 2-dose vaccination series may not prevent infection, it likely will prevent severe disease (see Section 4: Immunizations).

Prevention of STIs

Recommendations

- Individuals with recurrent STIs and ongoing sexual activities that place them at high likelihood of STI acquisition should receive tailored HIV and STI prevention messages that are appropriate to the individual's sexual health goals. If available, persons with recurrent STIs may benefit from counseling or more structured programs that offer interventions to reduce acquisition.
- Clinicians should discuss the potential benefits and harms of doxyPEP with individuals who may benefit from it. DoxyPEP should be discussed with and offered to cisgender gay, bisexual, and other men who have sex with cisgender men; transgender women; and people with HIV who have had syphilis, chlamydia, or gonorrhea in the last 12 months or who anticipate engaging in sexual activities associated with the increased likelihood of acquiring an STI. The dose of doxycycline is 200 mg as a single dose (maximum 200 mg in 24 hours), ideally taken as soon as possible after sex but no later than 72 hours afterward.
- At present, data are inadequate to support the efficacy of doxyPEP in cisgender women, cisgender heterosexual men, transgender men, and gender-diverse persons assigned female at birth. Shared decision-making should be used in these populations.
- Persons who actively use doxyPEP should be screened for syphilis, chlamydia, and gonorrhea at 3- to 6-month intervals, depending on sexual practices.

Evidence Summary

Persons with frequent recurrent STIs may benefit from counseling and other structured interventions to decrease STI acquisition. Condoms can be effective in decreasing STI acquisition and should be offered. Some individuals with recurrent STIs may benefit from prevention of bacterial STIs using doxyPEP, defined as a single dose of doxycycline 200 mg taken as soon as possible after sex but no later than 72 hours afterward. The maximum dose of doxycycline is 200 mg within 24 hours.

Preliminary data that support the activity of doxycycline in preventing chlamydia and syphilis came from a substudy of the French National Agency for Reserch on AIDS (ANRS) Ipergay trial of intermittent HIV PrEP, in which participants took doxycycline 200 mg within 72 hours of sexual exposure. Doxycycline use was associated with a 70% decrease in chlamydia and syphilis but no decrease in gonorrhea [234]. Two randomized trials subsequently demonstrated the efficacy of doxyPEP in preventing chlamydia, gonorrhea, and syphilis among cisgender gay and bisexual men and transgender women. The DoxyPEP trial, a randomized, open-label trial in Seattle, Washington, and San Francisco, California, included 630 cisgender gay and bisexual men and transgender women. In May 2022, the study was stopped by its data and safety monitoring board after a planned interim analysis showed statistically significant reductions in syphilis (relative risk [RR], 0.23; 95% confidence interval [CI], .04–1.29), chlamydia (RR, 0.26; 95% CI, .12–.57), and gonorrhea (RR, 0.43; 95% CI, .26–.71) and no safety concerns, including among people with HIV [243]. In the PrEP cohort, the RRs were 0.45 (95% CI, .32–.65) for gonorrhea, 0.12 (95% CI, .05–.25) for chlamydia, and 0.13 (95% CI, .03–.59) for syphilis. In the cohort of people with HIV, the RRs were 0.43 (95% CI, .26–.71) for gonorrhea, 0.26 (95% CI, .12–.57) for chlamydia, and 0.23 (95% CI, .04–1.29) for syphilis [244]. The limited antimicrobial resistance data from this study are inconclusive, although 6 of 20 incident gonorrhea isolates in the doxycycline arm displayed tetracycline resistance [245]. ANRS 174 (DOXYVAC) was a French randomized, open-label, factorial-design trial that evaluated doxyPEP and meningococcal B vaccine (4CMenB) in gay and bisexual men on PrEP. The study was stopped by its data

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

and safety monitoring board after an unplanned interim analysis found statistically significant reductions in first cases of syphilis, chlamydia, gonorrhea, and Mgen in those on doxyPEP compared with no doxyPEP [246]. Although the interim analysis suggested that 4CMenB vaccination was protective against gonorrhea, this finding was not confirmed after missing study data were included. The final analysis confirmed statistically significant preventative effects of doxyPEP against first episodes of chlamydia (adjusted hazard ratio [aHR], 0.14; 95% CI, .09–.23; $P < .0001$), syphilis (aHR, 0.21; 95% CI, .11–.41; $P < .001$), and gonorrhea (aHR, 0.67; 95% CI, .52–.87; $P = .003$), although the effect against gonorrhea was modest and less than in the interim analysis. The effect of 4CMenB vaccination on incident gonorrhea was not statistically significant. Consistent with local epidemiology, tetracycline resistance was seen in all available gonorrhea samples from baseline and follow-up, and high-level tetracycline resistance (minimum inhibitory concentration > 8 mg/L) was more common in incident samples from the doxyPEP arm than the control arm (36% vs 13%; $P < .043$). No chlamydia resistance was detected, and there was no statistically significant difference between the arms in detection of pharyngeal methicillin-resistant *Staphylococcus aureus* or rectal extended-spectrum β-lactamase–producing *Escherichia coli* [247]. A randomized, open-label trial compared doxyPEP to standard of care among 449 nonpregnant cisgender Kenyan women aged 18–30 years who were taking HIV PrEP. The study (dPEP Kenya) showed no difference between the doxyPEP arm and the standard-of-care arm in the incidence of chlamydia or gonorrhea. In a subset of participants in the doxyPEP arm, doxycycline was present in only 29% of hair samples. Low uptake of the intervention limited the ability to understand the true efficacy of doxycycline for bacterial STI prevention in cisgender women under more ideal adherence conditions. In addition, high-level tetracycline resistance, previously described in Kenya, was seen in 100% of gonorrhea samples identified at baseline and at study visits in both study arms [248]. DoxyPEP, therefore, is recommended for cisgender gay, bisexual, and other men who have sex with cisgender men and for transgender women who have a history of at least 1 diagnosis of syphilis, chlamydia, or gonorrhea within the last 12 months or who anticipate sexual activities associated with increased likelihood of STI acquisition. No recommendations can be made at this time for the use of doxyPEP in cisgender women, cisgender heterosexual men, transgender men, and other gender-diverse persons; additional research is needed. Use of doxyPEP in these populations should be based on shared decision-making.

The main concern for doxyPEP implementation is the risk of antimicrobial resistance, particularly for gonorrhea, but also for the microbiome, including common organisms such as *Staphylococcus*. Additional data are needed to fully assess the public health impact of doxyPEP. Until more data are available, it will be important to judiciously target its use. Modeling based on a cohort at Fenway Clinic (Boston, Massachusetts) found that targeting doxyPEP to cisgender gay and bisexual men, transgender women, and nonbinary persons assigned male at birth who had been diagnosed with a bacterial STI within the last 12 months or with repeated STIs was the most efficient use of doxyPEP. Providing doxyPEP to all PrEP users or people with HIV prevented more STIs but was less efficient and exposed more people to doxycycline (higher number needed to treat to prevent 1 STI) [249]. As data evolve, the CDC recommendations for use of doxyPEP will be updated [250]. People who receive doxyPEP should continue to receive routine screening for asymptomatic STIs and ongoing evaluation of the need for continuing doxyPEP.

SECTION 7: METABOLIC AND OTHER NONCOMMUNICABLE COMORBIDITIES ASSOCIATED WITH HIV, ANTIRETROVIRAL THERAPY, AND AGING

Now that approximately 50% of the global population of people with HIV is aged >50 years, concern has heightened about increased rates of common comorbidities associated with age [251, 252], including long-term cardiovascular morbidity, especially in those with traditional risk factors such as dyslipidemia, glucose intolerance or diabetes mellitus, hypertension, and smoking. The benefits of ART used in accordance with published guidelines outweigh the risks of cardiovascular disease and other comorbidities associated with long-term exposure [253]. Multiple guidelines are available to assist providers in the identification and management of lipid abnormalities, diabetes mellitus, excess weight, liver steatosis, and other comorbidities [254–258]. People with HIV also are at higher risk for weight gain, loss of BMD, hypogonadism, frailty, and neurocognitive disorders.

Recommendations

- Fasting (optimal) or random lipid levels should be obtained prior to and within 1–3 months after starting ART. Abnormal random lipid levels should be repeated when fasting. Patients with abnormal lipid levels should be managed according to the National Lipid Association Part 2 and 2018 Multispecialty Blood Cholesterol Guidelines. All patients should be assessed for 10-year atherosclerotic cardiovascular disease (ASCVD) risk. Those at high risk should be further evaluated and managed according to established guidelines that recognize HIV risk-enhancing factors.
- Statin therapy is recommended for primary prevention of cardiovascular disease in people with HIV aged 40–75 years, regardless of lipid levels and ASCVD risk. The recommendation is strongest for those with a 10-year ASCVD risk of 5% or higher. For people with HIV aged <40 years, evidence is

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

insufficient to recommend for or against statin therapy for primary prevention of cardiovascular disease. Decisions in this age group should be individualized, taking into consideration risk-enhancing factors for the general population and for people with HIV.
  - High-intensity statins (atorvastatin 40–80 mg daily or rosuvastatin 20–40 mg daily) are recommended for persons with a 10-year ASCVD risk above 20%.
  - At least moderate-intensity statins (specifically, pitavastatin 4 mg daily, atorvastatin 20 mg daily, and rosuvastatin 10 mg daily) are recommended for persons with HIV and at lower risk.
- Prior to starting ART, random or fasting blood glucose and hemoglobin A1c (HbA1c) should be obtained. If random glucose is abnormal, fasting glucose should be obtained. After initiation of ART, HbA1C is insensitive and may significantly underestimate the risk of diabetes. However, an HbA1C that is >6.5% remains a reliable criterion for diagnosis of diabetes in people with HIV. If HbA1C is <6.5%, fasting plasma glucose is the best screening test for people with HIV receiving ART. Those with a diagnosis of diabetes mellitus should have their HbA1c level monitored at least every 6 months, with an HbA1c goal of <7% in accordance with the American Diabetes Association (ADA) guidelines.
- Weight should be obtained at every visit. In addition, waist circumference (an indirect marker of visceral fat) should be measured annually. Monitoring and counseling on diet, exercise, and alcohol intake should start at the time of ART initiation and be done at every visit.
- Current data do not support switching an ART regimen solely because of weight gain.
- If liver transaminases are increased, workup for nonalcoholic fatty liver disease (NAFLD) should include ultrasound, magnetic resonance imaging (MRI), or CT scan. Presence of steatosis should lead to a fibrosis workup that includes FIB-4, Fibroscan, or MRI elastography, although biopsy remains the standard. Weight reduction is the cornerstone of treatment of NAFLD. Persons with nonalcoholic steatohepatitis (NASH) or fibrosis should be referred to a hepatologist.
- Baseline bone densitometry (DXA) screening for osteoporosis should be performed in post-menopausal cisgender women and men aged ≥50 years. Screening for transgender people should follow national recommendations based on their individualized risk for osteoporosis.
- Testosterone replacement therapy for cisgender men should be prescribed with caution and only in those with symptomatic hypogonadism, given the long-term side effects. See Section 11 for discussion of hormone therapy for transgender men.
- Annual screening for frailty should be considered in people with HIV aged >50 years; the frailty phenotype screen is the most commonly used tool.

Evidence Summary

Lipid Abnormalities and Cardiovascular Risk

HIV infection is associated with dyslipidemia. In the absence of ART, HIV infection results in lower total cholesterol, high-density lipoprotein (HDL-C), and low-density lipoprotein (LDL-C) levels. Initiation of ART, specifically with boosted protease inhibitors (PIs), increases LDL-C and improves HDL-C, but the latter does not normalize to pre-HIV levels [259]. Among nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), TDF has been associated with lipid-lowering effect [260]; however, TDF is less commonly used currently due to its effect on kidney function and bone mineral density. Other NRTIs, such as TAF and abacavir, appear to have a similar and minimal effect on lipids [261].

HIV is a recognized independent atherosclerotic cardiovascular disease (ASCVD) risk enhancer in the 2018 American College of Cardiology/American Heart Association (ACC/AHA) multispecialty cholesterol management guidelines [255]. At this time, there are no validated cardiovascular risk assessment tools for use in people with HIV, and the default is to use the pooled cohort equations from the 2013 ACC/AHA guidelines and to adjust for the presence of HIV risk enhancers, understanding the limitations of such [255]. The frequency of follow-up testing and response to therapy should be based on the current National Lipid Association Recommendations for Patient-Centered Management of Dyslipidemia: Part 2 and the 2018 Multispecialty Blood Cholesterol guidelines [255, 262]. All patients should be assessed for ASCVD risk. Those with elevated risk should be further evaluated and managed according to established guidelines.

Statin drugs are known to exert a multifactorial effect to prevent cardiovascular disease in the general population. The randomized controlled the Stopping Atherosclerosis and Treating Unhealthy Bone With Rosuvastatin in HIV (SATURN)-HIV trial showed that in individuals with HIV and virologic suppression, LDL-C <130 mg/dL, and evidence of heightened inflammation, rosuvastatin decreased carotid intima-media thickness, improved kidney function, and attenuated systemic and vascular inflammation, including decreasing T-cell and monocyte activation [263–267], but worsened insulin resistance [268]. Recently, the Randomized Trial to Prevent Vascular Events in HIV (REPRIEVE) study, a multinational placebo-controlled study that enrolled 7769 participants with HIV aged 40–75 years who had low to intermediate ASCVD risk, found that pitavastatin 4 mg daily reduced the risk of major cardiovascular events by 36%, including for those with LDL-C levels below current guideline thresholds for statin initiation [269, 270]. Overall, the protective effect was seen across demographics, CD4 cell count ranges, and viral load levels. REPRIEVE is a practice-changing study, and statin use is now recommended in people with HIV aged ≥40 years, assuming no known allergy to statins or other contraindications,

Table 7. Effect of Protease Inhibitors and Nonnucleoside Reverse Transcriptase Inhibitors on Statins

Statin	Protease Inhibitors	Nonnucleoside Reverse Transcriptase Inhibitor
Atorvastatin	Use lowest atorvastatin starting dose and titrate, monitor for safety, as risk for myopathy/rhabdomyolysis can be increased with some protease inhibitors Do not coadminister with atazanavir/cobicistat Maximum dose of atorvastatin is 20 mg with darunavir/cobicistat or darunavir + ritonavir	Acceptable with appropriate dosing and monitoring Efavirenz and etravirine decrease atorvastatin's AUC No data for nevirapine; may need higher atorvastatin starting dose Doravirine does not affect levels of atorvastatin
Fluvastatin	Use lowest fluvastatin starting dose and titrate, monitor for safety, as risk for myopathy/rhabdomyolysis can be increased with some protease inhibitors	Acceptable with appropriate dosing and monitoring Etravirine may increase fluvastatin's AUC May need lower fluvastatin starting dose with etravirine No data on doravirine
Lovastatin	Contraindicated (greatly increases lovastatin's AUC)	Acceptable with appropriate dosing and monitoring Decrease in simvastatin AUC, so may need higher lovastatin starting dose No data on doravirine
Pitavastatin	Acceptable with appropriate dosing and monitoring No significant change in pitavastatin's AUC with lopinavir/ritonavir Pitavastatin's mean AUC decreased 26% with darunavir	No data for NNRTIs
Pravastatin	Acceptable with appropriate dosing and monitoring, except with darunavir Decrease in pravastatin's AUC, except with darunavir, which increases pravastatin's AUC by 81%	Acceptable with appropriate dosing and monitoring Efavirenz decreases pravastatin's AUC, but no change with etravirine No data for nevirapine, rilpivirine, doravirine May need higher pravastatin starting dose with efavirenz
Rosuvastatin	Use lowest rosuvastatin starting dose and titrate, monitor for safety, as risk for myopathy/rhabdomyolysis can be increased with some protease inhibitors Maximum dose of rosuvastatin is 10 mg with atazanavir, atazanavir/cobicistat, or atazanavir + ritonavir and 20 mg with darunavir/cobicistat Lopinavir/ritonavir and tipranavir + ritonavir increases rosuvastatin's AUC No dose adjustments with cobicistat; cobicistat increases Cmax 89% and AUC by 38%	Acceptable with appropriate dosing and monitoring No data on doravirine
Simvastatin	Contraindicated (greatly increase simvastatin's AUC)	Acceptable with appropriate dosing and monitoring Efavirenz and etravirine decrease simvastatin's AUC No data for nevirapine, doravirine May need higher simvastatin starting dose

Abbreviations: AUC, area under the curve; NNRTI, nonnucleoside reverse transcriptase inhibitor.

regardless of CVD risk or lipid levels. The strength of the benefit rises as the ACC/AHA pooled cohort equation score predicting 10-year risk of ASCVD events increases, with the number needed to treat to prevent a major event within 5 years decreasing from 130 and above for those with scores below 5% to 53 or lower for scores of 5% and above. Therefore, the recommendation for statin use is stronger for those with a 10-year ASCVD risk of 5% and higher. For those with lower scores, the benefit is still present but less pronounced. To decide on statin use in this population, additional risk factors, as described for the general population as well as risk-enhancing factors for people with HIV, should be considered. High-intensity statin therapy is recommended for those with risk greater than 20%, as for the general population, while at least moderate-intensity statin therapy is now recommended for those with lower risk. Additionally, statins may be considered in people with HIV who are younger than the REPRIEVE population (aged <40 years) with additional risk factors, including those with neonatal or pediatric acquired infection who are now adults with long-standing HIV, a population not included in the risk calculators. It is important to note that a slightly higher risk of diabetes was seen in REPRIEVE with pitavastatin than placebo (6.0% vs 4.7%, respectively), although at this time, it is unclear whether participants who developed incident diabetes in the study had pre-diabetes or were at high risk of diabetes at the time of enrollment in REPRIEVE. Treatment-limiting or grade 3 or higher muscle symptoms were seen in 2.3% of the pitavastatin group and 1.5% of the placebo group. Based on data from REPRIEVE, recommendations regarding statin therapy in people with HIV have been published by the HHS Adult and Adolescent Antiretroviral Guidelines Panel and a multisociety team that includes the ACC, AHA, and HIVMA [271].

Despite the fact that pitavastatin was used in REPRIEVE, it is likely that this preventive effect is generalizable across statins and that other statins can be used. High-intensity statins include atorvastatin 40–80 mg and rosuvastatin 20–40 mg, while moderate-intensity statins include pitavastatin 4 mg, atorvastatin 10–20 mg, and rosuvastatin 10 mg (all taken daily). Caution should be used, however, when prescribing statins with PIs (especially ritonavir), cobicistat, and some nonnucleoside reverse transcriptase inhibitors (NNRTIs) due to

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

potentially serious drug–drug interactions (Table 7). Most PIs and cobicistat inhibit the metabolism of statins, thereby increasing the potential for statin toxicity, with the strongest interactions seen with simvastatin and lovastatin, which are contraindicated with ritonavir or cobicistat. However, pitavastatin and pravastatin are metabolized by glucuronidation, thereby having little effect when coadministered with a boosted PI or cobicistat. However, pravastatin may adversely interact with darunavir, and dose modification may be needed. In addition, atorvastatin and rosuvastatin may be used in patients who take a boosted PI or boosted elvitegravir but should be initiated at low doses and titrated carefully according to tolerability and effect. Efavirenz induces statin metabolism, resulting in lowering of statin levels. Nevirapine, etravirine, and rilpivirine have not been extensively studied. Doravirine does not affect levels of atorvastatin [272]. Cobicistat is expected to have interactions that are similar to those for ritonavir with statins; however, these interactions have not been fully studied. There may be other pathways that affect drug metabolism and lead to unexpected interactions, and it is advisable to refer to the package insert of the ARV or drug–drug interaction tables from the HHS ART guidelines before prescribing lipid-lowering agents.

Glucose Metabolism and Diabetes

Among people with HIV, HbA1c is insensitive, although highly specific for diagnosing diabetes. As such, HbA1c is no longer the preferred method for diagnosing diabetes among persons with HIV [273–276]. The ADA established the diagnostic criteria of diabetes mellitus as a fasting plasma glucose level of ≥126 mg/dL (7.0 mmol/L), a 2-hour plasma glucose level of ≥200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test conducted with a standard loading dose of 75 g, or an HbA1c ≥ 6.5% [273]. However, recognizing the potential underestimation of the risk of diabetes by using HbA1C in HIV, the National Health and Nutrition Examination Survey and others endorse an HbA1C cutoff of ≥5.8% to improve the sensitivity for diagnosis in the population with HIV [274]. Although data are lacking on the effects of integrase inhibitors on HbA1c, some studies, but not all, suggest that NNRTIs, PIs, and the NRTIs zidovudine and abacavir may affect HbA1c and result in misleading results [274, 275, 277]. The ADA 2019 Standards recommend against the use of HbA1c to diagnose diabetes in persons with HIV on ART and states that in cases of HbA1c and fasting glucose discordance, the abnormal laboratory test should be repeated, and the diagnosis of diabetes should be made only if repeat testing is again above the diagnostic cut point [273].

Random or fasting serum glucose and HbA1c should be obtained prior to starting ART. If random blood glucose is abnormal, fasting blood glucose should be obtained. After initiation of ART, only plasma glucose criteria should be used to diagnose diabetes. A random glucose >200 mg/dL should prompt further testing with a fasting blood glucose. Therefore, either a random or fasting glucose should be obtained at entry to care and annually thereafter for screening of diabetes. Patients with diabetes mellitus should have their HbA1c level monitored at least every 6 months, with a HbA1c goal of <7% in accordance with the ADA guidelines. Though controversial, the American College of Physicians recommends less stringent control, with an aim to achieve an HbA1c between 7% and 8% [278]. Given the potential for over- or underestimation of HbA1c in patients on ART, it is prudent to assess the correlation of blood glucose levels with HbA1c values on an individual basis in order to determine the appropriate HbA1c target.

Lifestyle interventions such as weight loss, increased physical activity, and dietary modification remain the cornerstone of diabetes prevention and management. However, if treatment is needed, insulin-sensitizing agents are preferred. Patients should be managed according to the ADA guidelines [273, 279]. No data suggest that switching ARVs is beneficial in patients with impaired glucose tolerance associated with HIV infection itself or traditional risk factors.

Weight and Fat Gain

Weight gain is a well-recognized consequence of ART initiation and is more common in non-White and female individuals [280]. Some regimens, namely integrase inhibitors and TAF, have been associated with larger gains in weight. However, it is presently unclear whether the regimens used as comparators suppress weight gain with ART initiation. For instance, TDF use has been associated with weight suppression in PrEP studies and in HIV treatment initiation studies. Also, when TDF is switched to TAF, an increase in weight of about 1 kg on average is seen in the initial 6–12 months after switch [281, 282]. Similarly, the ADVANCE study showed that efavirenz (EFV) led to smaller gains in weight when compared with dolutegravir, both given with TAF/FTC [283]. A substudy that assessed the genetic mutations that control EFV metabolism revealed that only slow metabolizers (high EFV blood level) had blunted weight gain, whereas fast metabolizers gained an amount of weight that was similar compared with those on dolutegravir [284]. These data suggest that the weight-suppressive effect of EFV may not be desirable and may signal toxic effects. TDF has been associated with mitochondrial dysfunction in subcutaneous adipose tissue, signaling the potential for adipose dysfunction with TDF [285]. As such, the weight-suppressive effect of TDF should not necessarily be viewed as desirable.

The weight gain seen with ART is concerning for patients and providers as studies have linked it to a higher incidence of diabetes [286] and hypertension [287]. There is also evidence of ectopic fat depositions in people with HIV, for example, in the liver and pericardium, which may be detrimental. The HIV provider who is treating a patient with large gains in weight after ART may contemplate switching ART. It is important to know that switches have not been successful at reversing

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

weight gain [288, 289], including switches off of INSTIs, unless the switch is from INSTI to EFV. However, the EFV-linked weight suppressive effect is likely a toxic effect and should not be seen as desirable. A randomized, placebo-controlled switch study in virologically [290] suppressed individuals on BIC/TAF/FTC showed similar weight gain at 48 weeks after switching to islatravir/doravirine compared with continuing on BIC/TAF/FTC [291]. Discontinuation of TAF did not improve weight in the TANGO study, questioning the independent effect of TAF on weight [289]. The TAF-to-TDF switch effect, for the purpose of suppressing weight gain, is modest at best, could lead to adipose tissue dysfunction and mitochondrial toxicity, and thus is not recommended as a strategy to decrease weight [292]. The benefit of the modest effect on weight of TAF-to-TDF switch also needs to be weighed against the bone and renal toxicities of TDF. Switch studies from daily oral BIC/FTC/TAF to injectable cabotegravir/rilpivirine given every 2 months did not lead to a significant change in weight compared with continuation of the oral regimen, further evidence that TAF is not likely a culprit in weight gain [293]. Glucagon-like peptide (GLP)-1 receptor agonists for obesity should be reserved for select situations while awaiting results of ongoing trials among people with HIV.

All patients on ART should be routinely counseled on lifestyle modifications, including alcohol reduction/cessation, increased physical activity, healthier diet with reduction in saturated fat and added sugars, and increase in dietary fiber. Patients with large gains in weight may benefit from some of the new agents recommended for obesity in the general population, such as GLP-1 receptor agonists. Although there are few data on their use in people with HIV, a randomized controlled trial in people with lipohypertrophy (abdominal obesity) showed excellent safety and efficacy with decrease in weight and visceral and trunk fat [294].

Liver Steatosis

More data show that NAFLD is common in HIV, with prevalence ranging from 20% to 63%, even in people with HIV without HCV. Liver steatosis is linked to obesity and happens at lower body mass index (BMI) in the HIV population. NAFLD represents the most common cause of increased transaminases in people with HIV without excess alcohol or infectious hepatitis. NAFLD has been associated with older toxic ART such as didanosine or stavudine but not clearly with newer regimens. NAFLD can progress to NASH, liver cirrhosis, fibrosis, and ultimately cancer. NAFLD is also an independent risk factor for cardiovascular disease, diabetes mellitus, and all-cause mortality [295, 296]. Although NAFLD is known to be associated with obesity, HIV-associated NAFLD occurs at lower BMI than in the general population. Diagnosis of NAFLD may involve histology (liver biopsy) or imaging (ultrasound, CT scan, or MRI). Once NAFLD is identified, further workup should be performed to assess for fibrosis. Although biopsy remains the standard, newer modalities, including Fibroscan and MRI elastography, are increasingly used. In addition, clinicians have used soluble markers to estimate fibrosis, such as FIB-4, with low FIB-4 (<1.3) conferring a low likelihood of advanced fibrosis. Lifestyle modification and weight reduction are the cornerstone of treatment. Pharmacotherapy should be reserved for individuals with NASH, particularly for those with significant fibrosis ≥ F2 or individuals with less severe disease but at high risk of faster disease progression, such as persons with diabetes. Promising investigational therapies for HIV-associated NAFLD include tesamorelin [297] and GLP-1 receptor agonists [298].

Bone Metabolism

Baseline bone densitometry by DEXA should be performed in all post-menopausal cisgender women and men aged ≥50 years, based on expert opinion with limited supporting evidence [299–304]. If DEXA scan reveals osteopenia or osteoporosis, a workup for secondary causes of osteopenia should be performed. The most common secondary causes of osteopenia are vitamin D deficiency, hypogonadism, excess alcohol (>3 drinks/day), smoking, and hyperthyroidism or hyperparathyroidism. The initiation of any ART regimen leads to a decrease in BMD of 2%–6%, and the decrease is more prominent in the first 24–48 weeks of ART. Among all ART, TDF has been shown to lead to a 1%–2% larger decrease in BMD when compared with any other non-TDF regimen, including TAF [305, 306]. When TDF is combined with ritonavir-boosted PI, bone loss is even more accentuated than when combined with unboosted integrase inhibitors [307, 308]. If the DEXA demonstrates osteoporosis or there is a history of fragility fracture, intervention with vitamin D, calcium, and a bisphosphonate or other medical therapy may be warranted. Bisphosphonates appear to be safe and effective in improving BMD [309] and in blunting the initial drop in BMD after ART initiation [310]. It is important to exclude osteomalacia prior to initiating a bisphosphonate, as this could lead to increased fragility and fracture. Common reasons for osteomalacia in this population are tenofovir-induced renal phosphate wasting and vitamin D deficiency, which have been reported in 40%–80% of people with HIV. The spectrum and severity of metabolic complications associated with vitamin D deficiency among adults with HIV remain to be better characterized. Patients with vitamin D deficiency and osteopenia by DEXA should be treated with vitamin D and calcium without bisphosphonates until the vitamin D deficiency has resolved. A follow-up DEXA should be repeated 1 year later to monitor the response to therapy. It is now clear that switching off of TDF to another NRTI or to an NRTI-sparing regimen is effective at increasing BMD and should be considered [311, 312].

Routine screening for vitamin D deficiency in patients with normal or unavailable DEXA is not recommended, given the

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

lack of data among people with HIV. The USPSTF concludes that the evidence on screening for vitamin D deficiency in asymptomatic adults to improve health outcomes is insufficient [313]. However, patients should be counseled about the health benefits of regular exercise, with resistance exercise being especially important to bone building, normal dietary calcium, and vitamin D intake and the harmful risks of cigarette smoking and excessive alcohol consumption.

In people with HIV, avascular necrosis (AVN) was reported to be associated with exposure to tenofovir for longer than 1 year in one study [314]. Other more common causes of AVN include moderate to high alcohol consumption, hyperlipidemia, and corticosteroid use [314, 315]. Routine radiographic monitoring for AVN in asymptomatic persons is not recommended. However, for patients who present with persistent hip pain who have normal standard radiologic studies, MRI is the preferred method of diagnosis, and both sides should be imaged regardless of whether pain is bilateral or not. Most patients with symptomatic AVN will ultimately require surgical intervention, including hip replacement [315, 316].

Hypogonadism

The prevalence of hypogonadism among cisgender men with HIV has been reported to be high prior to the introduction of ART. However, screening for hypogonadism is recommended only for men who have symptoms [317, 318]. In 2014, the FDA released safety alerts that warned of potential increased cardiac risk associated with testosterone replacement products [319–321]. Subsequently, a large systematic review and meta-analysis failed to demonstrate an increased risk of cardiac events in the general population; however, caution remains [322]. Although the Endocrine Society Guidelines [323] recommend short-term testosterone replacement therapy (TRT) for cisgender men with HIV and low testosterone, many patients have remained on TRT long term. It is unclear whether those who were diagnosed with hypogonadism at the time of their HIV diagnosis need to remain on TRT after immune recovery on ART. Since the FDA advisory, the overall percentage of cisgender men who use TRT has declined, but less so among those with HIV [324, 325]. As the population of men with HIV ages, clinicians should balance the benefits against the harms of continuing TRT that may no longer be indicated. TRT may result in testicular atrophy and permanent inability to produce the natural hormone. Men may experience "withdrawal" when TRT is stopped, given the steroidal effects of testosterone as well. Therefore, initial TRT should be prescribed with caution and only in cisgender men with symptomatic hypogonadism, given the long-term side effects.

Neurocognitive Impairment

Neurocognitive impairment is more common in older people with HIV than those not living with HIV [326]. HIV-associated neurocognitive disorder (HAND) encompasses multiple neurocognitive effects of HIV and associated inflammation on the central nervous system, resulting in deficits that range from asymptomatic neurocognitive impairment to dementia [327]. While there are no specific treatments for HAND at this time, clinicians should be aware that some persons with HIV may experience neurocognitive decline that is out of proportion to their age and should provide an appropriate workup when such symptoms present.

Frailty

People with HIV are disproportionately affected by frailty and at a younger age than those without HIV [328]. Prevalence of frailty and prefrailty in people with HIV aged >50 years is about 11% and 47%, respectively [329]. Frailty is a strong predictor of both mortality and incident comorbidity in people with HIV, independent of other risk factors [330]. Annual screening for frailty should be considered in people with HIV aged >50 years. The most commonly used screening tools include the frailty phenotype [331] and the frailty index [332], with the former being simpler and more commonly recommended, although it requires a dynamometer. HIV virologic suppression decreases the risk of frailty [333]. The most effective interventions to prevent and treat frailty are increasing physical activity and structured exercise [334]. Nutritional optimization is effective and increases the efficacy of an exercise intervention [334]. Diagnosing and treating concomitant depression is also paramount. There are no data yet to recommend pharmacologic interventions for HIV frailty.

SECTION 8: SPECIAL CONSIDERATIONS FOR INDIVIDUALS OF CHILDBEARING POTENTIAL AND FOR PREVENTION OF PERINATAL HIV TRANSMISSION

People with HIV who are of childbearing potential are living long, healthy lives, and the need for routine gynecological care has increased. They have the same reproductive health needs and concerns as those not living with HIV. As part of the initial assessment, a comprehensive gynecologic and obstetrical history should be obtained that consists of menstrual history, sexual practices, hormonal therapy history and current use, male or female condom use and consistency of use, previous STIs and other genital tract infections, prior abnormal Pap test results including subsequent evaluation and treatment, pregnancy history, history of gynecologic conditions (including uterine fibroids, endometriosis, and infertility) or surgery (including gender reassignment surgery), and current gynecologic symptoms (including abnormal vaginal discharge, abnormal vaginal bleeding, amenorrhea, and pelvic pain). Recommendations for care during menopause do not differ from those for persons not diagnosed with HIV.

Contraception and Prepregnancy Care

Recommendation

- All persons with HIV who are of childbearing potential should be asked about their plans and desires regarding pregnancy upon initiation of care and routinely thereafter. Clinicians should ensure that informed decisions are made about contraception to prevent unintended pregnancy and offer counseling if pregnancy is desired. Counseling should include considerations for the choices of ART and infant feeding methods.

Evidence Summary

Any encounter with a nonpregnant patient with reproductive potential is an opportunity to counsel about wellness and healthy habits that may improve reproductive and obstetrical outcomes if the patient decides to reproduce [335]. An in-depth discussion about childbearing is indicated if the patient expresses the desire for future pregnancy, is not trying to conceive but is not using appropriate contraception, or expresses uncertainty about reproductive plans. Regardless of the patient's sex, the goal is to ensure that informed decisions are made about contraception with prevention of an unintended pregnancy and to offer counseling if pregnancy is desired. Patients should explicitly be asked to communicate with their provider if their plans change, when they are ready to consider pregnancy, or when they have questions related to reproduction and parenthood. In persons who are at risk for pregnancy (trying to conceive or not using effective and consistent contraception), providers should carefully review all medications, including over-the-counter medications, and avoid drugs with potential reproductive toxicity. The time of greatest risk to the fetus is early in pregnancy, often before the pregnancy has been recognized. Ideally, a prenatal vitamin with folic acid should be prescribed prior to conception. Choice of ART for use during pregnancy and breast/chest feeding is discussed in detail in HHS perinatal guidelines [120].

Individuals who do not wish to become pregnant should be counseled on effective contraception. Combined estrogen–progestin hormonal contraceptives (birth control pill, transdermal patch, and vaginal ring) are one option; however, they may have interactions with several ARVs, resulting in decreased effectiveness or increased risk of adverse effects. Contraceptive implants, injectable contraception (depot medroxyprogesterone acetate), and intrauterine devices are other available options. Spermicides have been associated with an increased risk of HIV acquisition and are not recommended for use with partners who are not diagnosed with HIV [336].

Providers should be prepared to discuss conception among serodifferent couples. The partner with HIV should always be started/continued on ART and achieve/maintain sustained HIV RNA suppression to below the limits of detection prior to beginning efforts to conceive. With durable viral suppression, there is effectively no risk of sexual transmission. For couples that are using condoms and wish to limit their episodes of condomless sex, a discussion about sex during the time of peak fertility is appropriate. Prepregnancy administration of ARV PrEP for the partner not diagnosed with HIV offers an additional means to reduce the risk of sexual transmission [336].

Prevention of Perinatal Transmission

Recommendations

- To prevent perinatal transmission, all pregnant and breast-/chest-feeding persons with HIV should be treated with ART, regardless of their immunologic or virologic status. Therapy should be initiated as early as possible, preferably prior to conception.
- Infants exposed to HIV in utero should be managed according to HHS perinatal guidelines.

Evidence Summary

Perinatal transmission of HIV is preventable if pregnant persons are screened for HIV and, if diagnosed with HIV, receive immediate ART according to HHS perinatal guidelines [120, 337]. If HIV status is unknown, pregnant people should be tested for HIV at the first antenatal visit and again in the third trimester if there is ongoing risk of exposure to HIV. In those who start ART before conception and maintain viral load suppression <50 copies/mL, there is essentially zero risk of perinatal transmission [120, 337].

If an individual in labor presents for delivery without having antenatal HIV testing, an expedited HIV test (preferably fourth-generation HIV antigen/antibody testing) should be performed. If the test is positive, intravenous zidovudine should be initiated immediately without waiting for confirmatory tests [120]. Persons who are pregnant and who have an HIV viral load that is unknown or >1000 copies/mL at or near delivery (within 4 weeks), independent of antepartum ART, should be counseled regarding the potential benefit of cesarean delivery. If the patient consents, a scheduled cesarean delivery at 38 weeks' gestation should be offered to reduce the risk of perinatal transmission [120]. All newborns who were exposed perinatally to HIV should receive postpartum ARV drugs to reduce the risk of perinatal transmission of HIV. Post-exposure prophylaxis in the neonate should be initiated ideally within 6 hours [120]. A newborn's ARV regimen should be determined by maternal HIV transmission risk factors according to the perinatal guidelines. Providers with questions about ARV management of perinatal HIV exposure should consult an expert in pediatric HIV infection or the Perinatal HIV/AIDS National Clinician Consultation Center hotline [338].

Infant Feeding

Recommendations

- In the United States, persons with HIV should receive evidence-based, patient-centered counseling to support shared decision-making about infant feeding.
- Individuals with HIV who are on ART with a sustained undetectable viral load and who choose to breast/chest feed should be supported in their decision.
- Engaging Child Protective Services is not an appropriate response to the choice of infant feeding for individuals with HIV.

Evidence Summary

Counseling about infant feeding should begin prior to conception or as early as possible in pregnancy and should be repeated throughout pregnancy and again after delivery [120]. Choosing a method of feeding for a baby is one of the most important decisions a new parent makes. The decision can be compounded by mixed messages from providers who are uncomfortable talking about infant feeding for people with HIV. With current ART, rates of HIV transmission through breast/chest feeding are low but not zero. Currently, there is no consensus on a universal approach, and diverse strategies are used for HIV RNA monitoring for the breast-/chest-feeding parents, infant HIV testing, and ARV prophylaxis [120, 339]. Individuals with HIV who choose to formula feed should be supported in this decision. Providers should ask about potential barriers to formula feeding and explore ways to address them. Replacement feeding with formula or banked pasteurized donor human milk is recommended to eliminate the risk of HIV transmission through breast/chest feeding when people with HIV are not on ART and/or do not have a suppressed viral load during pregnancy (at a minimum throughout the third trimester), as well as at delivery. Engaging Child Protective Services or similar agencies is not an appropriate response to the infant feeding choices of an individual with HIV.

SECTION 9: SPECIAL CONSIDERATIONS FOR CHILDREN

Recommendations

- A plasma HIV NAAT (HIV RNA or HIV DNA) is equally recommended to diagnose HIV in infants and children aged <18 months with perinatal and post-natal HIV exposure.
- In infants with perinatal and post-natal HIV exposure, the results of a plasma HIV NAAT can be affected by maternal ART or by ARV drugs administered to the infant as prophylaxis or presumptive HIV therapy.
- For children aged 18 to ≤24 months with nonperinatal HIV exposure and for all children aged >24 months, HIV antibody or HIV antigen/antibody tests are recommended for diagnostic testing.
- Infants and children diagnosed with HIV should be started on ART immediately or within days of diagnosis. The urgency of Rapid ART initiation is especially critical for children aged <1 year who carry the highest risk of rapid disease progression and mortality.
- In children with disseminated *Mycobacterium avium* complex disease, *M. tuberculosis* disease, and cryptococcal meningitis, ART initiation may be delayed by 2–8 weeks with treatment for the OI prioritized. Appropriate timing of ART initiation in these cases should be discussed with a pediatric HIV specialist.
- If a child with HIV has not initiated ART, healthcare providers should closely monitor the virologic, immunologic, and clinical status at least every 3–4 months while continuing to educate and work with the family to overcome barriers to treatment.
- Absolute CD4 cell count (or CD4 percentage in children aged <5 years) and HIV RNA levels should be evaluated at the time of diagnosis and should be monitored at least every 3–4 months in infants and children. Close follow-up also allows for timely weight-based ART dose adjustment in infants and young children.
- Childhood vaccinations should be administered according to ACIP schedules for infants and children with HIV.
- Infants and children with HIV should be managed by a specialist with knowledge of the unique therapeutic, pharmacologic, behavioral, psychosocial, and developmental issues associated with pediatric HIV infection.

Evidence Summary

Most pediatric HIV infections are caused by perinatal transmission of the virus from the mother during pregnancy, delivery, or breastfeeding. The racial and ethnic disparities in the HIV epidemic among adults in the United States are, therefore, mirrored in pediatric populations. The rate of acquisition of HIV infection among infants has decreased significantly in the United States, primarily because of effective measures to prevent mother-to-child transmission of HIV. Between 2010 and 2019, annual perinatal HIV diagnosis rates declined from 1.9 to 0.9 per 100 000 live births, and perinatal HIV transmission rates declined from 1.6% to 0.9%. National elimination goals for diagnosis and transmission rate of perinatal HIV were first achieved in 2019. However, perinatal transmission of HIV still occurs, and racial and ethnic disparities persist, requiring ongoing public health investment and efforts [340]. Other routes of HIV transmission in children include feeding blood-tinged premasticated food, contact of nonintact skin with blood-containing body fluid, transfusion of contaminated blood products, and sexual abuse. These scenarios should prompt testing of the child for HIV infection. HIV testing should also

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

be conducted among all children in foster care and those who were adopted domestically (if unknown exposure or at risk for acquiring HIV) and internationally (since perinatal HIV screening is variable in global settings) [341]. Children with HIV are frequently born outside the United States, including adopted children and members of immigrant families. These children may have non-B subtypes of HIV, incomplete medical and treatment histories, and an increased risk of tuberculosis and other infections.

Neonates and infants (including breastfed infants) who are exposed to HIV perinatally or postpartum should be managed according to HHS perinatal and pediatric guidelines [91]. Plasma HIV RNA and HIV DNA NAATs are equally recommended for diagnosis of HIV in infants aged <18 months. However, both tests can be affected by maternal ART through transplacental transfer of ARV drugs from the mother to the fetus or by ARV drugs administered to the infant as prophylaxis or presumptive HIV therapy. Qualitative whole blood HIV proviral DNA PCR assays to detect cell-associated virus are less affected by ARV drugs [120]. For children aged 18 to ≤24 months with nonperinatal HIV exposure and for all children aged >24 months, HIV antibody or HIV antigen/antibody tests are used for diagnostic testing. For suspected acute HIV infection, an additional HIV NAAT may be necessary to diagnose HIV infection.

All infants and children diagnosed with HIV should be started on ART as soon after diagnosis as possible (immediately or within days) using regimens based on pediatric HHS guidelines [91]. Multiple studies have reported that early ART initiation in infants and children preserves immune function and is associated with improved growth and neurodevelopmental outcomes [342–344]. In infants with perinatally acquired infection, early ART initiation may limit the formation of the viral reservoir and control of viral replication before HIV can evolve into diverse and potentially more pathogenic and/or resistant quasi-species, preserve immune function, prevent clinical disease progression, and improve neurodevelopmental outcomes. Early initiation of suppressive ART in infants aged <6 months results in a considerable proportion of infants with HIV who fail to produce their own HIV-specific antibodies. These infants are HIV-seronegative when tested; however, viral reservoirs remain, and viral rebound occurs if ART is stopped [342–344]. It is, therefore, important to educate the caregiver on the importance of continuing consistent ART without treatment interruptions.

Genotypic resistance testing should be performed at the time of diagnosis; however, ART can be initiated before results are available. All infants should receive *Pneumocystis jirovecii* prophylaxis in the first year of life, irrespective of CD4 cell count or percentage [110]. In general, infants with untreated perinatally acquired HIV have higher viral loads than adults, and there are age-specific differences in CD4 cell counts, with infants having higher normal absolute lymphocyte counts than adults. In young children (aged <5 years), CD4 percentages are less variable than absolute counts [345]. Infants and children with undiagnosed HIV are likely to present with unexplained fevers, hepatosplenomegaly, generalized lymphadenopathy, parotitis, persistent oral and diaper candidiasis, recurrent invasive bacterial infections, recurrent diarrhea, failure to thrive, central nervous system diseases, and delays in growth and development [346].

While initiating and managing pediatric ART, it is essential to understand that achieving consistent adherence in children is often challenging. Intensive adherence counseling and follow-up during the first few weeks to months after ART initiation is recommended to support the child and caregiver, including detailed instructions on the administration of ARV drugs and caregiver treatment literacy [91]. After initiation of ART or after a change in ARV regimen, children should be followed up in 1–2 weeks to assess effectiveness, tolerability, and adverse events and to evaluate and support medication adherence. Head circumference should be measured in children aged <3 years and plotted against standard growth curves. Furthermore, developmental assessment is important in infants and children. Laboratory testing for toxicity and viral load response is recommended at 2–4 weeks after treatment initiation or change in ARV regimen. Clinicians and multidisciplinary teams should schedule frequent clinical in-person and/or telemedicine visits to monitor patients closely during the first few months after initiating a new ART regimen. For infants, more frequent clinical visits are required to ensure that growth and development are on schedule, that appropriate adjustments of dosage are made, and that the infant is tolerating ART. CD4 cell count can be monitored less frequently (every 6–12 months) in children who are adherent to therapy, who have sustained virologic suppression and CD4 cell count values that are well above the threshold for OI risk, and who have stable clinical status [91]. Viral load measurement every 3–4 months is recommended to monitor ART adherence.

Caregivers, families, and children with HIV face a wide array of socioeconomic, educational, legal, immigration, and structural challenges that affect adherence and retention in care and require ongoing case management support to achieve and sustain positive HIV disease, health, and developmental outcomes. Disclosure of HIV status to children with perinatally acquired HIV is an emotionally and socially complex process that requires caregiver and child support. Studies suggest that disclosure of perinatal HIV status can increase self-esteem and adherence to ART and improve access to psychosocial support [347–350].

All recommended childhood immunizations should be administered to infants exposed to HIV. If HIV infection is confirmed, immunologic status (CD4 cell count or percentage) should be assessed, and guidelines for the immunizations of

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

the child with HIV should be followed [156, 346]. Children with HIV should be immunized with all age-appropriate inactivated vaccines. Inactivated influenza vaccine should be administered annually according to the most current recommendations. In general, the administration of live vaccines, such as MMR and varicella, is guided by the CD4 cell count or percentage. Rotavirus vaccine, however, should be administered to infants with HIV or exposed to HIV irrespective of CD4 cell count or percentage [346].

In the era of ART, there has been a substantial decrease in frequency of OIs and malignancies in children [346]. Prevention and treatment of OIs in children should be managed according to the HHS pediatric OI guidelines [110]. Leiomyosarcomas and non-Hodgkin B-cell lymphomas of the Burkitt type (including those in the central nervous system) occur more frequently in children with HIV than in immunocompetent children. Kaposi sarcoma, caused by human herpesvirus 8, is rare in children in the United States but has been documented in children with HIV who have emigrated from sub-Saharan African countries.

SECTION 10: SPECIAL CONSIDERATIONS FOR ADOLESCENTS

Recommendations

- Adolescents with HIV require an individual and developmentally guided approach to therapy and care, ideally through an HIV specialist and team with expertise in this population.
- Adolescents with HIV should be counseled about preventative measures, including smoking cessation, alcohol and other substance use prevention, gender, and sexual health, including safer sex practices, to prevent development of comorbidities.
- Screening for early detection and management of comorbidities should be considered for adolescents with HIV.
- Vaccinations should be administered according to ACIP schedules for children with HIV, including ensuring catch-up vaccinations, if applicable, and administration of vaccines that prevent comorbidities, if applicable.
- Adolescents with HIV should have a coordinated, deliberate transition to adult care, with an emphasis on supporting their capacity for self-care including, but not limited to, retention, adherence to care, medical literacy, and engagement in mental health and substance use treatment.

Evidence Summary

The care of adolescents with HIV, whether perinatally or nonperinatally acquired, presents many challenges [347, 348, 351]. The median age of the US cohort of children who acquired HIV early in life, primarily via perinatal transmission, is now mid to late teens, and many have reached adulthood [352, 353] with varying degrees of health. Youth with HIV, in addition to the biological and psychosocial changes that normally occur in adolescence, often cope with stigma, disclosure, loss of family members, and negotiation of sexual activity. In many studies, rates of cognitive, psychiatric, and behavioral problems are higher in those with perinatally acquired infection [354, 355]. As a result of these challenges, many youths with perinatally acquired infection have poorer adherence to ART and may experience decreased engagement in care compared to with other populations [347]. Disclosure for this population is complicated as it includes becoming aware of one's own diagnosis and the subsequent self-disclosure of one's diagnosis to others (eg, sexual partners). While disclosure of diagnosis by the caregiver to the child or adolescent can be overwhelming to caregivers, it should occur by late childhood and prior to adolescence, as it has been correlated with better adjustment to illness, lower rates of depression, and improved adherence with care and ART [91, 348, 351]. Support should be provided for both types of disclosure. Screening for and addressing mental health challenges and concerns is an important part of caring for this population.

Puberty may affect drug metabolism, underscoring the importance of adolescent-specific studies. Decisions regarding dosing should take into consideration sexual maturity, with those with a sexual maturity rating ≥4 being dosed according to adult treatment guidelines. This is becoming less relevant because weight-based dosing is becoming the standard of care. Special attention should be paid to attaining and maintaining viral suppression, along with risk reduction counseling, STI and pregnancy prevention, and secondary HIV prevention in early or later adolescence [356, 357].

Long-term treatment, which may result in treatment fatigue, viral resistance due to suboptimal adherence or good adherence to suboptimal regimens, or potential end-organ toxicity, therefore, requires monitoring [358]. Early-acquired HIV, particularly in the setting of suboptimal viral suppression, can result in chronic immune activation and inflammation, which leads to noncommunicable disease comorbidities (eg, metabolic syndrome, dyslipidemia, chronic kidney disease, obesity, bone disease, atherosclerotic vascular disease, and cardiopulmonary abnormalities) [352, 358–361]. This risk is compounded by modifiable risk factors, particularly smoking/vaping and poor diet, which often begin during adolescence. Caring for youths with early-acquired HIV necessitates a life course approach with counseling regarding modifiable risk factors; prevention, including smoking cessation, dietary modification, and vaccination against preventable conditions; and screening for and early management of comorbidities [362, 363].

Youth who acquired HIV through sexual activity or injection drug use, in addition to the biological and psychosocial changes that normally occur in adolescence, have issues that are similar to those for adults, including high rates of substance use; STIs;

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

mental health comorbidities such as depression, anxiety, and PTSD [352]; and social determinants that may present barriers to care [7]. Sexual and gender identity and sexual behaviors should be discussed in a nonjudgmental manner in order to understand sexual risk and diminish stigma [364]. Multidisciplinary teams that simultaneously address biological and psychosocial issues are critical in optimizing outcomes, including early initiation of therapy and adherence support to maximize immune recovery and health and minimize transmission risk [365, 366]. ART should be prescribed according to established adult and adolescent treatment guidelines [7] (see also Section 1: Optimizing Care).

The transition of adolescents from pediatric to adult care usually occurs between the ages of 18 and 25 years and is impacted by variable factors, from patient preference to availability of providers and system/clinic rules. Youths are at high risk of falling out of care and experiencing poor clinical outcomes during this transition period [367, 368]. The transition of care from pediatric or adolescent providers to adult providers should be a deliberate, comprehensive, and coordinated multidisciplinary youth-friendly process that involves the healthcare team and the patient [369–371]. Care must be given to synergistically attend to the diverse needs of the adolescent that extend beyond medical care, including employment, independent living, and intimate relationships. Over time, youths must learn to negotiate the healthcare system and assume increasing responsibility for their healthcare. There are several resources on best practices for transitioning youths with HIV to adult care [7, 372–375].

SECTION 11: CONSIDERATIONS FOR TRANSGENDER AND GENDER-DIVERSE ADULTS

Recommendations

- Transgender and gender-diverse persons with HIV should have access to care that is gender-affirming, nondiscriminatory, nonstigmatizing, and culturally sensitive.
- Intake forms, medical records, and other documentation should include gender identity options in addition to sex assigned at birth, chosen name and pronouns, and legal name.
- Transgender persons should be offered medically necessary gender-affirming interventions in accordance with national guidelines.
- HIV care providers should be familiar with gender-affirming hormone treatment and necessary clinical and laboratory monitoring or provide referral to a clinician or endocrinologist experienced in transgender care.

Evidence Summary

Transgender people identify with a gender that differs from their sex assigned at birth. Recent data estimate that approximately 1.3 million adults in the United States identify as transgender or gender diverse [376]. It is important to use the appropriate terminology when talking with and about transgender persons. Many terms are used and often are confused with each other or used incorrectly (Table 8). Gender dysphoria refers to the discomfort that some transgender people may experience due to the discrepancy between their gender identity and sex assigned at birth. Some individuals opt for medical interventions, such as the use of gender-affirming hormones and surgeries, to align their physical characteristics with their gender identity.

Table 8. Terminology Associated With Gender Identity and Hormonal Therapy

Gender identity: An individual's sense of being male, female, nonbinary, agender, etc.
Transgender, trans, nonbinary, gender diverse: Adjectives used to refer to persons whose gender identity does not align with their sex recorded at birth (the latter primarily based on visible physical anatomy)
Nonbinary: An adjective used to refer to persons whose gender identity is outside the gender binary, that is, do not identify exclusively as a man or a woman; some nonbinary persons may not identify with any gender (agender)
Cisgender: An adjective used to refer to people whose gender identity corresponds to the sex they were assigned at birth
Gender expression: How a person communicates their gender through appearance, dress, name, pronouns, mannerisms, and speech
Gender-affirming hormone treatment and surgeries: Broad categories of medical interventions that transgender persons might consider to align their appearance and their gender identity
Gender affirmation: An overall process of alignment of physical characteristics and/or gender expression with gender identity
Gender dysphoria: Discomfort felt by some persons due to lack of alignment between gender identity and the sex recorded at birth; not all transgender persons have dysphoria, but many US insurance companies require this diagnosis for payment for gender-affirming medical and surgical interventions
Feminizing hormone therapy: The use of estrogens and often androgen blockers with the objective of inducing changes in physical characteristics to better match patient gender identity
Masculinizing hormone therapy: The use of testosterone with the objective of inducing changes in physical characteristics to better match patient gender identity
Sex assigned at birth: Refers to a person's status as male, female, or intersex based on physical characteristics at birth

Stigma and discrimination are serious issues that threaten the quality of care for transgender and gender-diverse persons, regardless of HIV status. Nearly half of transgender persons face family rejection, 40% report a history of attempted suicide, 29% live in poverty, 30% have experienced homelessness, 33% have experienced discrimination within the healthcare system, and 23% avoid the healthcare system due to fear of discrimination [377]. Global estimates show a pooled HIV prevalence of 19.9% (95% CI, 14.7%–25.1%) among transgender women, with 66-fold higher odds of HIV prevalence than the general population [378]. Data among transgender men are limited, but estimated HIV prevalence is 2.56% (95% CI, .0%–5.9%) [378]. Given the disproportionate impact of HIV on transgender individuals and the psychosocial barriers they face, health systems and healthcare providers should strive to create more

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

welcoming, affirming, and trauma-informed clinical environments. Clinic intake and registration forms should allow selection of gender identity in addition to assigned sex at birth [379]. Patients should be addressed using their chosen name (when different from legal name) and pronouns. Additionally, educational and health promotional materials designed for transgender individuals create a better sense of inclusion. Staff should undergo training on gender diversity and delivery of culturally competent and sensitive care. This comprehensive approach by all staff may facilitate patient empowerment, care engagement, and viral suppression [380, 381].

Gender-affirming hormone therapy (GAHT) is safe when provided under medical supervision. This care is often provided by primary care providers and HIV specialists who have received training, including informally, through mentorship or continuing medical education [224]. HIV care providers should be familiar with gender-affirming hormone treatment and necessary clinical and laboratory monitoring or provide referral to a medical provider or endocrinologist experienced in transgender care. Persons should be offered GAHT in accordance with established clinical practice guidelines, such as those published by the Endocrine Society [382] and the World Professional Association for Transgender Health [224]. Before initiating gender-affirming medical therapy for adult patients, the clinician should ascertain that the patient's gender identity is persistent and that they have the capacity to consent to treatment. The clinician should review expectations in terms of the timeline for changes and types of changes associated with hormone therapy, as well as a balanced risk assessment of those therapies. Prior to initiating hormone therapy or undergoing gonadectomy, clinicians should discuss parenthood goals, the impact of these interventions on fertility, and available options for sperm or oocyte preservation [224]. Some payers may require an assessment and referral letter from a mental health professional prior to gender-affirming medical interventions.

Feminizing hormone regimens typically use estrogen and antiandrogen medications, such as spironolactone. In 3–6 months, patients may start to experience breast growth, decreased muscle mass, softer skin, redistribution of body fat, and fewer spontaneous erections [224]. Transgender individuals who receive estrogen therapy may be at increased risk of hypertriglyceridemia, venous thromboembolism (VTE), and cardiovascular disease. Transdermal estrogen formulations may pose lower risk of thrombosis and are preferred for those aged >45 years, with a history of VTE, or with known risk factors for cardiovascular disease [224]. Oral conjugated estrogen formulations and ethinyl estradiol are not recommended due to an increased risk of thromboembolic events [224]. Smoking cessation should be encouraged. Clinical evaluations with laboratory monitoring of serum estradiol and testosterone should occur every 3 months for the first year and once to twice per year thereafter, with potassium monitoring at the same intervals for those on spironolactone. Target levels for individuals receiving feminizing GAHT are serum total testosterone <50 ng/dL and serum estradiol approximately 100–200 pg/mL [224].

For masculinizing hormone therapy, testosterone remains the mainstay treatment. Results, including cessation of menses, deepening of voice, increased muscle mass, and facial hair, typically start within 3–6 months [224]. Androgen therapy may result in erythrocytosis, increases in LDL cholesterol, and increases in serum creatinine [224, 383]. After initiating testosterone therapy, hemoglobin/hematocrit and serum testosterone should be measured every 3 months for the first year and 1–2 times per year thereafter. The serum total testosterone level should be maintained in the normal physiologic cisgender male range of 400 to 700 ng/dL [224].

Several ARV regimens, including NRTIs, unboosted INSTIs, rilpivirine, and doravirine, are not anticipated to impact GAHT and require no additional monitoring [384, 385]. Estradiol levels may be decreased by the NNRTIs efavirenz, etravirine, and nevirapine. Ritonavir-boosted PIs may increase or decrease estradiol levels, while cobicistat-boosted PIs may increase estradiol [386]. Testosterone levels are increased by boosted PIs and elvitegravir/cobicistat and decreased by efavirenz, etravirine, and nevirapine [386]. When pharmacokinetic interactions are anticipated, clinicians should monitor clinical effects as well as serum hormone concentrations and adjust hormone doses as needed. It is important to provide patients with accurate information on drug–drug interactions between their ART and hormone therapy, including the lack of deleterious effects on hormone therapy, and to make dose adjustments as appropriate. Lack of communication around this concern may contribute to fear of drug–drug interactions and poor adherence to one therapy or the other [387].

SECTION 12: COVID-19 AND HIV

People with HIV have been impacted by SARS-CoV-2 infection (COVID-19) since the early days of the pandemic. Early on, the presumption was that people with HIV would fare poorly due to damaged immune systems, but that has not necessarily proven to be the case. This section discusses the interaction of COVID-19 and HIV only. IDSA has excellent living guidelines for COVID-19 management and treatment for the general population [388]. The best protections against COVID-19 for people with HIV are up-to-date vaccinations and good health hygiene and safety. It is important for providers to remember that HIV care should not be disrupted simply due to COVID-19. In fact, aiming for viral suppression and maximization of CD4 count is recommended to prevent more severe COVID-19 infections [389, 390]. Early in the pandemic, and even 1 year after general quarantines ended, access to HIV care was limited, and many people with HIV had disruptions in HIV

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

care, including refills of ART, disease monitoring, provider visits, and laboratory testing [390, 391]. Providers who care for people who are more severely immunocompromised (CD4 <200 cells/μL) should ensure that their office is safe for people with HIV. The CDC guidelines should be consulted for the latest healthcare facility guidelines[392].

Recommendations

- CD4 count and viral suppression should be maximized to lower risk for COVID.
- Weight loss should be encouraged because obesity is a significant risk factor for severe COVID-19 infection.
- Pulmonary comorbidities should be treated to maximize protection against severe COVID-19 infection.
- It is important to ensure that patients with more advanced HIV are fully vaccinated, including vaccines targeted to newer SARS-CoV-2 variants, and to use mRNA vaccines when possible (see Section 4).
- There is no evidence that people with HIV and COVID-19 require a change to their ART simply due to presence of COVID-19 coinfection.
- HIV is not a contraindication to COVID-19 vaccination, and COVID-19 vaccination does not impact HIV viremia.
- Treatment recommendations for COVID-19 in people with HIV are the same as for people without HIV, and treatment recommendations do not change by HIV viral load or CD4 cell count.
- Treatment of COVID-19 is not changed by HIV infection, and ART is not changed due to treatment for COVID-19.
- Dexamethasone and other corticosteroids should not be used in the outpatient setting when caring for people with HIV who have COVID-19 in the absence of other indications.
- It is important to be cognizant of significant drug–drug interactions with ritonavir-boosted nirmatrelvir and all medications and supplements. Antiretroviral therapy does not require dose adjustments in this setting.
- Previously disproven COVID-19 treatment should not be used for people with HIV, including ivermectin and sotrovimab in the outpatient setting.
- Because people with HIV may be at increased risk of PCCs, ask about PCC-related symptoms among people with HIV who are post-30 days from COVID-19 diagnosis.

Evidence Summary

People with HIV are at increased risk of acquiring SARS-CoV-2 infection and possibly of becoming reinfected with SARS-CoV-2, with risk inversely proportional to CD4 cell count, especially if CD4 count is <200 cells/μL [180, 393–395]. In multiple studies, it was found that a CD4 count <200 cells/μL was associated with increased mortality, while CD4 <350 cells/μL was associated with an increased risk of hospitalization [393, 396]. People with HIV should be on ART and aim for CD4 count >200 cells/μL but ideally >350 cells/μL. This is especially important for decreasing the risk of hospitalization or more severe COVID-19 infection [393]. Additional evidence suggests that all persons (regardless of HIV status) would benefit from weight loss, as obesity is associated with more severe COVID-19 infection [397]. Data also suggest that a higher risk for more severe COVID-19 is associated with cirrhosis, alcoholic hepatitis, chronic kidney disease, diabetes mellitus, and smoking [395]. Further, chronic pulmonary disease, specifically bronchiectasis, chronic obstructive pulmonary disease, interstitial lung disease, pulmonary embolism, and pulmonary hypertension, have been associated with more severe COVID-19 infection, including greatly increased risk of hospitalization and death. All of these conditions should be maximally optimized prior to infection (including stopping smoking) to lower the risk of severe infection.

Early data (from 2020) showed an association between decreased access to testing among non-Latino Blacks and Latinos and late diagnoses with more severe COVID-19 infections [398]. While testing access improved during the pandemic and the public health emergency has ended, access to testing may remain key for certain subpopulations. Vaccination against COVID-19, including all recommended boosters, is key for COVID-19 prevention and lowering risk for severe COVID-19 infections in people with HIV (see Section 4). Consistent evidence indicates that people with HIV with CD4 count >200 cells/μL have robust immune response (approximating that of people without HIV infection), but mRNA vaccines perform superiorly to other vaccines [396, 399, 400]. Further, HIV is not a contraindication to COVID-19 vaccination, regardless of CD4 count or degree of HIV viral suppression, and COVID-19 vaccination does not impact HIV viremia [181, 401]. Even with effective vaccination, there is still some evidence that people with HIV are at increased risk for breakthrough infection; however, the need for hospitalization or risk of death is not increased relative to people without HIV [399, 402].

Controversy persists on the role of ARV agents in preventing COVID-19 infection or mitigating the severity of infection in people with HIV. Observational evidence from several studies has suggested that tenofovir may be associated with lower risk of severe COVID-19; however, no confirmatory data from randomized trials exist [403]. Similarly, evidence for PIs and prevention of COVID-19 remains inconclusive [404]. There is no evidence to suggest that people with HIV and COVID-19 require a change to their ART simply because of the COVID-19 infection. No change is required to ART while on anti–COVID-19 treatment, including remdesivir or ritonavir-boosted nirmatrelvir. Close monitoring for potential increased risk of side effects is recommended. However, dexamethasone and other corticosteroids used as anti–COVID-19

Downloaded from https://academic.oup.com/cid/advance-article/doi/10.1093/cid/ciae479/7818967 by guest on 23 April 2026

treatment should be avoided in the outpatient setting because side effects may increase due to drug–drug interactions [405].

As discussed in Section 4, PCCs are an ever-increasing phenomenon following SARS-CoV-2 infection. The exact incidence is unclear, and treatment is mainly symptomatic. There is some evidence that people with HIV may be at increased risk for PCCs, especially if not virally suppressed or with a lower CD4 count [406–408]. As such, providers should ask about PCC-related symptoms among people with HIV who are 30 days post–COVID-19 diagnosis. No treatment modifications for ART or comorbidities are indicated in the presence of PCCs.

Notes

Acknowledgments. The authors thank the following individuals for their contributions to this guidance: Andrea Weddle, MSW (HIV Medicine Association [HIVMA] executive director), Helaine Resnick, PhD, MPH (consultant, literature reviews), Kendra Porter, BS, and Lily Fathi, BA. The authors also thank the reviewers (Joseph Cherabie, MD, MSc, Carolyn Chu, MD, MSc, Michael Mugavero, MD, Tim Horn, MS, and members of the Infectious Disease Society of America [IDSA] Standards and Practice Guidelines Subcommittee) for their thoughtful comments that improved the manuscript.

Disclaimer. This guidance cannot account for individual variation among patients and is not intended to supplant clinician judgment with respect to particular patients or special clinical situations. The HIVMA and the IDSA consider adherence to this guidance to be voluntary, with the ultimate determination regarding its application to be made based on individual patient circumstances.

Financial support. The IDSA provided financial support for this guidance.

Potential conflicts of interest. The following list includes what has been reported to IDSA. To provide thorough transparency, IDSA requires full disclosure of all relationships, regardless of relevancy to the guideline or guidance topic. Evaluation of such relationships as potential conflicts of interest is determined by a review process that includes assessment by the Board of Directors liaison to the Standards and Practice Guidelines Committee and, if necessary, the Conflicts of Interest and Ethics Committee. The assessment of disclosed relationships for possible conflicts of interest is based on the relative weight of the financial relationship (ie, monetary amount) and the relevance of the relationship (ie, the degree to which an association might reasonably be interpreted by an independent observer as related to the topic or recommendation of consideration). IDSA requests panel members to disclose activities and financial relationships/investments related to consultant/advisory roles, promotional speakers bureau, stocks/bonds, honoraria, expert testimony, ownership interest, research grants, organizational benefits, intellectual property, other numeration, activities with other organizations, and relevant financial interest of family members. Readers of this guidance should be mindful of this when the list of disclosures is reviewed.

HIV SURVEILLANCE REPORT

SPECIAL REPORT

Individual-level Social Determinants of Health and Quality of Life Among Persons With Diagnosed HIV Infection

Medical Monitoring Project, United States, 2022 Data Cycle (June 2022–May 2023)

Centers for Disease Control and Prevention
National Center for HIV, Viral Hepatitis, STD, and TB Prevention

This HIV Surveillance Special Report is published by the Behavioral and Clinical Surveillance Branch of the Division of HIV Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention (CDC), U.S. Department of Health and Human Services, Atlanta, Georgia.

The HIV Surveillance Special Report is not copyrighted and may be used and copied without permission. Citation of the source is, however, appreciated.

This report was prepared by the following staff and contractors of the Division of HIV Prevention, CDC: Linda Beer, Sharoda Dasgupta, Stacy M. Crim, Xin Yuan, Tim McManus, Yunfeng Tie, Kristal Stevenson, Mohua Basu, Rodel Desamu-Thorpe, Catherine Espinosa, Jennifer L. Fagan, Kamal Hughes, Ruth E. Luna-Gierke, Irma Kocer, Taylor Robbins, Sandra Stockwell, Jennifer Taussig, Nabeeha Virani, John Weiser, Jason A. Craw, and Michael Friend (editing).

Acknowledgments

This report was prepared by members of the Clinical Outcomes Team within the Division of HIV Prevention.

This report would not be possible without the contributions of Medical Monitoring Project (MMP) respondents, community and provider advisory boards, interviewers, and abstractors; the Data Coordinating Center for HIV Supplemental Surveillance at ICF International; and members of the Clinical Outcomes Team, Division of HIV Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, CDC, Atlanta, Georgia.

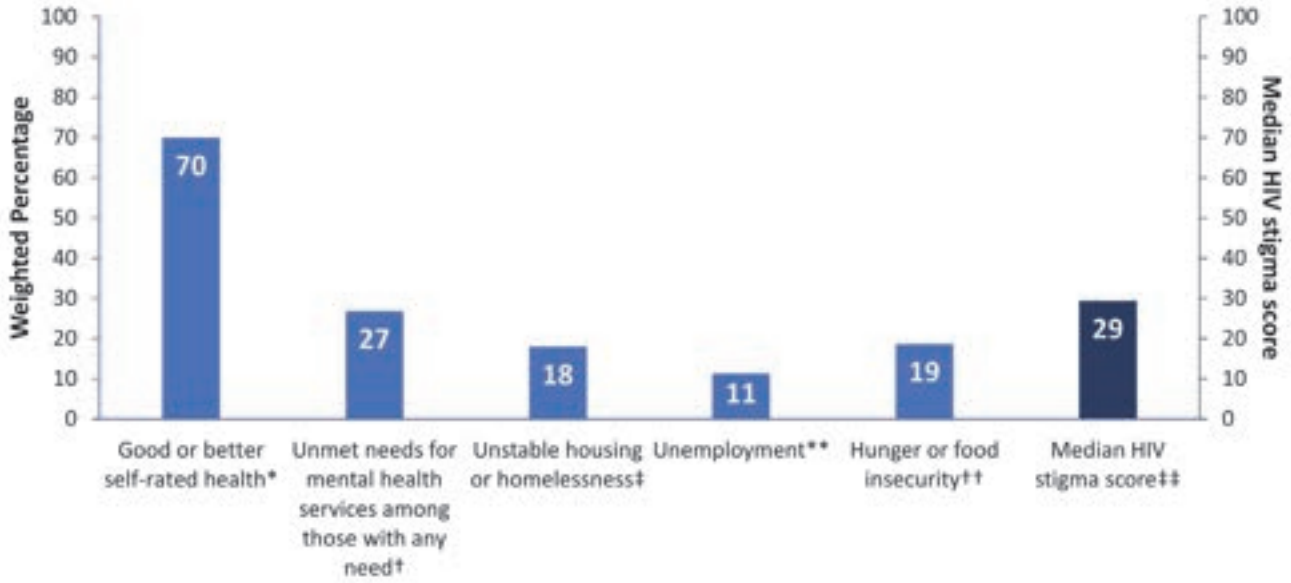
Technical Notes and Appendix 64

Commentary

Social determinants of health (SDOH) are the "conditions in the places where people live, learn, work, and play that affect a wide range of health and quality-of-life risks and outcomes" [1]. Addressing social determinants of health among people with HIV (PWH) is a national priority highlighted in the White House's National HIV/AIDS Strategy (NHAS), as it is essential for reducing disparities in health outcomes and achieving health equity among people with HIV [2, 3], particularly among priority groups, including: gay, bisexual, and other men who have sex with men (MSM) (in particular, Black, Latino, and American Indian/Alaska Native men); Black women; transgender women; youths aged 13–24 years; and people who inject drugs. Further, NHAS added several indicators in 2022 based on community input to monitor quality of life (QoL) among PWH that are related to SDOH, including aspects of physical health (i.e., self-reported health status), mental or emotional health (i.e., unmet needs for mental health services), and structural or subsistence factors (i.e., unemployment, hunger/food insecurity, and unstable housing or homelessness) [4].

The Centers for Disease Control and Prevention (CDC) Medical Monitoring Project (MMP) is the only source of nationally representative data on individual-level SDOH and QoL among adults with diagnosed HIV in the United States, including among priority populations highlighted in NHAS. Estimates are also representative for each of MMP's reporting project areas, including: California (including the separately funded jurisdictions of Los Angeles County and San Francisco), Delaware, Florida, Georgia, Illinois (including the separately funded jurisdiction of Chicago), Indiana, Michigan, Mississippi, New Jersey, New York (including the separately funded jurisdiction of New York City), North Carolina, Oregon, Pennsylvania (including the separately funded jurisdiction of Philadelphia), Puerto Rico, Texas (including the separately funded jurisdiction of Houston), Virginia, and Washington state. Data from MMP are critical for achieving the goals of NHAS [4] and the Ending the HIV Epidemic in the U.S. (EHE) initiative [5], which seek to reduce new HIV infections in the United States by 90% by 2030 and prioritize reducing HIV-related disparities and health inequities and improving PWH's health and well-being. Continuing to monitor SDOH and QoL among PWH is an essential step towards meeting national goals to end the HIV epidemic and ensuring good health and well-being among PWH in the United States.



This report presents unweighted frequencies and weighted prevalence estimates with 95% confidence intervals (CIs) for all characteristics represented by categorical variables. Continuous variables are represented using median values and 95% CIs. The period referenced for estimates is the 12 months before the respondents' interviews unless otherwise noted. Statistical software (SAS, version 9.4) was used for analysis of weighted data. For categorical variables, data are not reported for estimates derived from a denominator size <30 or for estimates with a coefficient of variation ≥0.30. For continuous variables, estimates based on a denominator sample size <30 were suppressed. In both the tables and the narrative, estimates with an absolute confidence interval width ≥30, estimates with an absolute confidence interval width between 5 and 30 and a relative confidence interval width ≥130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution. Estimates are rounded to the nearest whole number in the commentary and figures, and to the nearest tenth in the tables; comparisons between groups in the commentary are based on estimates presented in the tables. Estimates from the 2020–2022 cycles presented in this report may have been affected by the COVID-19 pandemic. Estimates for persons identifying as American Indian/Alaska Native or Native Hawaiian/other Pacific Islander were suppressed for all measures due to small numbers. Many estimates for Asian persons were also unreliable and were suppressed. Additional information on MMP is available at https://www.cdc.gov/hiv-data/mmp/index.html.

HIGHLIGHTS OF ANALYSES

Individual-level SDOH and QOL

MMP reports information on QoL indicators and HIV stigma to monitor progress towards meeting national HIV prevention and treatment goals highlighted in NHAS. During 2022, 70% of persons with HIV had good or better self-rated health (2025 NHAS goal: 95%), and 27% had an unmet need for services from a mental health professional among those with any need (2025 NHAS goal: 12%) (Figure 1; Table 1). Overall, 18% experienced unstable housing or homelessness during the past 12 months (2025 NHAS goal: 11%), 11% were unemployed (2025 NHAS goal: 7%), and 19% experienced hunger or food insecurity during the past 12 months (2025 NHAS goal: 11%). During 2022, the median HIV stigma score based on a scale that ranged from 0 (no stigma) to 100 (high stigma) was 29 among PWH (2025 NHAS goal: 16).

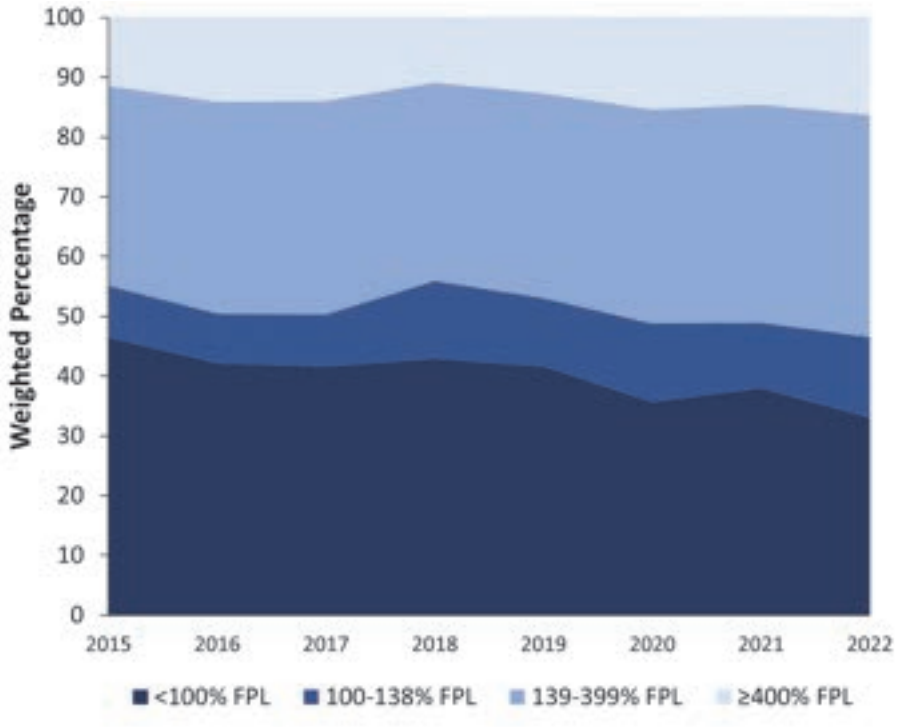
Figure 1. National HIV/AIDS Strategy indicators among adults with diagnosed HIV—Medical Monitoring Project, United States, 2022

* "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

† "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

‡ "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

** Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.



†† "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

‡‡ "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico.

MMP also collects information on other individual-level SDOH related to economic stability, education, health-related factors, and social and community context. During 2022, 84% of PWH were living in a household with an income <400% of the federal poverty level (FPL); 33% were living in a household with an income <100% of the FPL, 14% in a household with an income between 100%–138% of the FPL, and 37% in

a household with an income between 139%–399% (Figure 2; Table 1). The percentage of PWH living in a household with an income <100% of the FPL was lowest in 2022 (33%) and highest in 2015 (46%).

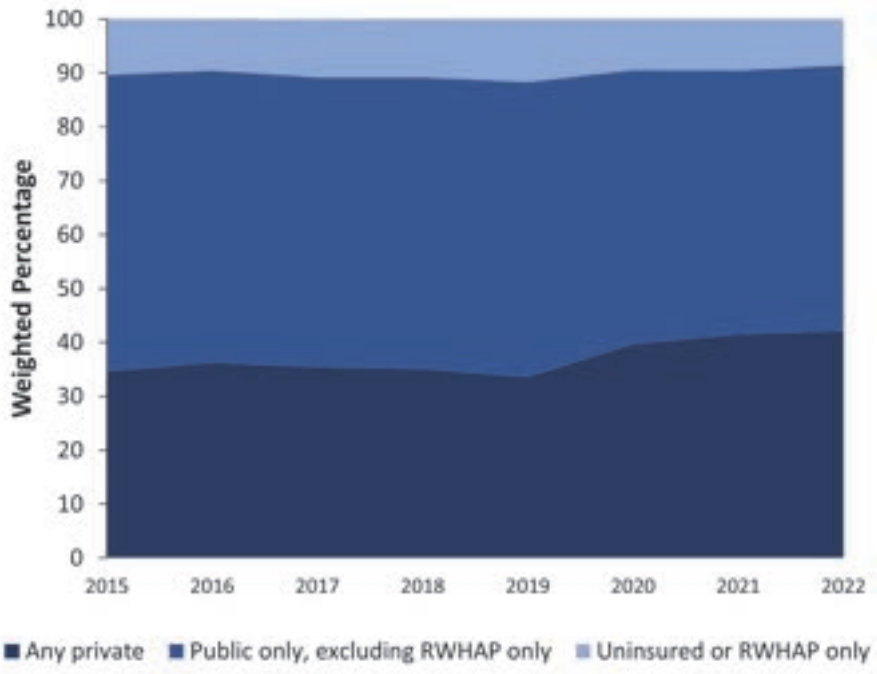


Figure 2. Household poverty level of adults with diagnosed HIV—Medical Monitoring Project, United States, 2015–2022

Note. Poverty guidelines as defined by HHS. Respondents were asked about their household income from all sources during the calendar year prior to the interview date. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

During the past 12 months, 42% had any private insurance coverage, 49% had public insurance or coverage only (excluding those who had Ryan White HIV/AIDS Program [RWHAP] assistance only), and 9% were uninsured or received RWHAP assistance only (Figure 3; Table 1). The percentage of PWH who had any private insurance was lowest during 2019 (34%) and highest during 2022 (42%). In addition, 47% received any RWHAP assistance during the past 12 months (Table 1).

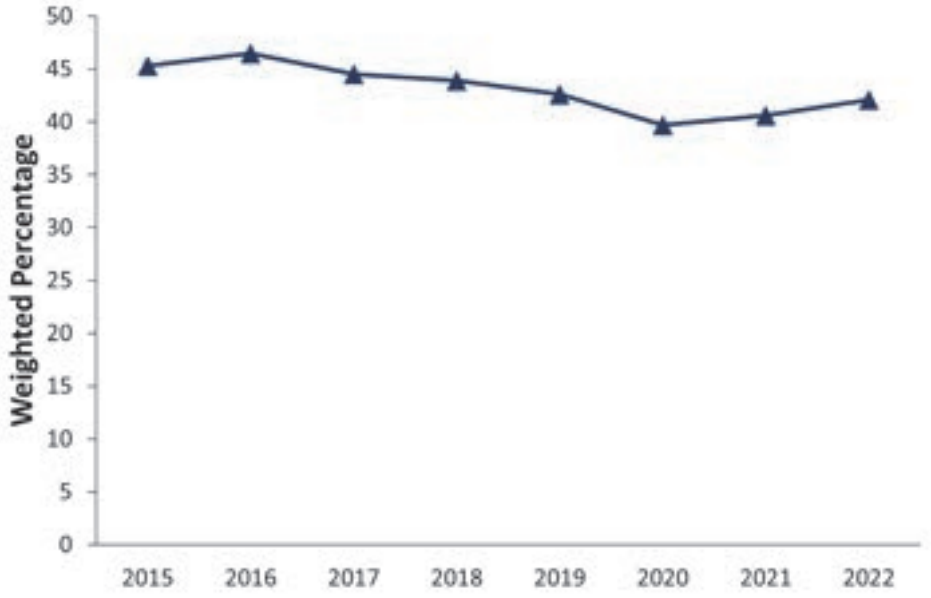

Figure 3. Health insurance or coverage among adults with diagnosed HIV—Medical Monitoring Project, United States, 2015–2022

Abbreviation: RWHAP, Ryan White HIV/AIDS Program.

During 2022, 42% of PWH reported a physical, mental, or emotional disability; the percentage of PWH with one or more disabilities was lowest during 2020 (40%) and highest during 2016 (47%).

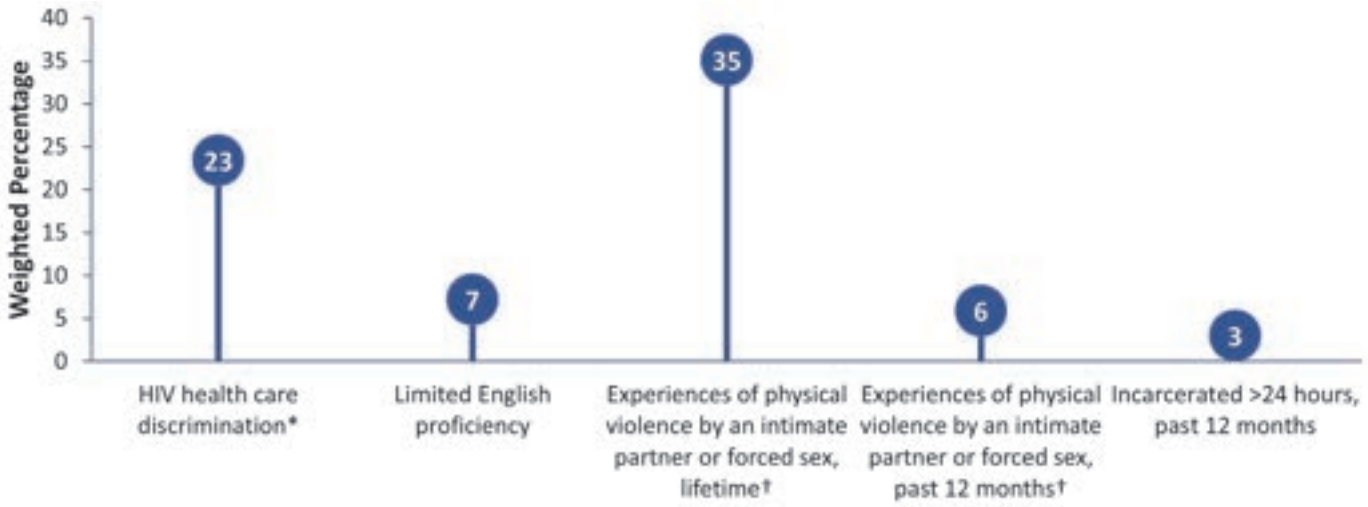

Figure 4. Disability among adults with diagnosed HIV—Medical Monitoring Project, United States, 2015–2022

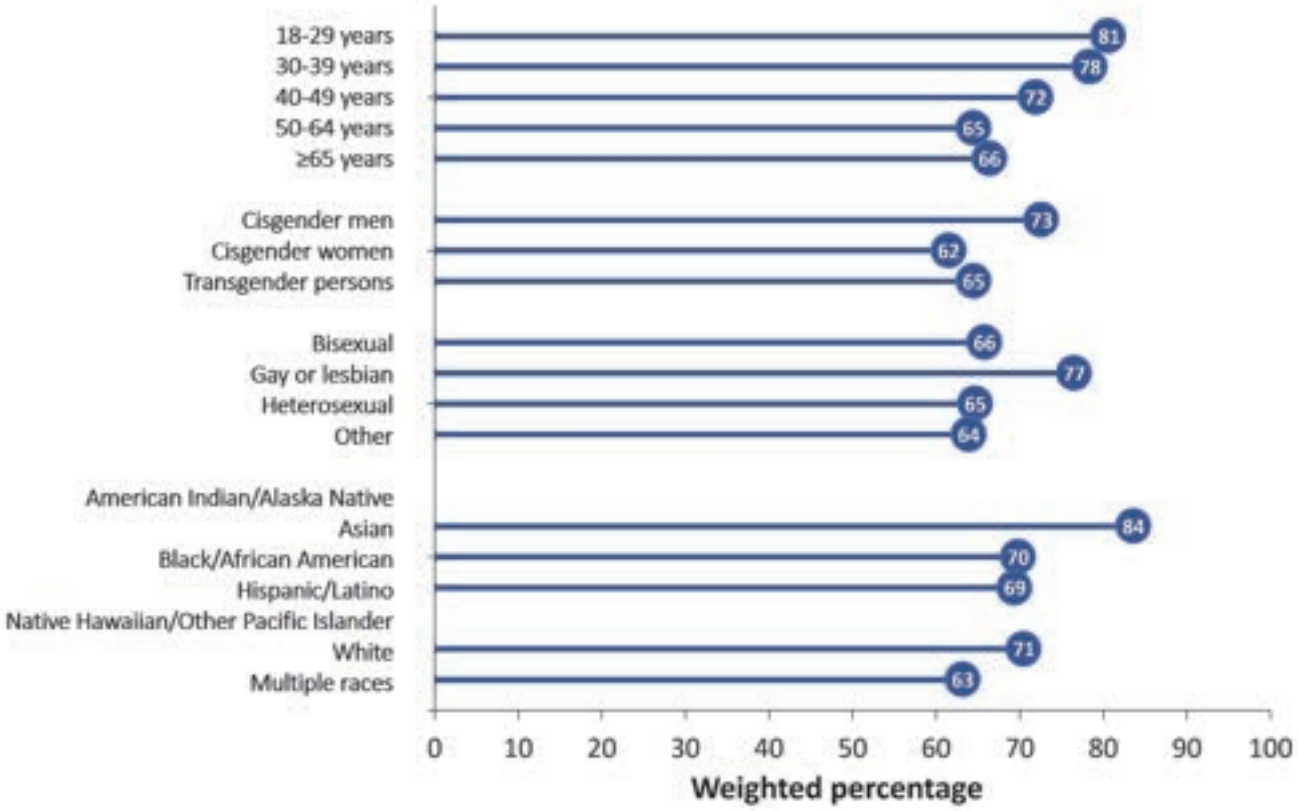
Note. Disabilities are self-reported and include physical, mental, and emotional disabilities.

During 2022, 23% of PWH experienced any HIV health care discrimination during the past 12 months, and 7% reported speaking English "less than well" (Figure 5; Table 1). Overall, 35% had experiences of physical violence by an intimate partner or forced sex during their lifetime, and 6% had these experiences during the past 12 months. Three percent of PWH reported being incarcerated during the past 12 months.

Figure 5. HIV health care discrimination, limited English proficiency, experiences with physical violence by an intimate partner or forced sex, and incarceration among adults with diagnosed HIV—Medical Monitoring Project, United States, 2022

* HIV health care discrimination among those who received HIV care during the past 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced this never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.



† Physical violence by an intimate partner was defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex was defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

NHAS Indicators and Other Individual-level SDOH by Demographic Characteristics

Estimates of all NHAS indicators and other individual-level SDOH are reported by demographic characteristics. Absolute and relative disparities (using prevalence differences and prevalence ratios, respectively) were used to quantify differences in indicators and other SDOH by demographic characteristics, which are reported in Tables 2–5.

Good or better self-rated health varied by age, current gender identity, sexual orientation, and race/ethnicity (Tables 2–5, Figure 6). When stratified by age, good or better self-rated health was highest among persons aged 18–29 years (81%) and lowest among persons aged 50–64 years (65%). When stratified by current gender identity, good or better self-rated health was highest among cisgender men (73%) and lowest among cisgender women (62%). When stratified by sexual orientation, good or better self-rated health was highest among persons who identified as gay or lesbian (77%) and lowest among persons who identified as another sexual orientation (i.e., not bisexual, gay or lesbian, or heterosexual; 64%). When stratified by race/ethnicity, good or better self-rated health was highest among persons who identified as Asian (84%) and lowest among persons who identified as multiple races (63%).

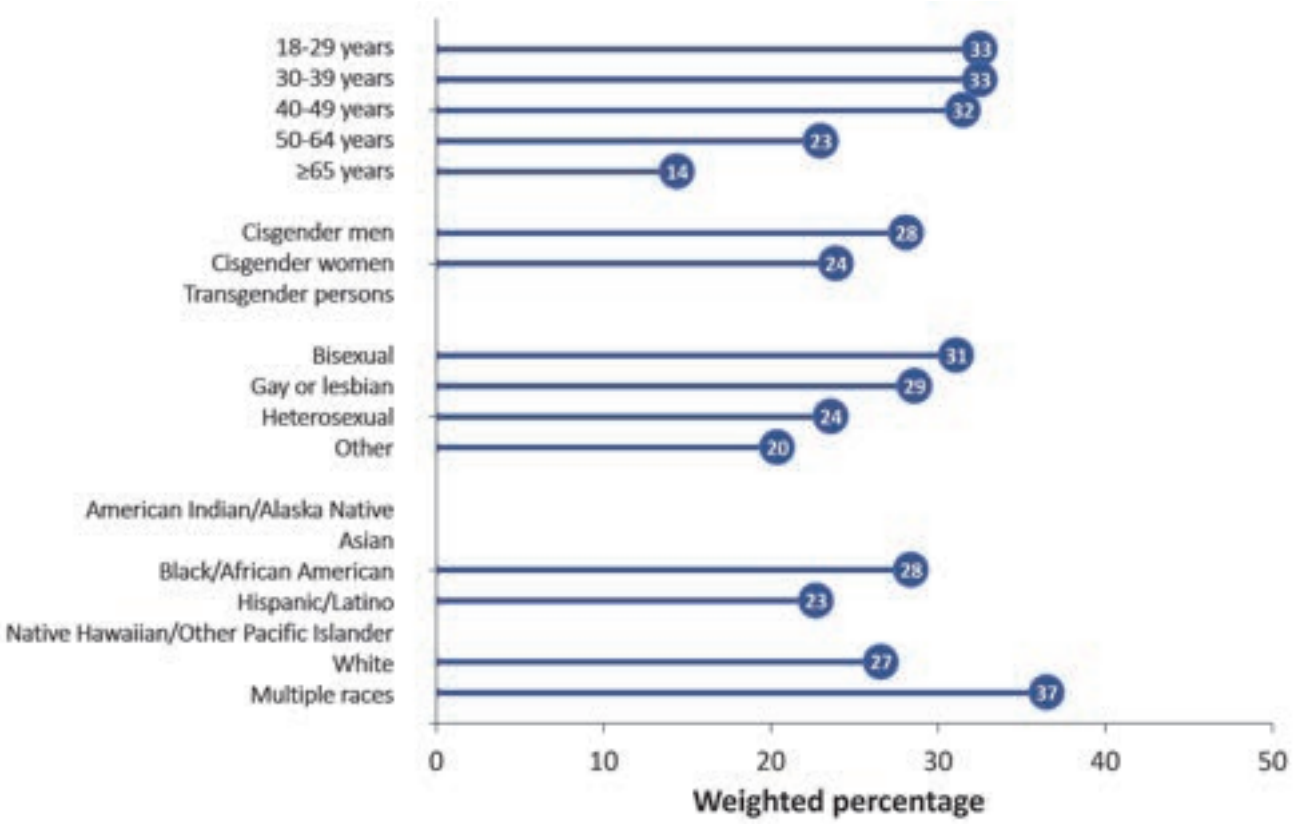


Figure 6. Good or better self-rated health among adults with diagnosed HIV, by age, gender, sexual orientation, and race/ethnicity—Medical Monitoring Project, United States, 2022

Note. "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30. Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender. Hispanics or Latinos can be of any race. Persons are classified in only 1 race/ethnicity category.

Unmet needs for services from a mental health professional among those who needed them varied by age, current gender identity, sexual orientation, and race/ethnicity (Tables 2–5, Figure 7). When stratified by age, unmet needs for mental health services among those who needed them were highest among persons aged 18–29 years and 30–39 years (both 33%) and lowest among persons aged ≥65 years (14%). When stratified by current gender identity, unmet needs for mental health services among those who needed them were highest among cisgender men (28%) and lowest among cisgender women (24%). When stratified by sexual orientation, unmet needs for mental health services among those who needed them were highest among persons who identified as bisexual (31%) and lowest among persons who identified as another sexual orientation (i.e., not bisexual, gay or lesbian, or heterosexual; 20%). When stratified by race/ethnicity, unmet needs for mental health services among those who needed them were highest among persons who identified as multiple races (37%) and lowest among persons who identified as Hispanic/Latino (23%).

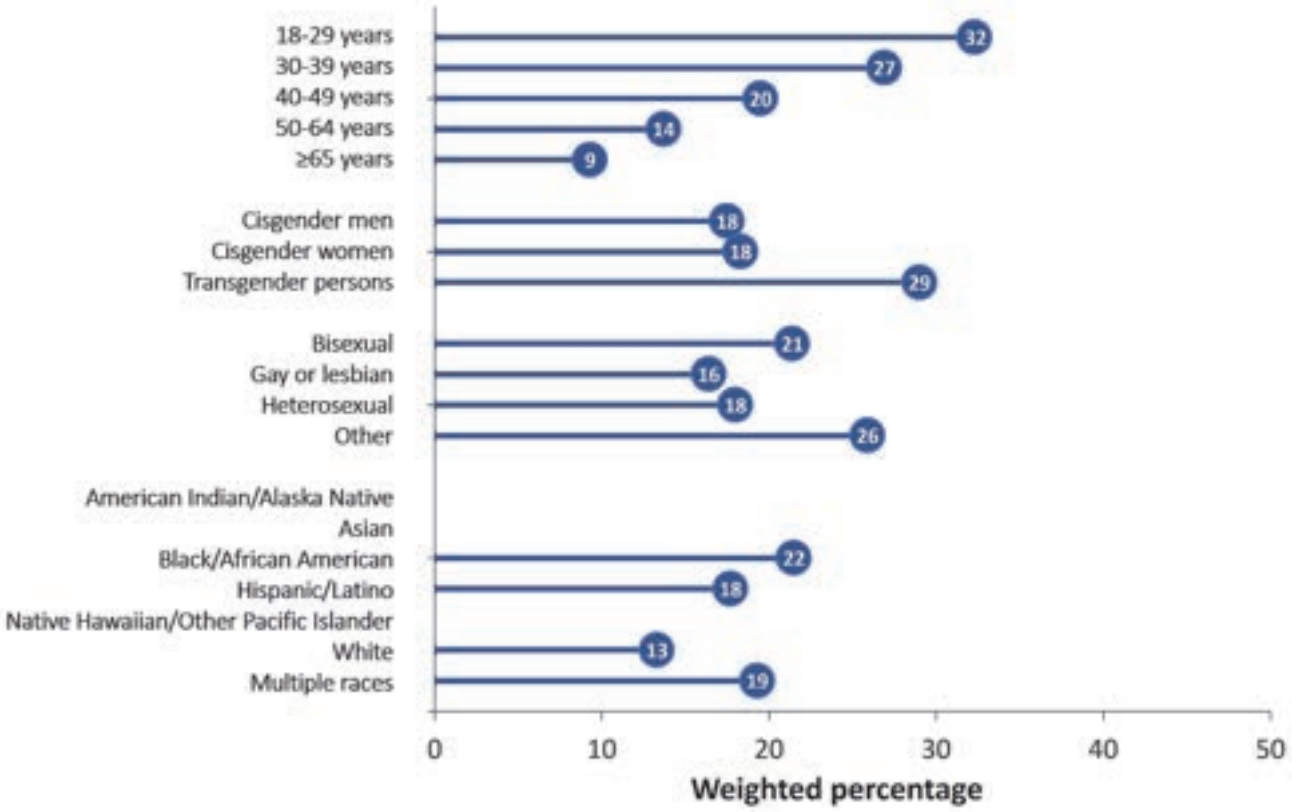

Figure 7. Unmet needs for services from a mental health professional among adults with diagnosed HIV with a need for services, by age, gender, sexual orientation, and race/ethnicity—Medical Monitoring Project, United States, 2022

Note. "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30. Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender. Hispanics or Latinos can be of any race. Persons are classified in only 1 race/ethnicity category.

Unstable housing or homelessness varied by age, current gender identity, sexual orientation, and race/ethnicity (Tables 2–5, Figure 8). When stratified by age, unstable housing or homelessness was highest among persons aged 18–29 years (32%) and lowest among persons aged ≥65 years (9%). When stratified by current gender identity, unstable housing or homelessness was highest among transgender persons (29%) and lowest among cisgender men (18%). When stratified by sexual orientation, unstable housing or homelessness was highest among persons who identified as another sexual orientation (i.e., not bisexual, gay or lesbian, or heterosexual; 26%) and lowest among persons who identified as gay or lesbian (16%). When stratified by race/ethnicity, unstable housing or homelessness was highest among persons who identified as Black/African American (22%) and lowest among persons who identified as White (13%).

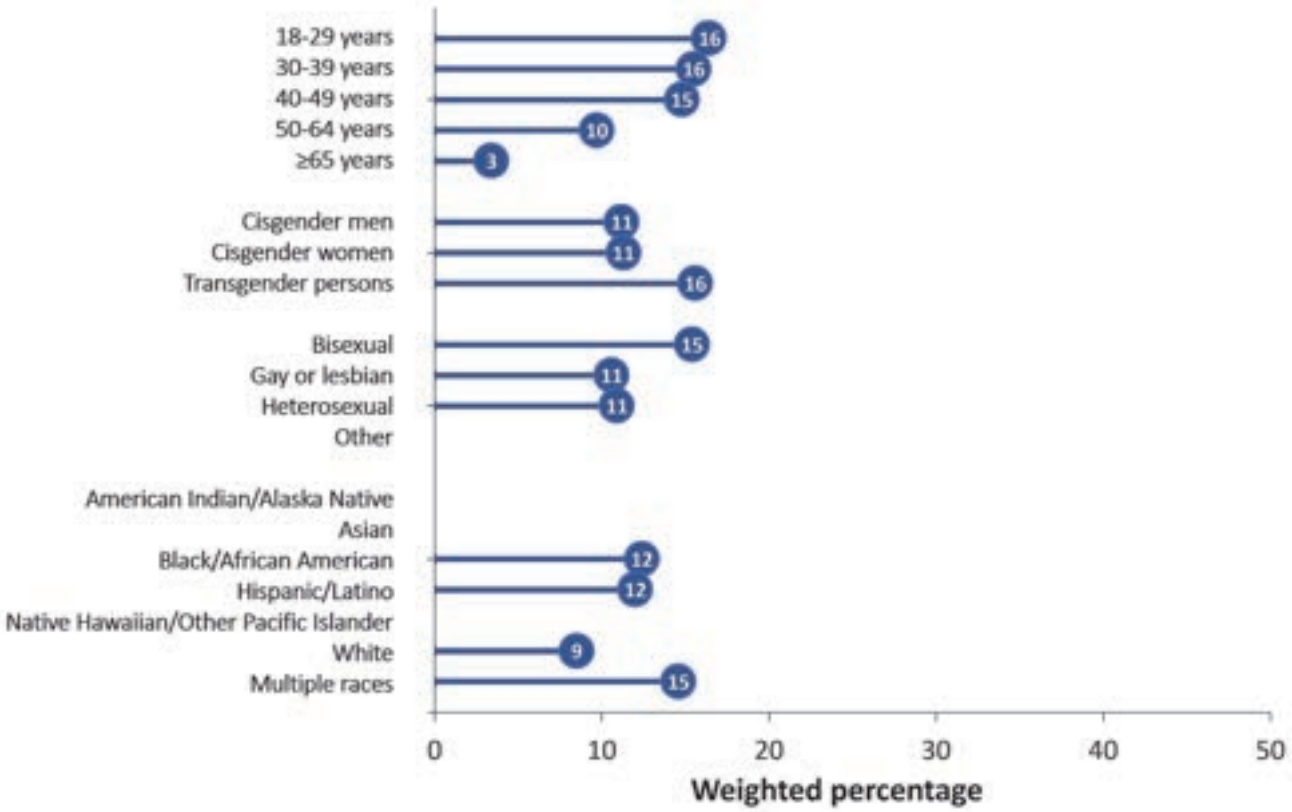

Figure 8. Unstable housing or homelessness among adults with diagnosed HIV, by age, gender, sexual orientation, and race/ethnicity—Medical Monitoring Project, United States, 2022

Note. "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30. Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender. Hispanics or Latinos can be of any race. Persons are classified in only 1 race/ethnicity category.

Unemployment varied by age, current gender identity, sexual orientation, and race/ethnicity (Tables 2–5, Figure 9). When stratified by age, unemployment was highest among persons aged 18–29 years (16%) and lowest among persons aged ≥65 years (3%). When stratified by current gender identity, unemployment was highest among transgender persons (16%) and lowest among cisgender men (11%). When stratified by sexual orientation, unemployment was highest among persons who identified as bisexual (15%) and lowest among persons who identified as gay or lesbian (11%). When stratified by race/ethnicity, unemployment was highest among persons who identified as multiple races (15%) and lowest among persons who identified as White (9%).

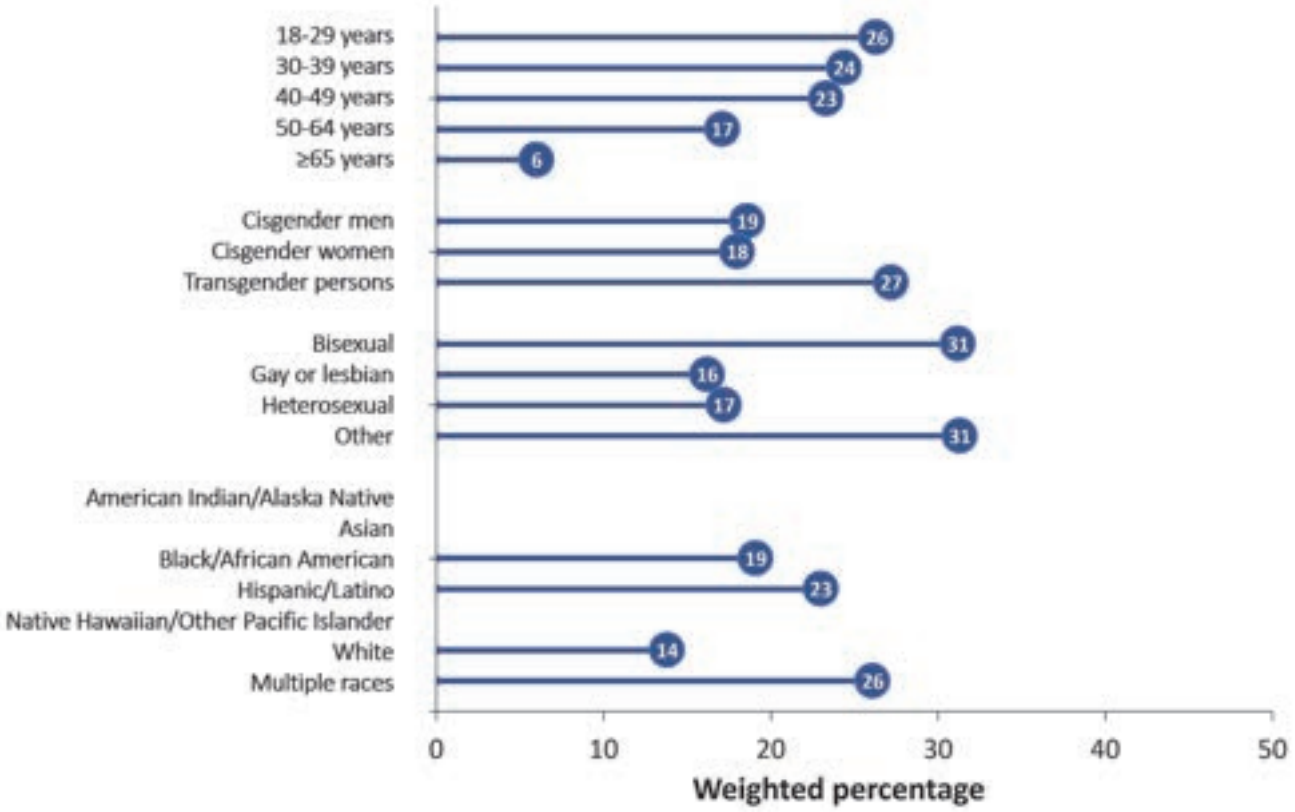

Figure 9. Unemployment among adults with diagnosed HIV, by age, gender, sexual orientation, and race/ethnicity—Medical Monitoring Project, United States, 2022

Note. Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30. Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender. Hispanics or Latinos can be of any race. Persons are classified in only 1 race/ethnicity category.

Hunger or food insecurity varied by age, current gender identity, sexual orientation, and race/ethnicity (Tables 2–5, Figure 10). When stratified by age, hunger or food insecurity was highest among persons aged 18–29 years (26%) and lowest among persons aged ≥65 years (6%). When stratified by current gender identity, hunger or food insecurity was highest among transgender persons (27%) and lowest among cisgender women (18%). When stratified by sexual orientation, hunger or food insecurity was highest among persons identifying as another sexual orientation (i.e., not bisexual, gay or lesbian, or heterosexual; 31%) and lowest among persons who identified as gay or lesbian (16%). When stratified by race/ethnicity, hunger or food insecurity was highest among persons who identified as multiple races (26%) and lowest among persons who identified as White (14%).

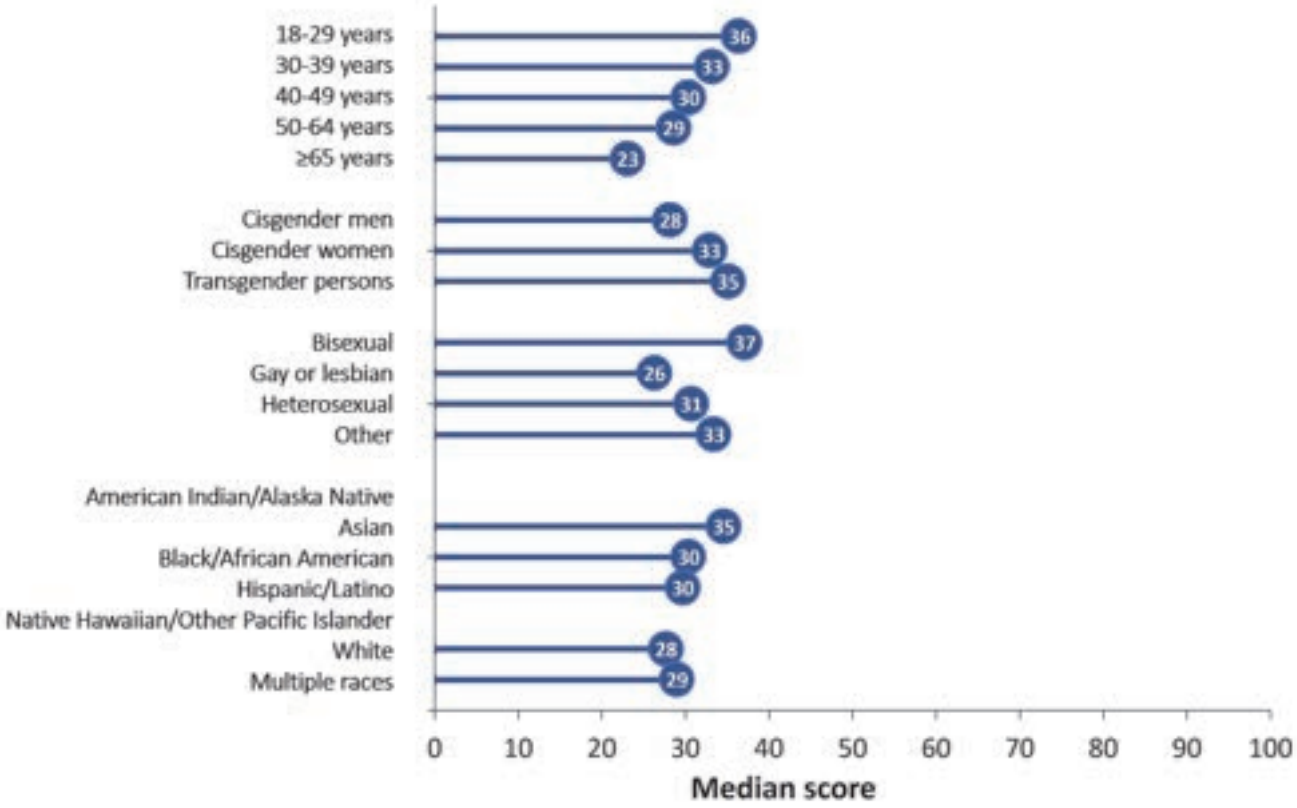

Figure 10. Hunger or food insecurity among adults with diagnosed HIV, by age, gender, sexual orientation, and race/ethnicity—Medical Monitoring Project, United States, 2022

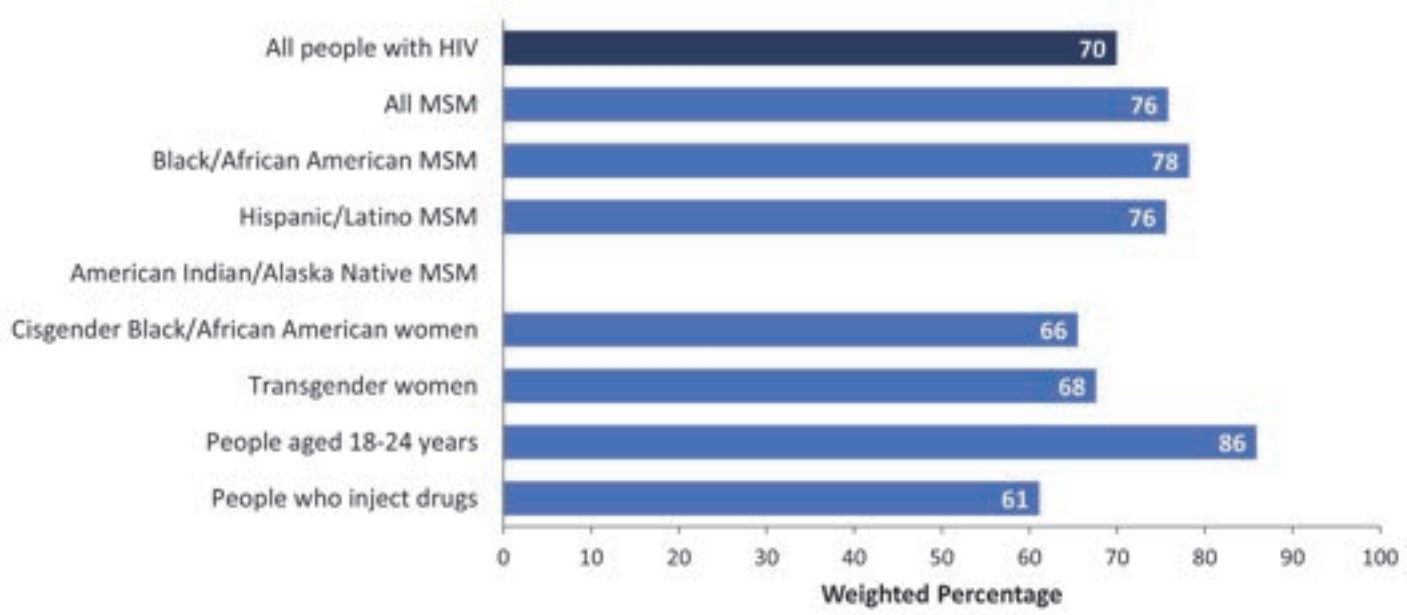
Note. "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30. Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender. Hispanics or Latinos can be of any race. Persons are classified in only 1 race/ethnicity category.

Median HIV stigma scores varied by age, current gender identity, sexual orientation, and race/ethnicity (Tables 2–5, Figure 11). When stratified by age, the median HIV stigma score was highest among persons aged 18–29 years (36) and lowest among persons aged ≥65 years (23). When stratified by current gender identity, the median HIV stigma score was highest among transgender persons (35) and lowest among cisgender men (28). When stratified by sexual orientation, the median HIV stigma score was highest among persons who identified as bisexual (37) and lowest among persons who identified as gay or lesbian (26). When stratified by race/ethnicity, the median HIV stigma score was highest among persons who identified as Asian (35) and lowest among persons who identified as White (28).

Figure 11. Median HIV stigma scores among adults with diagnosed HIV, by age, gender, sexual orientation, and race/ethnicity—Medical Monitoring Project, United States, 2022



Note. "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. Estimates were suppressed if they were based on a denominator sample size <30. Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender. Hispanics or Latinos can be of any race. Persons are classified in only 1 race/ethnicity category.

Stratifications of other SDOH by age, current gender identity, sexual orientation, and race/ethnicity are reported in Tables 2–5.

NHAS Indicators and Other SDOH by NHAS Priority Populations

Table 6 shows that patterns in NHAS indicators and SDOH differed for each NHAS priority population during the 2022 MMP cycle (Table 6, Figures 12–17). For instance, good or better self-rated health was highest among persons aged 18–24 years (86%) and lowest among persons who inject drugs (61%). Unmet needs for services from a mental health professional among persons who needed services were highest among persons who inject drugs (37%) and lowest among cisgender Black or African American women (19%). Unstable housing or homelessness was highest among persons who inject drugs (51%) and lowest among MSM (17%). Unemployment was highest among persons who inject drugs (26%) and lowest among MSM (11%). Hunger or food insecurity was highest among persons who inject drugs (44%) and lowest among cisgender Black or African American women (14%). Median HIV stigma score was highest among persons aged 18–24 years (37) and lowest among Black or African American MSM (27).

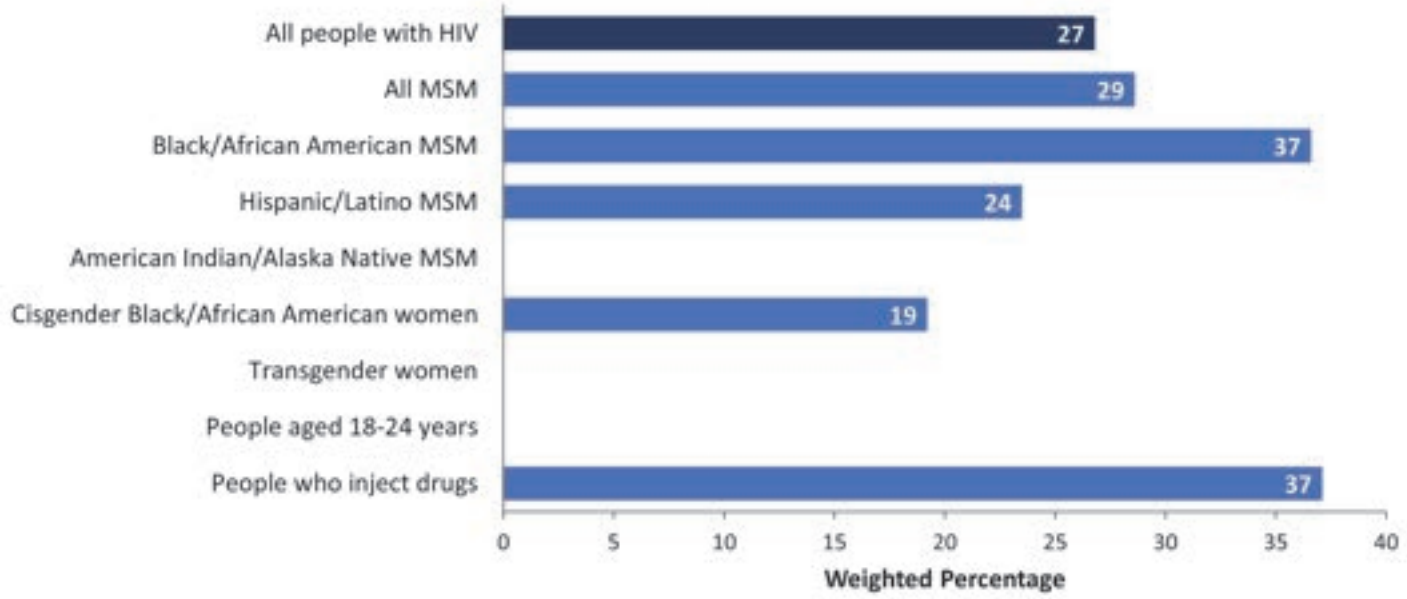


Figure 12. Good or better self-rated health among adults with diagnosed HIV, by NHAS priority population—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MSM, cisgender men who have sex with cisgender men.

Note. "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size < 30.

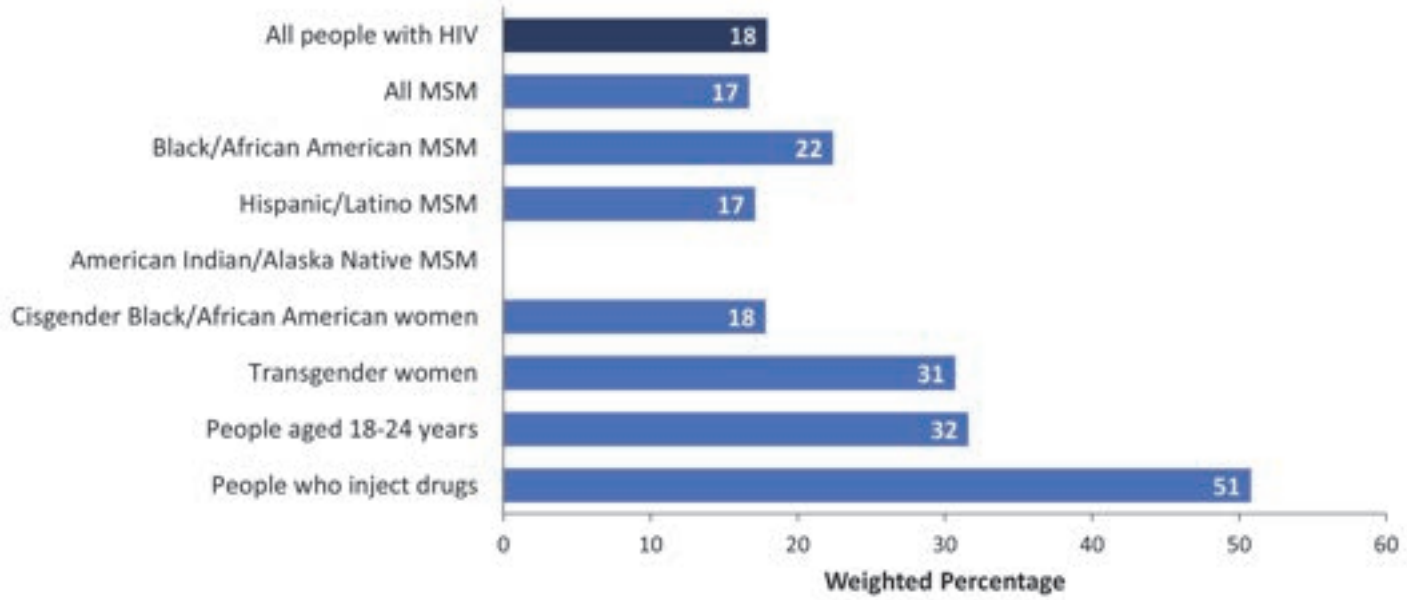

Figure 13. Unmet needs for services from a mental health professional among adults with diagnosed HIV who needed services, by NHAS priority population—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MSM, cisgender men who have sex with cisgender men.

Note. "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size < 30.

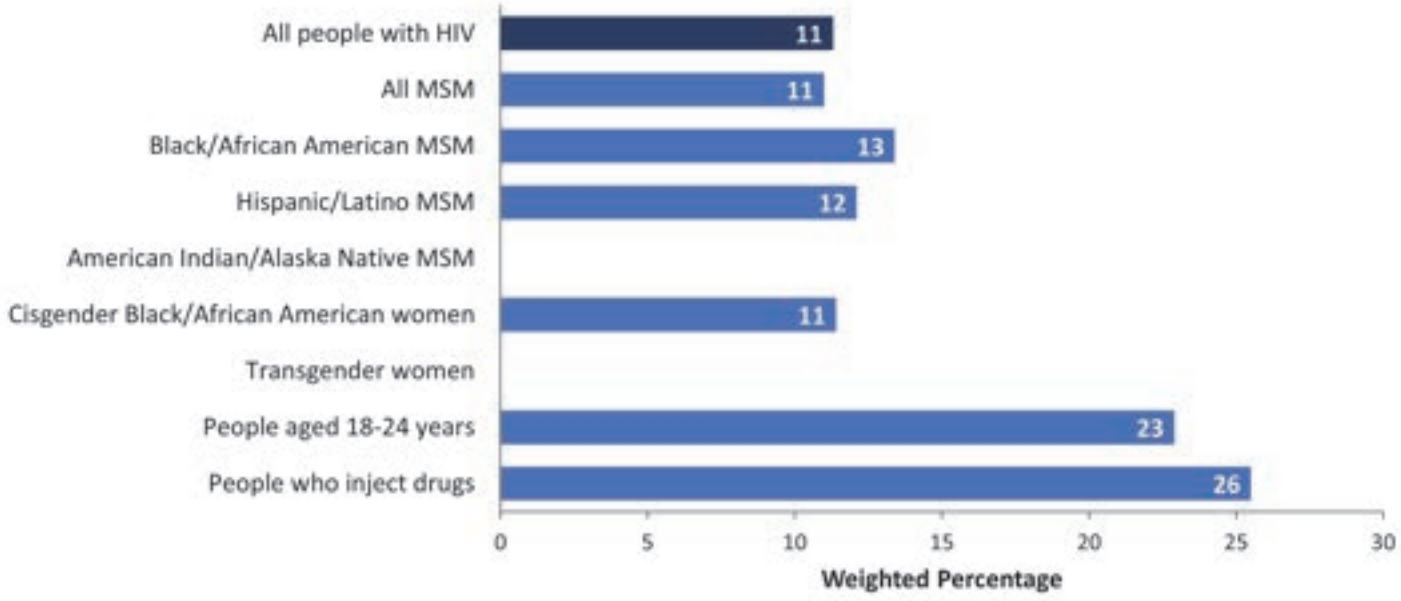

Figure 14. Unstable housing or homelessness among adults with diagnosed HIV, by NHAS priority population—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MSM, cisgender men who have sex with cisgender men.

Note. "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size < 30.

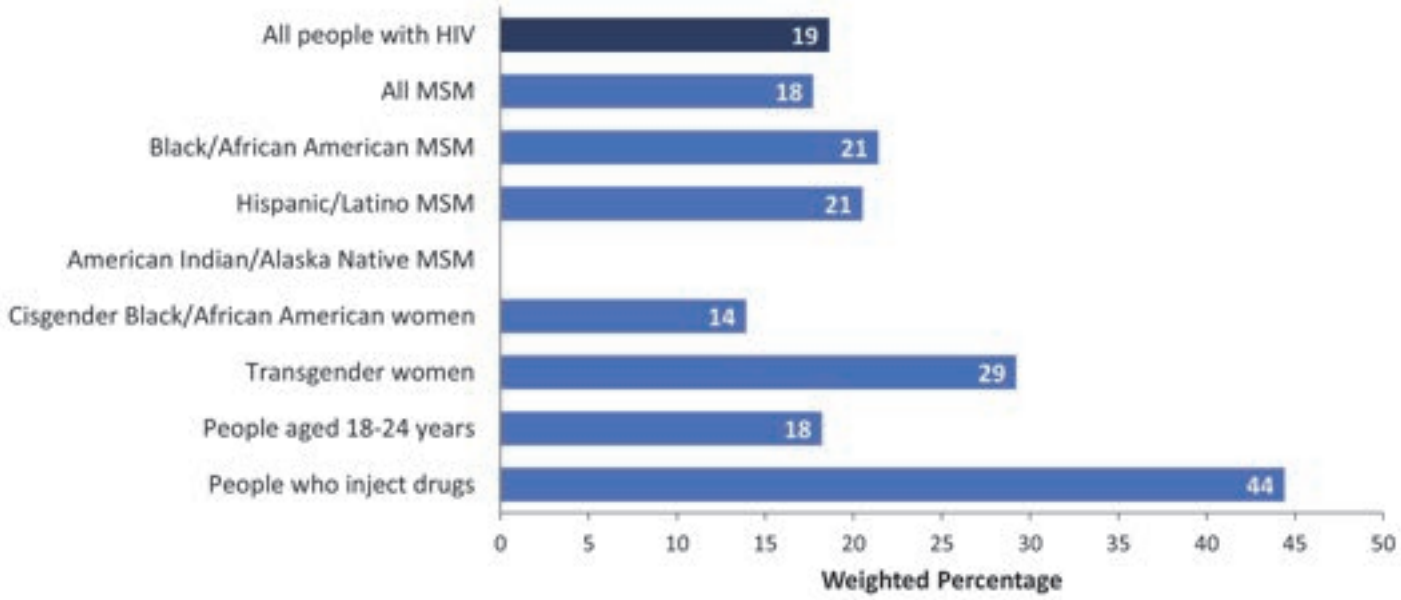

Figure 15. Unemployment among adults with diagnosed HIV, by NHAS priority population—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MSM, cisgender men who have sex with cisgender men.

Note. Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size < 30.

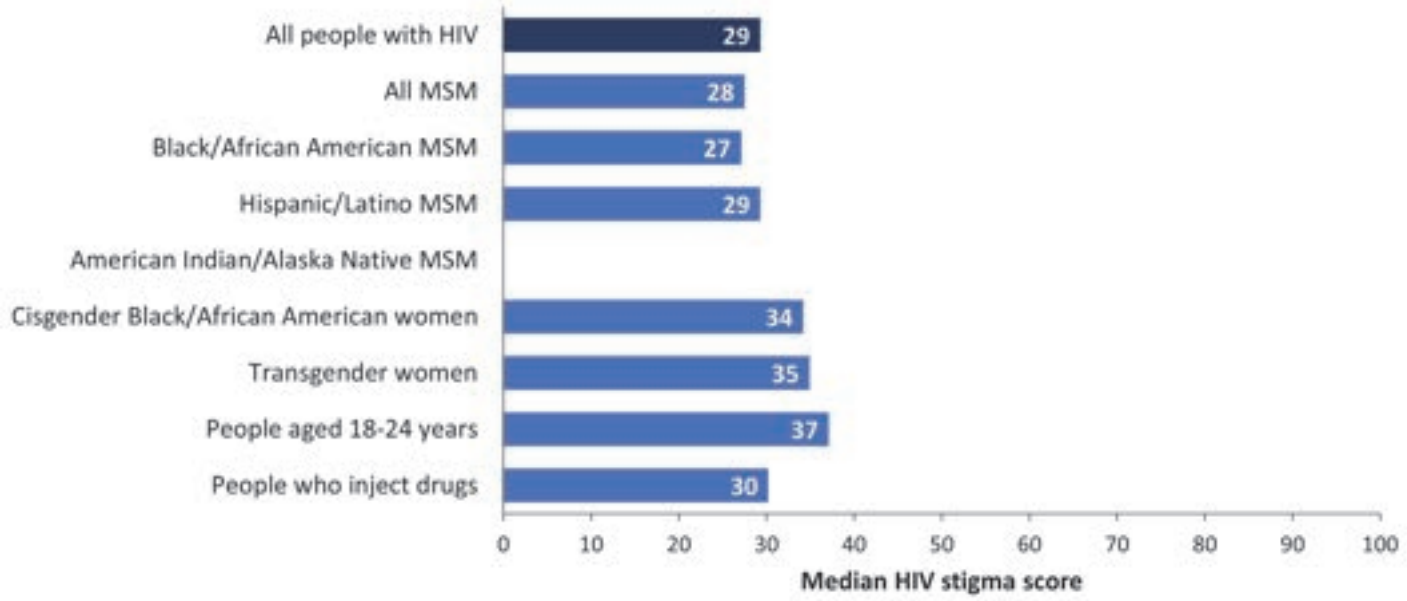

Figure 16. Hunger or food insecurity among adults with diagnosed HIV, by NHAS priority population—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MSM, cisgender men who have sex with cisgender men.

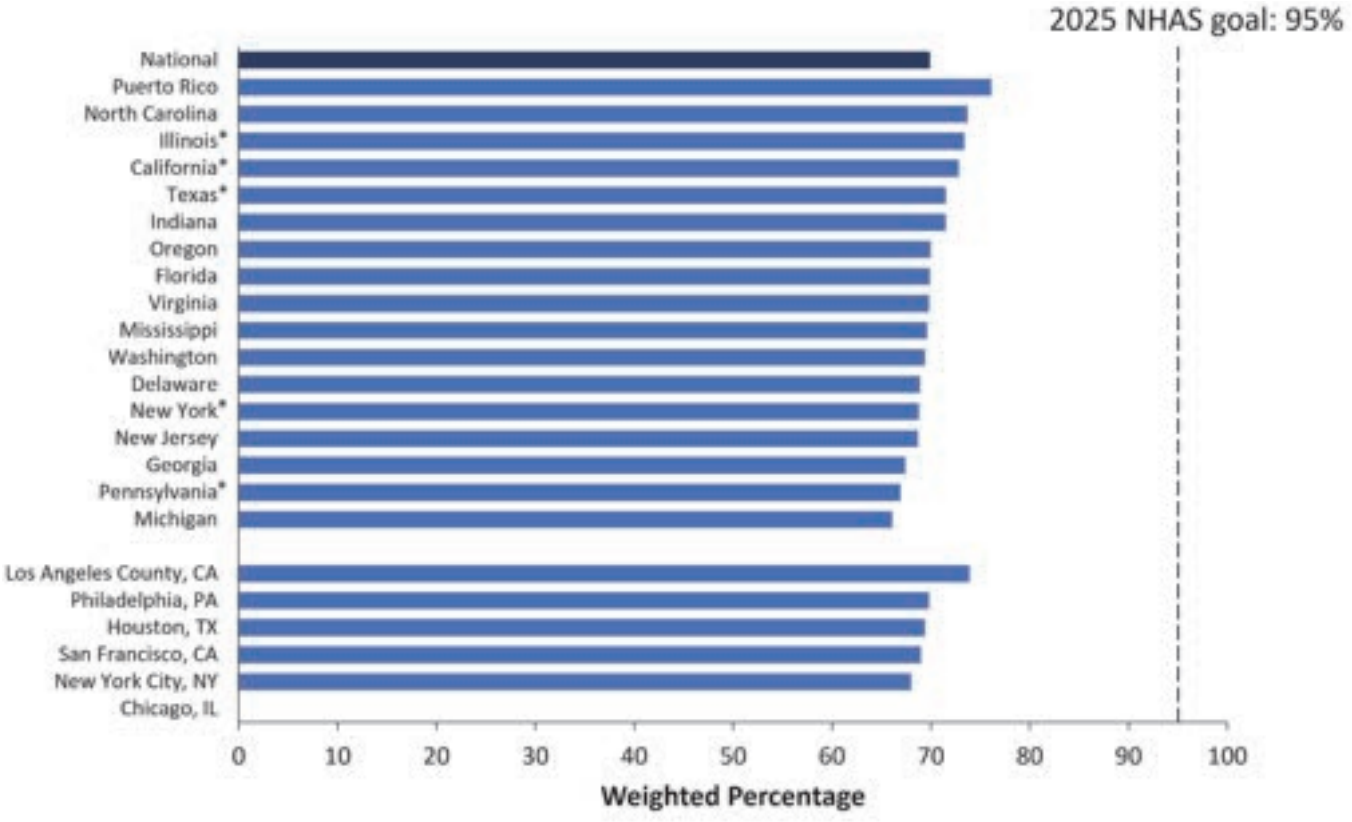
Note. "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size < 30.

Figure 17. Median HIV stigma scores among adults with diagnosed HIV, by NHAS priority population—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MSM, cisgender men who have sex with cisgender men.

Note. "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. Estimates were suppressed if they were based on a denominator sample size <30.

Estimates for other SDOH for each NHAS priority population are presented in Table 6.



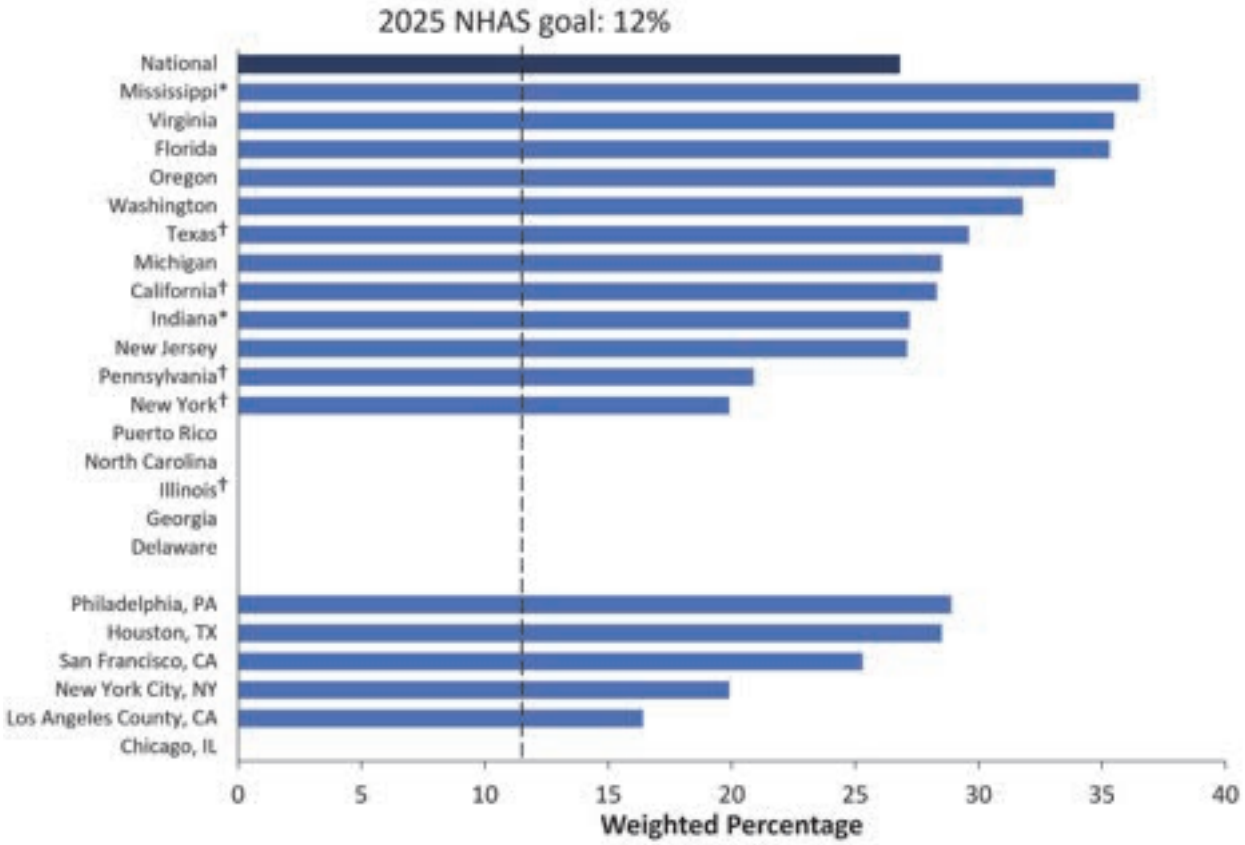
NHAS Indicators by Individual SDOH

During the 2022 MMP cycle, NHAS indicators related to QoL and HIV stigma varied by other SDOH related to economic stability, education, health-related factors, neighborhood and built environment, and social and community context (Table 7).

NHAS Indicators by MMP Jurisdictions

NHAS indicators related to QoL and HIV stigma varied by jurisdiction. During the 2022 MMP cycle, the percentage of persons with good or better self-rated health ranged from 66% in Michigan to 76% in Puerto Rico (Table 8; Figure 18). The percentage of persons with unmet needs for services from a mental health professional during the past 12 months among those who needed them ranged from 16% in Los Angeles County to 37%* in Mississippi (Table 8; Figure 19). The percentage of persons who experienced unstable housing or homelessness during the past 12 months ranged from 8% in Puerto Rico to 25% in Florida (Table 8; Figure 20). Unemployment ranged from 8% in Oregon to 19% in New York City (Table 8; Figure 21). Hunger or food insecurity ranged from 12% in Puerto Rico to 24% in Texas (Table 8; Figure 22). Median HIV stigma scores ranged from 24 in San Francisco to 34 in Michigan (Table 8; Figure 23).

Figure 18. Good or better self-rated health among adults with diagnosed HIV, by jurisdiction—Medical Monitoring Project, United States, 2022

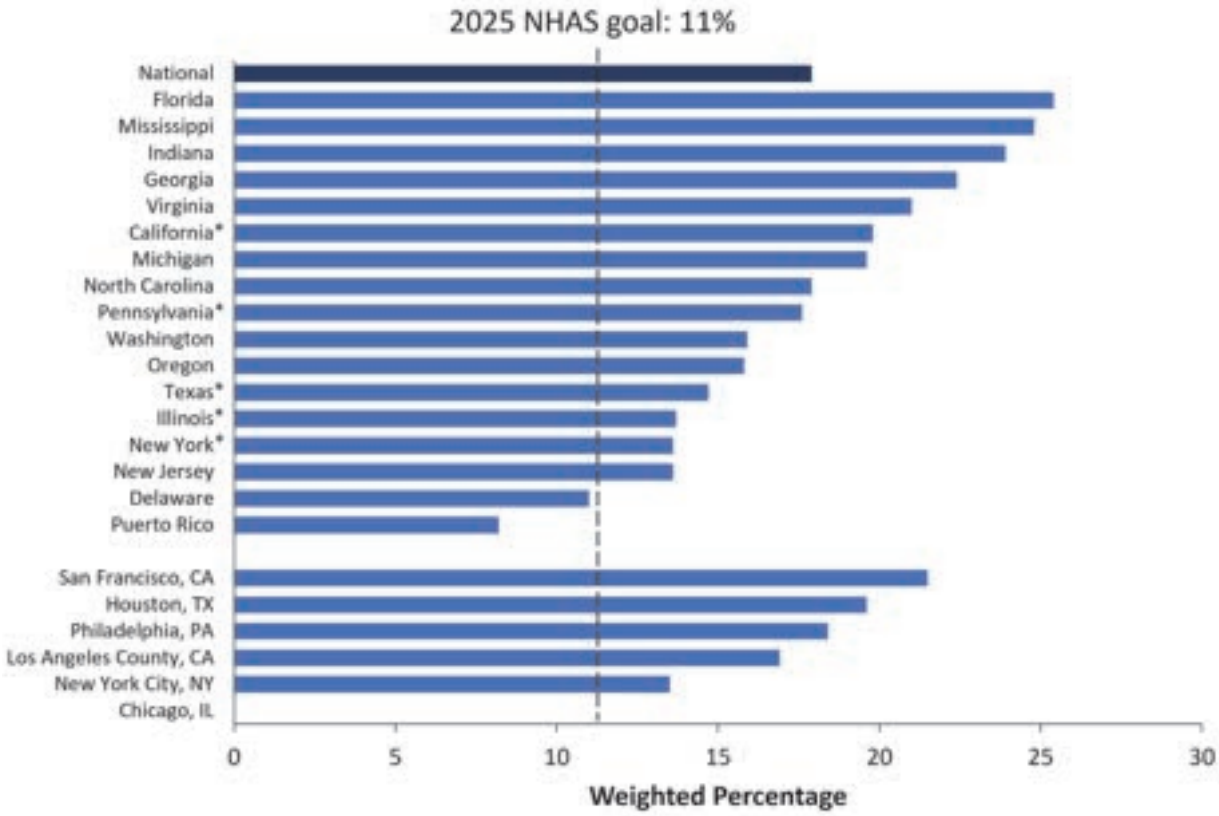


Abbreviations: NHAS, National HIV/AIDS Strategy; MMP, Medical Monitoring Project.

Note. "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30.

* Includes separately funded jurisdictions within each state.

Figure 19. Unmet needs for services from a mental health professional among adults with diagnosed HIV who needed services, by jurisdiction—Medical Monitoring Project, United States, 2022



Abbreviations: NHAS, National HIV/AIDS Strategy; MMP, Medical Monitoring Project.

Note. "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30. Estimates with an absolute CI width >30, estimates with an absolute CI width between 5 and 30 and a relative CI width >130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution.

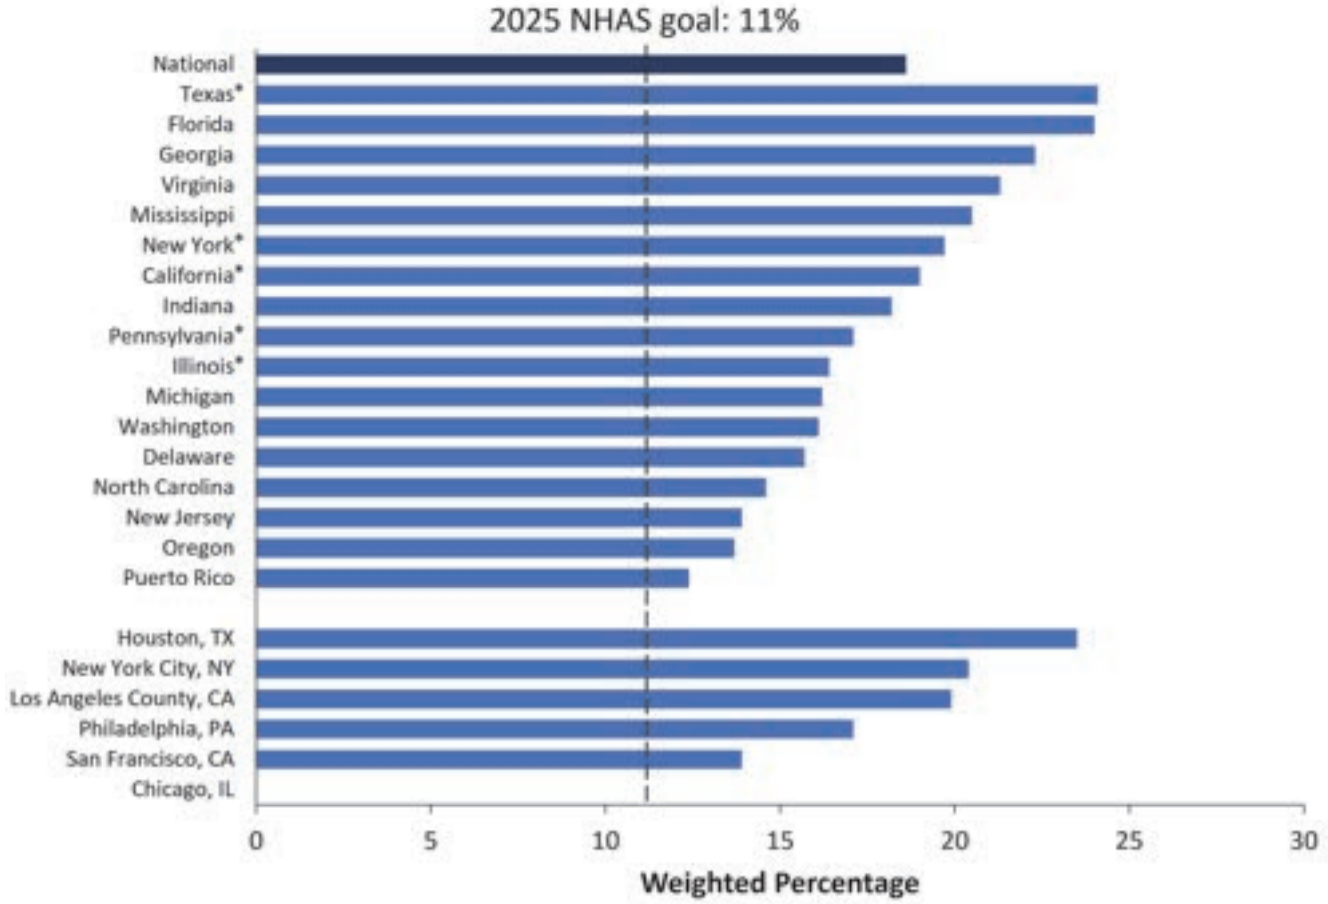
Figure 21. Unemployment among adults with diagnosed HIV, by jurisdiction—Medical Monitoring Project, United States, 2022

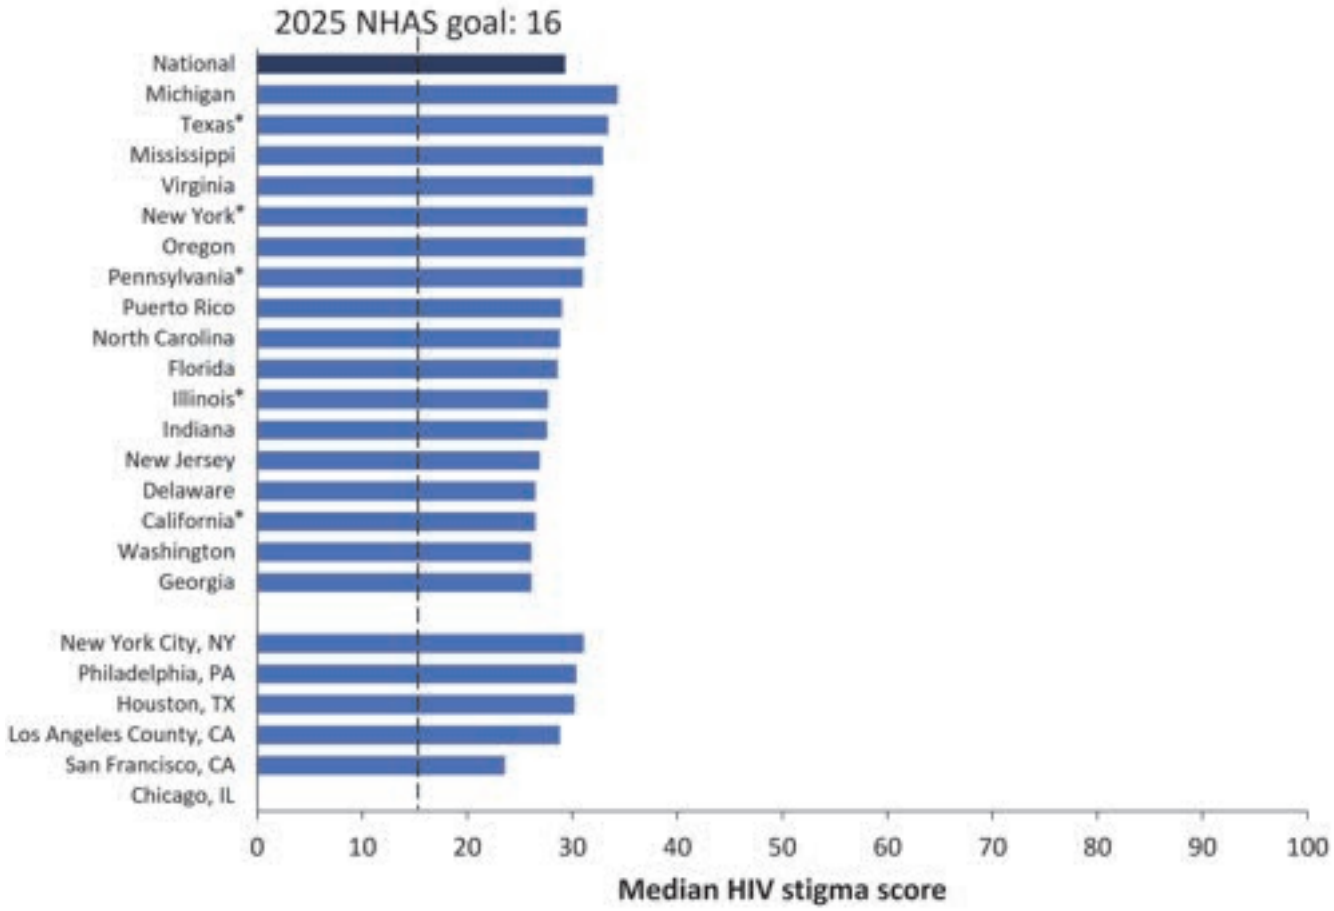


Abbreviations: NHAS, National HIV/AIDS Strategy; MMP, Medical Monitoring Project.

Note. Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30.

* Includes separately funded jurisdictions within each state.

Figure 22. Hunger or food insecurity among adults with diagnosed HIV, by jurisdiction—Medical Monitoring Project, United States, 2022



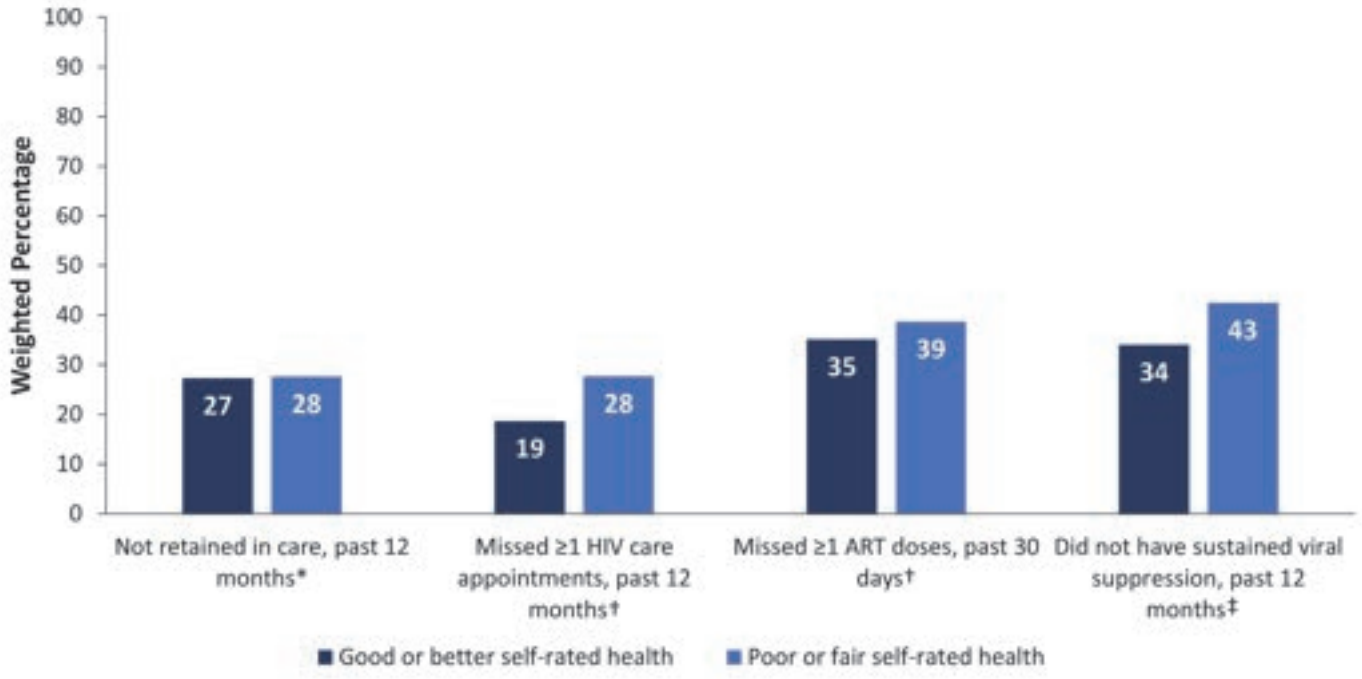
Abbreviations: NHAS, National HIV/AIDS Strategy; MMP, Medical Monitoring Project.

Note. "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months. Estimates were suppressed if they had a coefficient of variation ≥0.30 or were based on a denominator sample size <30.

* Includes separately funded jurisdictions within each state.

Figure 23. Median HIV stigma score among adults with diagnosed HIV, by jurisdiction—Medical Monitoring Project, United States, 2022

Abbreviations: NHAS, National HIV/AIDS Strategy; MMP, Medical Monitoring Project.



Note. "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. Estimates were suppressed if they were based on a denominator sample size <30.

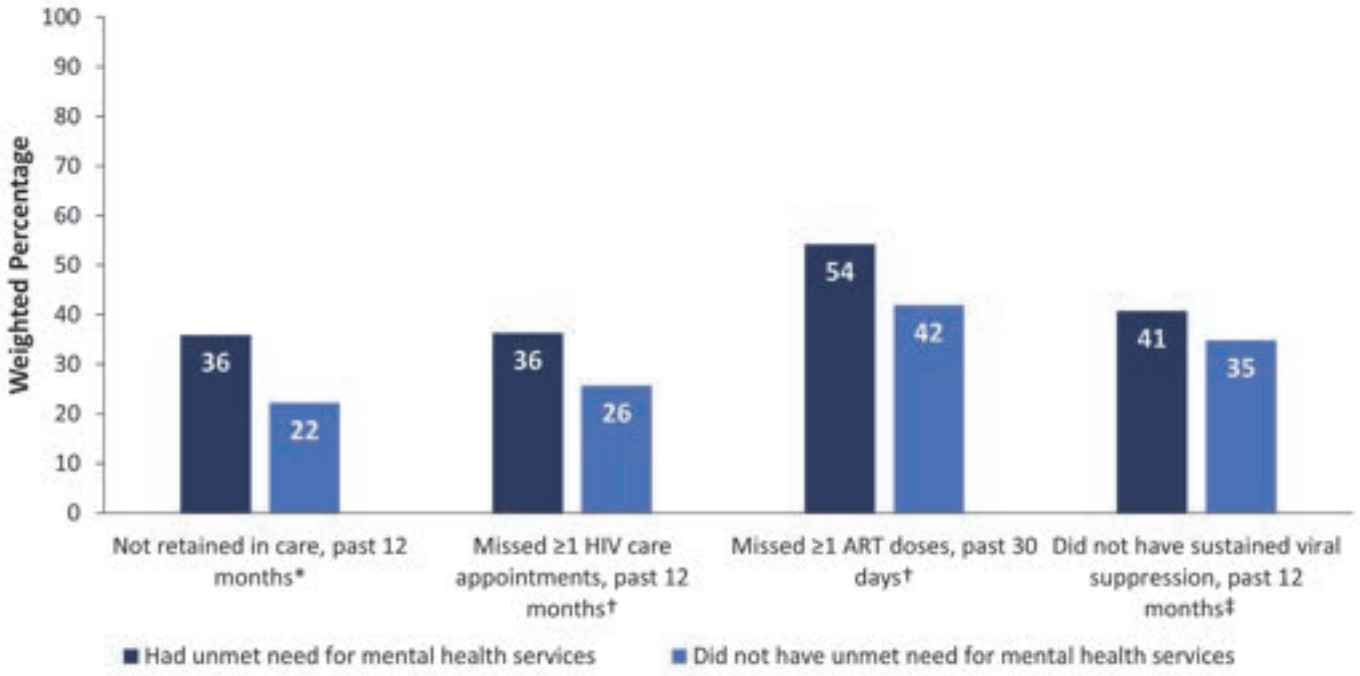
* Includes separately funded jurisdictions within each state.

Prevalence of Adverse HIV Outcomes by NHAS QoL Indicators

The prevalence of not being retained in care was similar among those who had good or better self-rated health (27%) and those who had poor or fair self-rated health (28%) (Table 9; Figure 24). The prevalence of certain adverse HIV outcomes was lower among persons with good or better self-rated health than those with poor or fair self-rated health, including missing ≥1 HIV care appointments during the past 12 months (19% vs. 28%) and not having sustained viral suppression during the past 12 months (34% vs. 43%).

Figure 24. Prevalence of adverse clinical outcomes among adults with diagnosed HIV, by self-rated health—Medical Monitoring Project, United States, 2022

Note. Self-rated health evaluated at the time of interview.



* Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart during the past 12 months.

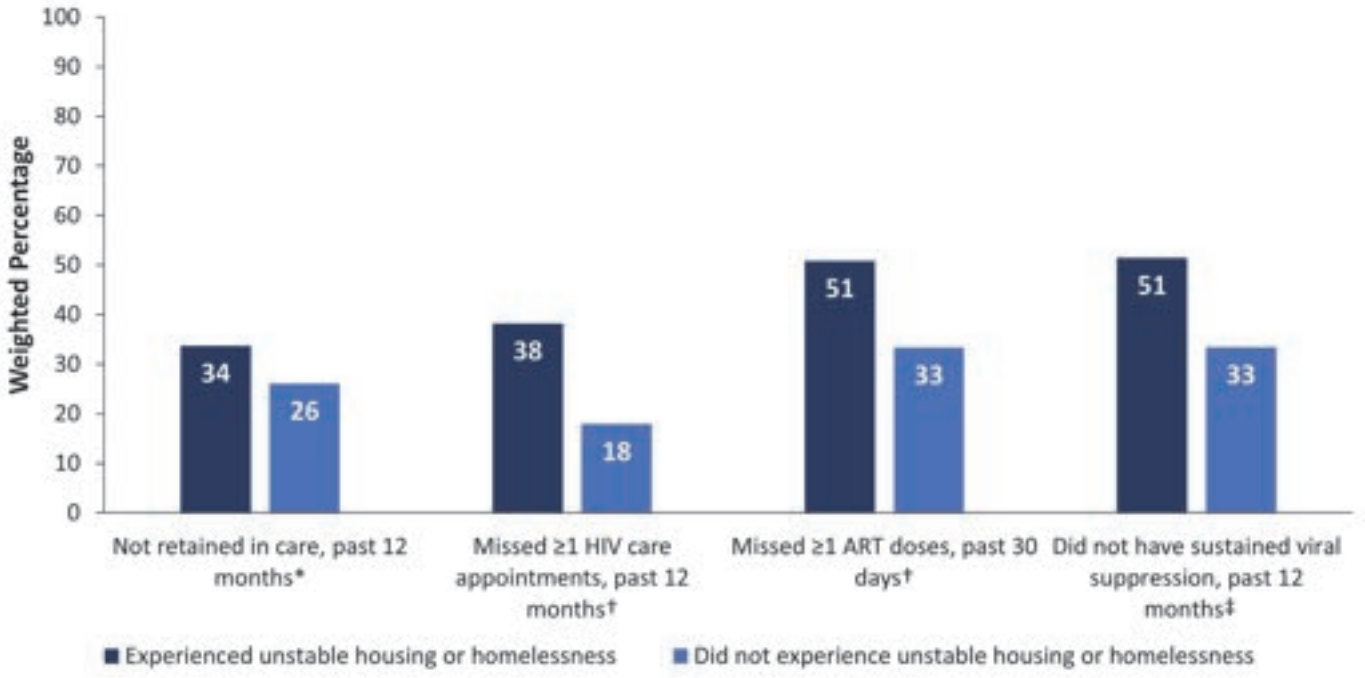
† Based on self-report.

‡ Defined as having ≥1 viral load measurements documented detectable or ≥200 copies/mL during the past 12 months.

The prevalence of certain adverse HIV outcomes was higher among persons with unmet needs for services from a mental health professional among those who needed it than those who did not, including not being retained in care during the past 12 months (36% vs. 22%), missing ≥1 HIV care appointments during the past 12 months (36% vs. 26%), and missing ≥1 ART doses during the past 30 days (54% vs. 42%) (Table 9; Figure 25).

Figure 25. Prevalence of adverse clinical outcomes among adults with diagnosed HIV, by whether or not persons experienced unmet needs for mental health services among those who needed them—Medical Monitoring Project, United States, 2022

Note. "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.



* Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart during the past 12 months.

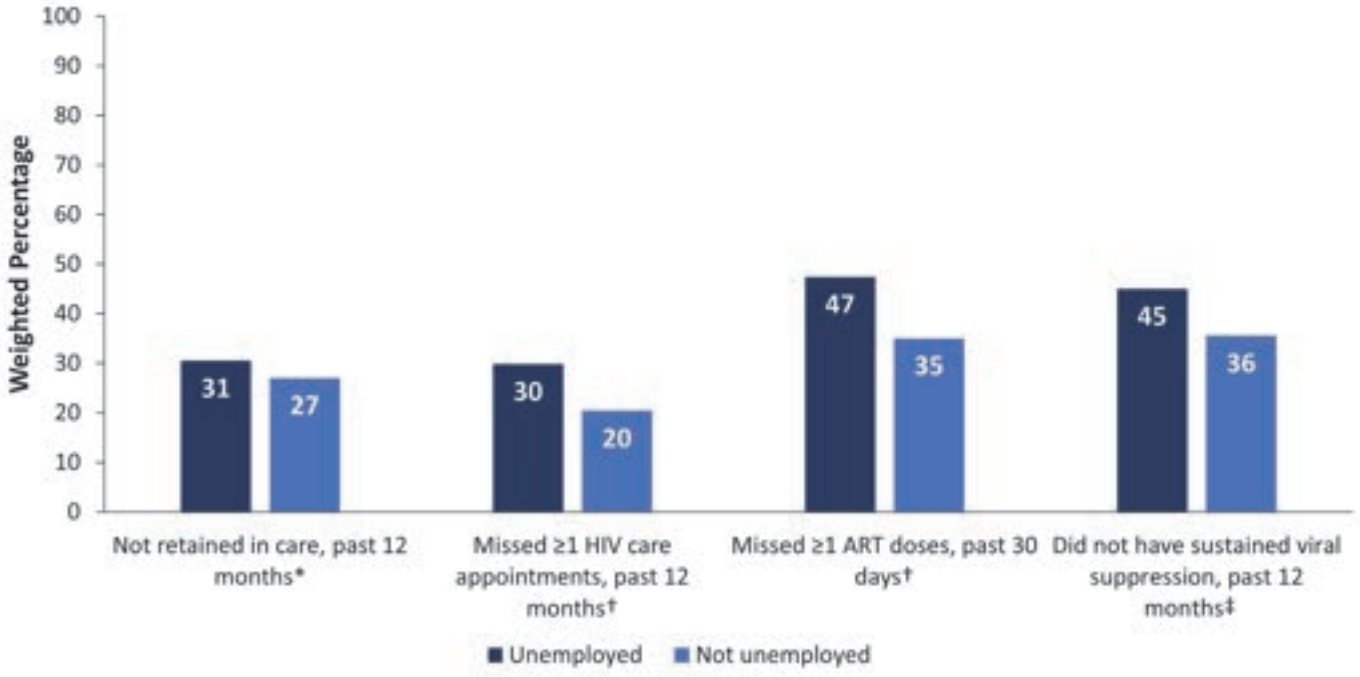
† Based on self-report.

‡ Defined as having ≥1 viral load measurements documented detectable or ≥200 copies/mL during the past 12 months.

The prevalence of certain adverse HIV outcomes was higher among persons who experienced unstable housing or homelessness during the past 12 months than those who did not, including not being retained in HIV care during the past 12 months (34% vs. 26%), missing ≥1 HIV care appointments during the past 12 months (38% vs. 18%), missing ≥1 ART doses during the past 30 days (51% vs. 33%), and not having sustained viral suppression during the past 12 months (51% vs. 33%) (Table 9; Figure 26).

Figure 26. Prevalence of adverse clinical outcomes among adults with diagnosed HIV, by whether or not persons experienced unstable housing or homelessness—Medical Monitoring Project, United States, 2022

Note. "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.



* Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart during the past 12 months.

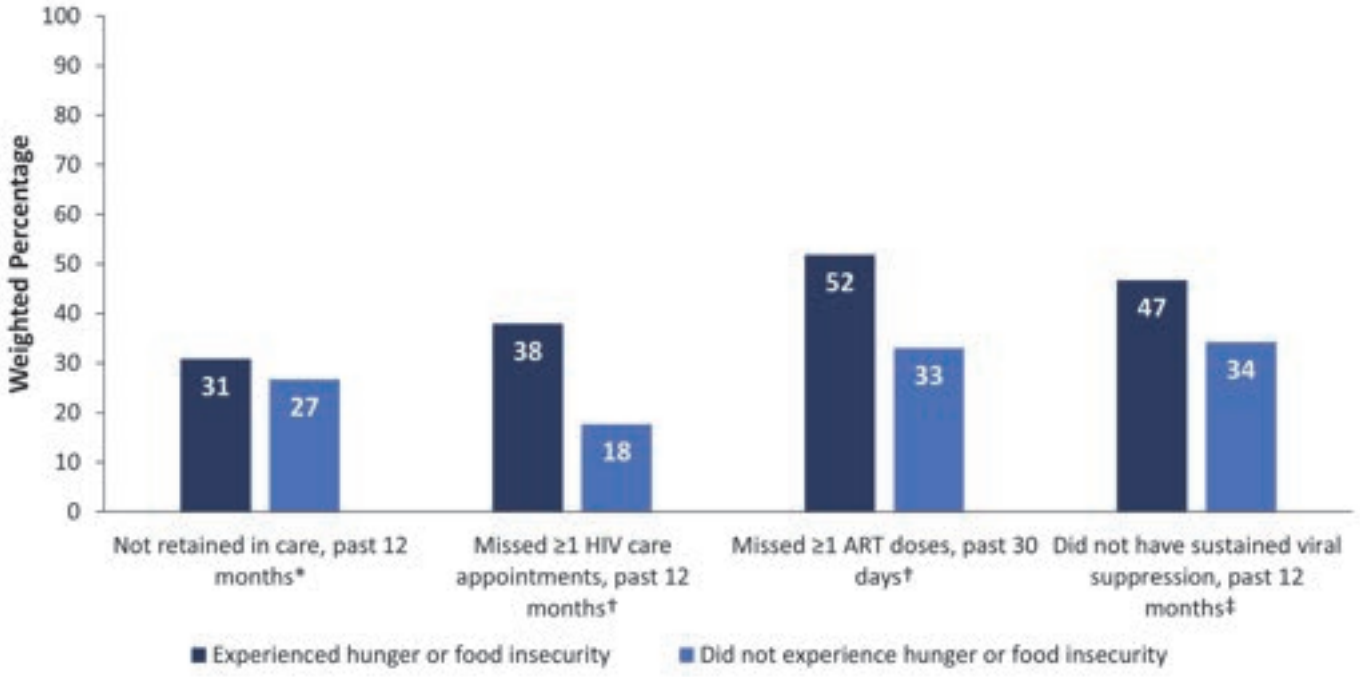
† Based on self-report.

‡ Defined as having ≥1 viral load measurements documented detectable or ≥200 copies/mL during the past 12 months.

The prevalence of certain adverse HIV outcomes was also higher among persons who were unemployed than those who were not, including missing ≥1 HIV care appointments during the past 12 months (30% vs. 20%), missing ≥1 ART doses during the past 30 days (47% vs. 35%), and not having sustained viral suppression during the past 12 months (45% vs. 36%) (Table 9; Figure 27).

Figure 27. Prevalence of adverse clinical outcomes among adults with diagnosed HIV, by whether or not persons were unemployed—Medical Monitoring Project, United States, 2022

Note. Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.



* Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart during the past 12 months.

† Based on self-report.

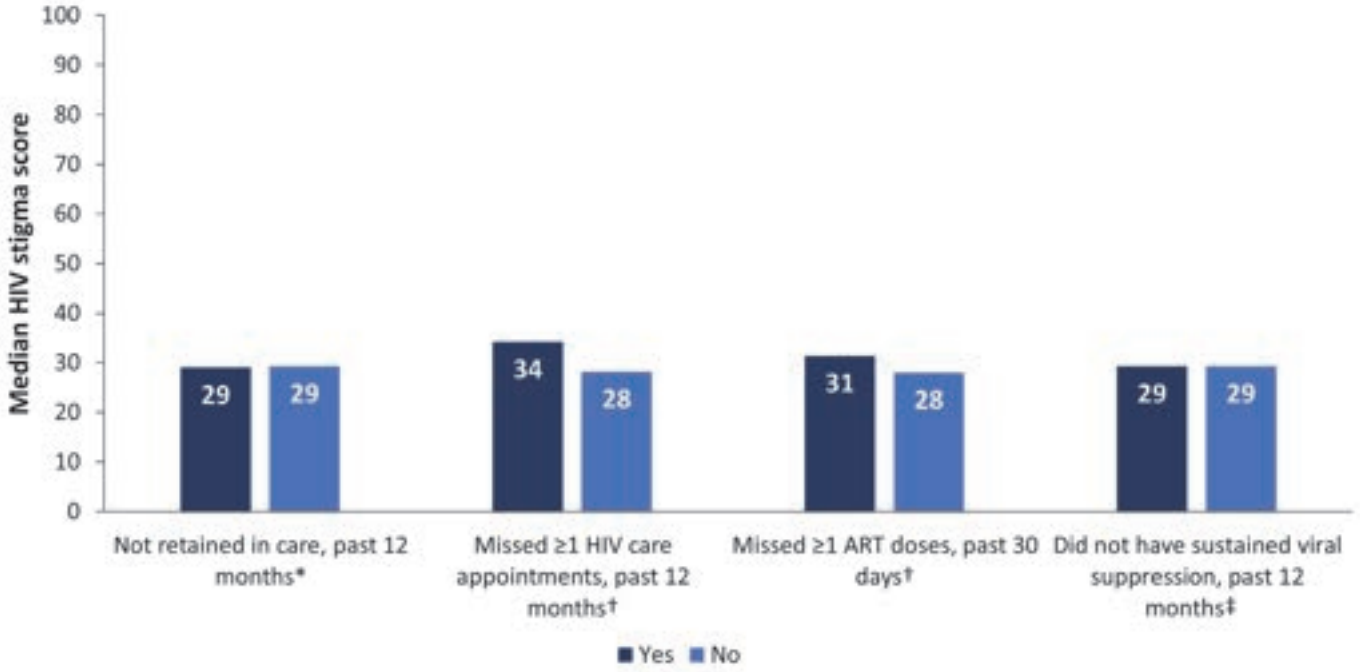
‡ Defined as having ≥1 viral load measurements documented detectable or ≥200 copies/mL during the past 12 months.

The prevalence of certain adverse HIV outcomes was higher among persons who experienced hunger or food insecurity during the past 12 months than those who did not, including missing ≥1 HIV care appointments during the past 12 months (38% vs. 18%), missing ≥1 ART doses during the past 30 days (52% vs. 33%), and not having sustained viral suppression during the past 12 months (47% vs. 34%) (Table 9; Figure 28).

Figure 28. Prevalence of adverse clinical outcomes among adults with diagnosed HIV, by whether or not persons experienced hunger or food insecurity—Medical Monitoring Project, United States, 2022

Note. "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

* Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart during the past 12 months.



† Based on self-report.

‡ Defined as having ≥1 viral load measurements documented detectable or ≥200 copies/mL during the past 12 months.

HIV Stigma by HIV Outcomes

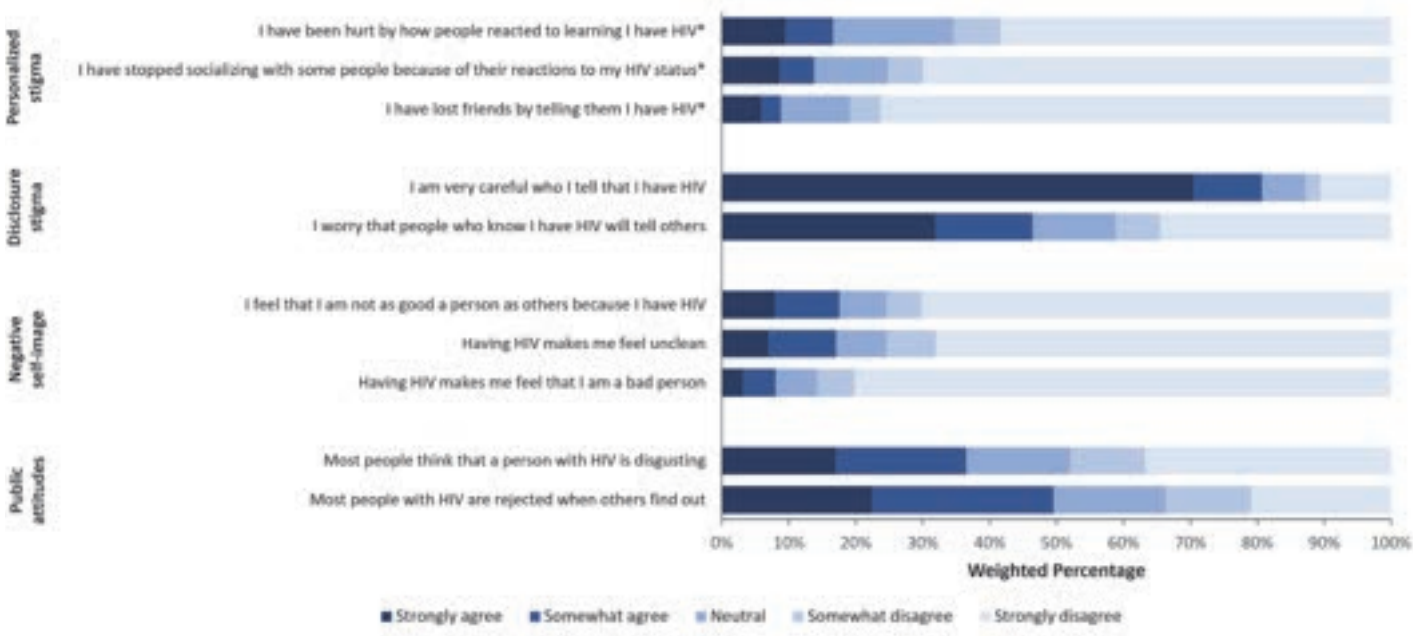
Median HIV stigma scores were higher among those who missed ≥1 HIV care appointments during the past 12 months versus those who did not (34 vs. 28) or missed ≥1 ART doses during the past 30 days versus those who did not (31 vs. 28; Figure 29). Median scores were similar by retention in care (not retained in care: 29, retained in care: 29) and viral suppression status (did not have sustained viral suppression: 29, had sustained viral suppression: 29) (Table 10; Figure 29).

Figure 29. Median HIV stigma scores among adults with diagnosed HIV, by selected HIV outcomes—Medical Monitoring Project, United States, 2022

Note. "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico.

* Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart during the past 12 months.

† Based on self-report.



‡ Defined as having ≥1 viral load measurements documented detectable or ≥200 copies/mL during the past 12 months.

HIV Stigma Scale Responses by Stigma Domain

During 2022, the most highly endorsed "strongly agree" responses to the HIV stigma scale questions were within the disclosure domain (Table 11; Figure 30). Specifically, 70% of PWH strongly agreed with the statement "I am very careful who I tell that I have HIV," and 32% strongly agreed with the statement "I worry that people who know I have HIV will tell others."

During 2022, the most highly endorsed "strongly disagree" responses were within negative self-image and personalized stigma domains. Specifically, 80% of PWH strongly disagreed with the statement "Having HIV makes me feel that I am a bad person, and 76% strongly disagreed with the statement "During the past 12 months, I have lost friends by telling them I have HIV."

Figure 30. Experiences with HIV-related stigma among adults with diagnosed HIV, by domain—Medical Monitoring Project, United States, 2022

* During the past 12 months.

Abbreviations: n, number; col, column; CI, confidence interval; N/A, not applicable; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[h] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city-, county-, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[i] Self-reported, and includes physical, mental, and emotional disabilities.

[j] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[k] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[l] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[m] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: n, number; col, column; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[h] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[i] Self-reported, and includes physical, mental, and emotional disabilities.

[j] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[k] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[l] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[m] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: PR, prevalence ratio; PD, prevalence difference; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. persons aged ≥65 years were the referent group for each disparity assessment. Excluded are prevalence ratios and prevalence differences that are based on estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[h] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[i] Self-reported, and includes physical, mental, and emotional disabilities.

[j] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[k] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[l] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[m] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: n, number; col, column; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30. Estimates with an absolute CI width >30, estimates with an absolute CI width between 5 and 30 and a relative CI width >130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution.

[a] Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender.

[b] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[c] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[d] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[e] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[f] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[g] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[h] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[i] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[j] Self-reported, and includes physical, mental, and emotional disabilities.

[k] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[l] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[m] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[n] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: PR, prevalence ratio; PD, prevalence difference; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Cisgender males were the referent group for each disparity assessment. Excluded are prevalence ratios and prevalence differences that are based on estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30. Prevalence ratios and prevalence differences that are based on one or more estimates with an absolute CI width >30, estimates with an absolute CI width between 5 and 30 and a relative CI width >130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution.

[a] Persons were classified as cisgender if sex at birth and gender reported by the person were the same. Persons were classified as transgender if sex at birth and gender reported by the person were different, or if the person chose "transgender" in response to the question about self-identified gender.

[b] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[c] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[d] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[e] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[f] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[g] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[h] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[i] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[j] Self-reported, and includes physical, mental, and emotional disabilities.

[k] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[l] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[m] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[n] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: n, number; col, column; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[h] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[i] Self-reported, and includes physical, mental, and emotional disabilities.

[j] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[k] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[l] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[m] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: PR, prevalence ratio; PD, prevalence difference; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Gay or lesbian persons were the referent group for each disparity assessment. Excluded are prevalence ratios and prevalence differences that are based on estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[h] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[i] Self-reported, and includes physical, mental, and emotional disabilities.

[j] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[k] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[l] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[m] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: n, number; col, column; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30. Estimates with an absolute CI width >30, estimates with an absolute CI width between 5 and 30 and a relative CI width >130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution.

[a] Hispanic or Latino persons can be of any race. Persons are classified in only 1 race/ethnicity category.

[b] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[c] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[d] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[e] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[f] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[g] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[h] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[i] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[j] Self-reported, and includes physical, mental, and emotional disabilities.

[k] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[l] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[m] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[n] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: PR, prevalence ratio; PD, prevalence difference; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. White persons were the referent group for each disparity assessment. Due to sample size issues with other racial/ethnic groups, disparities could only be assessed for Black/African American persons and Hispanic/Latino persons, versus White persons. Excluded are prevalence ratios and prevalence differences that are based on estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] Hispanic or Latino persons can be of any race. Persons are classified in only 1 race/ethnicity category.

[b] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[c] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[d] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[e] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[f] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[g] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[h] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[i] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[j] Self-reported, and includes physical, mental, and emotional disabilities.

[k] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[l] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[m] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[n] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: MSM, men who have sex with men; AI/AN, American Indian/Alaska Native; n, number; col, column; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30. Estimates with an absolute CI width >30, estimates with an absolute CI width between 5 and 30 and a relative CI width >130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution.

[a] Includes cisgender men with diagnosed HIV who reported having sex with ≥1 cisgender men in the past 12 months (among persons who had sex during the past 12 months) and cisgender men with diagnosed HIV who reported identifying as gay or bisexual (among those who did not have sex during the past 12 months).

[b] Includes MSM with diagnosed HIV who identified as non-Hispanic/Latino Black/African American race/ethnicity.

[c] Includes MSM who identified as Hispanic/Latino race/ethnicity. Hispanic or Latino MSM can be of any race.

[d] Includes MSM who identified as American Indian/Alaska Native race/ethnicity.

[e] Includes cisgender women with diagnosed HIV who identified as non-Hispanic Black/African American race/ethnicity.

[f] Persons with diagnosed HIV were classified as transgender women if the person reported that their sex assigned at birth was male but identified as female or transgender.

[g] Priority population for youths includes persons with diagnosed HIV aged 13–24 years; however, data from MMP are only available and presented for persons aged 18–24 years.

[h] Includes persons with diagnosed HIV who reported injecting drugs during the past 12 months.

[i] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[j] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[k] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[l] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[m] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[n] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[o] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[p] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[q] Self-reported, and includes physical, mental, and emotional disabilities.

[r] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[s] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[t] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on seven forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[u] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: n, number; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; HHS, U.S. Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[h] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance includes Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[i] Self-reported, and includes physical, mental, and emotional disabilities.

[j] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[k] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[l] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on 7 forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[m] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Abbreviations: n, number; CI, confidence interval.

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages. Excluded are estimates with a coefficient of variation ≥0.30 and those based on a denominator sample size <30. Estimates with an absolute CI width >30, estimates with an absolute CI width between 5 and 30 and a relative CI width >130%, and estimates of 0% or 100% are marked with an asterisk (*) and should be interpreted with caution.

[a] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[b] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[c] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[d] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[e] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[f] "Median HIV stigma score" defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is available at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2001277/ [Wright K, Naar-King S, Lam P, Templin T, Frey M. Stigma scale revised: reliability and validity of a brief measure of stigma for HIV+ youth. *J Adolesc Health* 2007;40(1):96–98].

[g] States include separately funded jurisdictions within those states.

Abbreviations: n, number; CI, confidence interval; FPL, federal poverty level; RWHAP, Ryan White HIV/AIDS Program; CD4, CD4+ T-lymphocyte count (cells/mm^3 or cells/μL) or percentage [footnotes only]; ART, antiretroviral therapy [footnotes only]; PCP, *Pneumocystis* pneumonia [footnotes only]; MAC, *Mycobacterium avium* complex [footnotes only]; ADAP, AIDS Drug Assistance Program [footnotes only]; SNAP, Supplemental Nutrition Assistance Program [footnotes only]; WIC, Special Supplemental Nutrition Program for Women, Infants, and Children [footnotes only]; HHS, Department of Health and Human Services [footnotes only]; VA, Veterans Administration [footnotes only].

Note. Unweighted numbers and weighted percentages are presented. CIs incorporate weighted percentages.

[a] Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart in the past 12 months. Outpatient care was defined as any documentation of the following: encounter with an HIV care provider, viral load test result, CD4 test result, HIV resistance test or tropism assay, ART prescription, PCP prophylaxis, or MAC prophylaxis.

[b] Based on self-report.

[c] Defined as having most recent viral load documented in medical record as detectable or ≥200 copies/mL

[d] Defined as having ≥1 viral load measurements documented as detectable or ≥200 copies/mL

[e] Defined as needing, but not receiving, ≥1 HIV ancillary services related to HIV support (i.e., HIV case management, medicine through ADAP, adherence support, patient navigation, HIV peer group support), non-HIV medical services (i.e., dental care, mental health services, drug or alcohol counseling or treatment, domestic violence services), or subsistence services (i.e., SNAP or WIC, meal or food services, transportation assistance, shelter or housing services). Calculated among all persons.

[f] "Good or better self-rated health" defined as rating one's health as good, very good, or excellent (as opposed to poor or fair) at the time of interview.

[g] "Unmet need for mental health services from a mental health professional" defined as needing, but not receiving, services from a mental health professional among those who indicated needing mental health services (i.e., receiving or needing but not receiving) during the past 12 months.

[h] "Unstable housing or homelessness" defined as experiencing unstable housing (i.e., moving in with others due to financial issues, moving 2 or more times, or being evicted) or homelessness (living on the street, in a shelter, in a single-room–occupancy hotel, or in a car) at any time during the past 12 months.

[i] Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV.

[j] "Hunger/food insecurity" defined as going without food due to lack of money during the past 12 months.

[k] Poverty guidelines defined by HHS. For persons interviewed in a particular calendar year, the HHS poverty guidelines from the previous year were used. For instance, the 2020 guidelines were used for persons interviewed in 2021. More information regarding HHS poverty guidelines can be found at https://aspe.hhs.gov/frequently-asked-questions-related-poverty-guidelines-and-poverty.

[l] Persons could select more than 1 response for health insurance or coverage. Mutually exclusive categories are presented based on responses. Private coverage defined as receiving health insurance through a person's employer or a family member's employer or purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance included Medicaid, Medicare, VA, RWHAP, or other city, county, or state-funded insurance. Uninsured or RWHAP only category includes those who did not report having any insurance, or received RWHAP assistance only, without coverage through any other insurance categories.

[m] Self-reported, and includes physical, mental, and emotional disabilities.

[n] Represents those who needed, but did not receive, ≥1 HIV ancillary services, among all persons.

[o] Represents those who needed transportation assistance, regardless of whether that assistance was received, among all persons.

[p] HIV health care discrimination among those who received HIV care during the previous 12 months was assessed based on seven forms of discrimination, including: being treated with less courtesy than other persons, being treated with less respect than other persons, receiving poorer service than others, having a doctor or nurse act as if he or she believed they were not smart, having a doctor or nurse act as if he or she were afraid of them, having a doctor or nurse act as if he or she were better than them, and having a doctor or nurse not listen to what they were saying. Respondents were asked if they experienced these forms of discrimination never, rarely, some of the time, most of the time, or all the time. Respondents who reported experiencing at least one form of health care discrimination rarely, some of the time, most of the time, or all of time were considered to have experienced discrimination in an HIV health care setting.

[q] Physical violence by an intimate partner defined as ever being slapped, punched, shoved, kicked, choked, or otherwise physically hurt by a romantic or sexual partner. Forced sex defined as ever being threatened with harm or physically forced to have unwanted vaginal, anal, or oral sex.

Table 10. Median HIV stigma scores by key clinical outcomes among adults with diagnosed HIV—Medical Monitoring Project, 2022

	n	Median score	95% CI
Not retained in care, past 12 months[a]			
Yes	682	29.0	(26.3–31.8)
No	2,534	29.3	(28.1–30.6)
Missed ≥1 HIV care appointments, past 12 months[b]			
Yes	668	34.2	(29.9–38.4)
No	2,635	28.2	(26.7–29.7)
Missed ≥1 ART doses, past 30 days[b]			
Yes	1,160	31.4	(29.8–33.1)
No	2,054	28.0	(26.5–29.4)
Virally unsuppressed at last test, past 12 months[c]			
Yes	865	29.2	(26.3–32.1)
No	2,454	29.4	(28.3–30.5)
Did not have sustained viral suppression, past 12 months[d]			
Yes	1,005	29.3	(26.6–32.0)
No	2,314	29.3	(28.2–30.4)
Had ≥1 unmet needs for HIV ancillary services, past 12 months[e]			
Yes	1,579	34.1	(32.4–35.8)
No	1,736	25.5	(23.7–27.4)
Had ≥1 emergency room visits, past 12 months			
Yes	1,296	31.8	(28.6–34.9)
No	2,012	28.2	(26.8–29.5)
Had ≥1 hospitalizations, past 12 months

Abbreviation: n, number; CI, confidence interval; ART, antiretroviral therapy; CD4, CD4+ T-lymphocyte count (cells/mm^3 or cells/μL) or percentage [footnotes only]; PCP, *Pneumocystis* pneumonia [footnotes only]; MAC, *Mycobacterium avium* complex [footnotes only]; ADAP, AIDS Drug Assistance Program [footnotes only]; SNAP, Supplemental Nutrition Assistance Program [footnotes only]; WIC, Special Supplemental Nutrition Program for Women, Infants, and Children [footnotes only].

Note. Unweighted numbers and weighted median scores are presented. CIs incorporate weighted medians.

HIV stigma scores were based on a 10-item scale that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about people living with HIV.

[a] Defined as not having 2 or more elements of outpatient HIV care at least 90 days apart in each 12-month period. Outpatient care was defined as any documentation of the following: encounter with an HIV care provider, viral load test result, CD4 test result, HIV resistance test or tropism assay, ART prescription, PCP prophylaxis, or MAC prophylaxis.

[b] Based on self-report.

[c] Defined as having most recent viral load documented in medical record as detectable or ≥200 copies/mL.

[d] Defined as having ≥1 viral load measurements documented as detectable or ≥200 copies/mL.

[e] Defined as needing, but not receiving, ≥1 HIV ancillary services related to HIV support (i.e., HIV case management, medicine through ADAP, adherence support, patient navigation, HIV peer group support), non-HIV medical services (i.e., dental care, mental health services, drug or alcohol counseling or treatment, domestic violence services), or subsistence services (i.e., SNAP or WIC, meal or food services, transportation assistance, shelter or housing services). Calculated among all persons.

Technical Notes & Appendix

TECHNICAL NOTES

Population of Inference

For the 2022 Medical Monitoring Project (MMP) data collection cycle (data collected June 1, 2022–May 31, 2023), the population of inference was adults with diagnosed HIV (aged ≥18 years) living in the United States.

A total of 23 areas were funded to conduct data collection for the 2022 cycle: California (including the separately funded jurisdictions of Los Angeles County and San Francisco), Delaware, Florida, Georgia, Illinois (including the separately funded jurisdiction of Chicago), Indiana, Michigan, Mississippi, New Jersey, New York (including the separately funded jurisdiction of New York City), North Carolina, Oregon, Pennsylvania (including the separately funded jurisdiction of Philadelphia), Puerto Rico, Texas (including the separately funded jurisdiction of Houston), Virginia, and Washington.

Data Collection

Persons with diagnosed HIV were sampled for MMP by using data from the National HIV Surveillance System (NHSS). Sampled persons were recruited by mail, by telephone, or in person. To be eligible to be included in MMP's 2022 data cycle, the person had to be, as of December 31, 2021: living with diagnosed HIV infection, aged ≥18 years, and residing in an MMP project area. The participant eligibility criteria were the same in all participating project areas.

A trained interviewer conducted an interview via telephone, in-person, or video format. English and Spanish versions of the questionnaire were used in the 2022 cycle. Persons speaking a language other than English or Spanish were offered an interview in their native language if an interpreter was available.

Persons who agreed to participate were offered an interview over the telephone or in person or video in a private location (e.g., at home or in a clinic). The interview (approximately 40 minutes) included questions about demographic characteristics, social determinants of health, health care use, met and unmet needs for ancillary services, sexual behavior, symptoms of depression and anxiety, gynecologic and reproductive history, substance use, and use of HIV/STD prevention services. Respondents were given a token of appreciation of no more than $50 in cash or the equivalent for participation; type of token differed by project area according to local considerations.

After the interview, MMP staff abstracted clinical data from the medical records of respondents at the health care facility identified by the respondents as their most frequent source of HIV care. Abstracted information included diagnoses of AIDS-defining conditions, prescription of antiretroviral therapy (ART) medications, laboratory results, and health care use in the 24 months before the interview.

For further technical details, please see the appendix.

APPENDIX

Methods

The Medical Monitoring Project (MMP) uses a stratified, 2-stage sampling design. States were sampled first, with probability proportional to size (PPS). All 50 states, the District of Columbia, and Puerto Rico (defined as primary sampling units [PSUs]) were eligible for selection.

From these 52 PSUs, 20 were selected by using PPS sampling based on AIDS prevalence at the end of 2002. According to the PPS sampling method, states with a higher AIDS prevalence had a higher probability of selection, and those with a lower AIDS prevalence had a lower probability of selection [1, 2]. Six municipal jurisdictions receive separate funding for HIV surveillance (Chicago, Illinois; Houston, Texas; Los Angeles County, California; New York City, New York; Philadelphia, Pennsylvania; and San Francisco, California); these areas were included with the state for first-stage sampling and constituted a city-state unit. If a state included a city with independent HIV surveillance authority (e.g., Texas, which includes Houston), selection of the state included selection of the city (i.e., city-state units were selected together).

In 2004, 19 states (including the 6 separately funded areas within those states) and Puerto Rico were selected from the 52 PSUs, resulting in 26 MMP project areas. Because of funding constraints for the 2009 data collection cycle, 3 project areas (Maryland, Massachusetts, and South Carolina) were randomly selected to discontinue participation in MMP, and the total number of MMP areas was reduced to 23.

Analyses carried out in 2014 and subsequently in 2021 found that the original measure of size with which states were originally sampled (i.e., AIDS prevalence in 2002) was still a reasonable proxy for the distribution of HIV prevalence. The selected sample of states was still sufficiently representative of the population of persons with diagnosed HIV; consequently, selecting a new sample for the 2015 and subsequent data collection cycles was unwarranted. In addition, the change in the sampling frame and the availability of national totals from the National HIV Surveillance System (NHSS) presented new options for calibrating weights, further lessening the need for any adjustments to the sample of states.

At the second stage, persons with a reported diagnosis in NHSS were sampled after the selection of the states. The sampling frame was the national case surveillance data set containing records submitted to the Centers for Disease Control and Prevention (CDC) as of December 31, 2021. Using NHSS data, the initial national frame dataset was created for persons who were alive, had diagnosed HIV infection, were aged 18 years or older, and were living in the United States, the District of Columbia, or Puerto Rico on the sampling date (i.e., December 31, 2021). Each case was assigned to a surveillance jurisdiction based on the most recently reported residence in NHSS. These addresses primarily came from case report forms and HIV-related laboratory reports. From this initial national frame, CDC staff drew simple random samples for each of the 23 project areas; project area staff then linked their samples to local case surveillance systems and extracted contact information for use in locating sampled persons, whom they then attempted to recruit.

Eligibility and Response Classifications

Persons were eligible for participation if, as of the sampling date, they had received a diagnosis of HIV, were aged ≥18 years, were alive, and were a resident of an MMP project area. Sampled persons were presumed to be eligible based on their information in NHSS unless data from another source contradicted this status. Persons were classified into 4 categories: (1) eligible respondents, (2) contacted nonrespondents, (3) nonrespondents who were not contacted, and (4) ineligible persons. These categories were used in calculating final response rates and contact rates following standard formulas [3].

Weighting

Overview

For the 2022 MMP cycle, sets of weights were produced nationally, for the city-state combinations, and for each project area. This report presents national weighted data and, thus, represents all adults with diagnosed HIV infection living in the United States. Nationally, data were weighted based on known probabilities of selection at the state or jurisdiction level and person level and then adjusted for multiplicity and nonresponse. After adjusting for nonresponse, the weights were poststratified to population totals from the NHSS frame. Extreme weights, if present, were trimmed, and the weights were adjusted to the same population totals.

For the weighting process, an updated sampling frame was obtained from NHSS data approximately a year and a half after sampling, during which time additional information reported to NHSS may have become available for sampled persons and additional diagnoses may have been reported. This updated sampling frame added records that would have been eligible if their information had been reported to NHSS on the date the initial sample was drawn; primarily, these were diagnoses that occurred during the year prior to the MMP sampling date (for the 2022 cycle, December 31, 2021). Additionally, some persons were found to have had multiple records at the time of sampling that were later identified as duplicate records. In some cases, updated information indicated that a person originally judged eligible and included on the original frame was ineligible. The updated sampling frame data also provided descriptive information for all sampled persons regardless of response and were the source of data used for nonresponse analysis and weighting.

Adjustments for unequal selection probabilities

The first step in the computation of weights was the calculation of base weights that reflect the sampling design probabilities. The base weight for each sampled person incorporates both the probability of selecting a project area and the probability of selecting a person within a project area. A person who was sampled from one jurisdiction but lived in another area at the time of sampling retained the original base weight. Prior to weighting, such cross-jurisdictional records were grouped with their project area of residence at the time of sampling. This moving of records did not affect the national weights but did affect the project area weight totals, increasing some while decreasing others.

Adjustments for multiplicity

A multiplicity factor was applied to the person weight for persons with records found to be present more than once after the original frame was compared to the updated sampling frame. This factor, which accounts for some persons' multiple opportunities for being sampled, was capped at 2.0 and was applicable for only 30 persons.

Adjustments for nonresponse

A nonresponse adjustment factor was applied to the multiplicity-adjusted base weight based on an analysis of nonresponse. In 2022, updated sampling frame data provided descriptive information about all sampled persons, which was used to assess how these characteristics were associated with nonresponse. The potential predictors of nonresponse were: race/ethnicity, male-to-male sexual contact (MMSC) HIV transmission category, HIV/AIDS disease stage, disease progression measured by most recent viral load test reported to NHSS, time since HIV diagnosis, age of most recent contact information, the person's frequency of receipt of HIV care (as indicated by NHSS records), movement to a different MMP jurisdiction since the time of sampling, non-U.S. birthplace, sex at birth, and age at sampling date. The nonresponse analysis followed a 2-step process. First, a bivariate analysis was conducted to determine which characteristics were potential predictors of nonresponse; then, a multivariate analysis using the significant characteristics from the bivariate analysis was conducted to identify independent predictors of nonresponse. Three significant predictors from this multivariate analysis were used to create weighting classes for the national data. In 2022, the significant predictors of nonresponse were: disease progression measured by the most recent viral load test reported to NHSS, time since HIV diagnosis, and the person's frequency of receipt of HIV care, as indicated by NHSS

records. Within weighting classes, the adjustment factor for nonresponse was the ratio of the sum of the multiplicity-adjusted base weights for eligible sampled cases to the sum of these weights for eligible respondents. The multiplicity adjusted weight within each nonresponse weighting class was then multiplied by the nonresponse adjustment factor to produce the nonresponse adjusted weights.

Poststratification and trimming

Poststratification methods ensure that weighted totals sum to known population totals and, therefore, minimize the potential for biases due to nonresponse and noncoverage. However, poststratification can also add additional variance to the weights. Thus, trimming procedures are used to control weight variability and reduce its impact on survey variances. MMP used an iterative approach that combines poststratification and trimming so that trimmed weights retain their variance-reducing features after poststratification and ensures that poststratified weights add up to known population totals.

The nonresponse adjusted weights were first poststratified to population totals from the updated sampling frame. The poststratification cells were defined by crossing sex at birth, race/ethnicity, and age group. Nationally, there were 32 poststratification cells. Poststratification adjustments were performed within each poststratification cell so that the weighted sum was preserved in each cell. To reduce additional variance added to poststratified weights, cells were collapsed and the need for weight trimming was evaluated. Poststratified cells were collapsed when cells had 2 or fewer respondents or had 5 or fewer respondents with an extreme adjustment factor ($\geq$1.75). The need for trimming was then assessed. If the design effect due to weighting (measured as $1 + CV^2$, where CV is the coefficient of variation of the weights) had exceeded 1.75, we would have capped the weights at the median weight plus 4 times the interquartile range of the weights; where trimming occurred, the weights were redistributed and poststratified again to the population totals. However, no trimming was needed for the 2022 MMP national weights.

Design variables

Nationally, design variables indicating strata and cluster membership for each participating person accounting for the sample design were created. Many project areas were sampled with certainty because of higher AIDS prevalence, and each of these was defined as its own stratum. Elsewhere, strata were created by grouping 2 to 3 project areas (PSUs in the stratified PPS design) that had similar selection probabilities. Among the 23 project areas, 14 were sampled with certainty. The 14 certainty project areas each represent a stratum, and each person within the stratum is a cluster. The remaining 9 noncertainty project areas were grouped to create strata, and each noncertainty project area was a cluster within the stratum. Multiple project areas within certainty states were effectively substrata, and each project area remained its own stratum. For local estimates, variance estimation was conditional on the initial sampling of states as PSUs, meaning that this stage of sampling was ignored. Respondents were treated as having come from a simple random sample with replacement, although the various adjustment factors induced unequal weights.

Definitions

NHAS indicators

- **Good or better self-rated health**: Self-rated health is assessed using a single question that captures the respondent's self-perceived general health at the time of interview using a Likert-type scale with the following responses: poor, fair, good, very good, or excellent. Self-rated health was dichotomized as good or better health (i.e., good, very good, or excellent) versus less than good health (i.e., poor, fair). This measure is also used in several other national initiatives and surveys examining self-rated health among the general U.S. population (e.g., Healthy People 2030, National Health and Nutrition Examination Survey [NHANES], Behavioral Risk Factor Surveillance System [BRFSS]) [4, 5, 6]. The 2025 NHAS target for good or better self-rated health is 95%.

- **Unmet needs for mental health services from a mental health professional among persons who needed services**: This measure was assessed through 2 questions. First, respondents were asked if they saw or talked to a mental health professional (e.g., psychologist, psychiatrist, psychiatric nurse, or clinical social worker) about their health during the past 12 months. Next, they were asked if they needed to see or talk to a mental health professional about their health. The denominator represents persons who needed mental health services (i.e., those with a met or unmet need), and was defined as those who received services (met need) and those who needed, but did not receive, services (unmet need). The numerator represents those who needed, but did not receive, services (unmet need). The 2025 NHAS target for unmet needs for mental health services from a mental health professional among persons who needed services is approximately 12%.
- **Hunger/food insecurity**: Persons who reported being hungry and not eating because there was not enough money for food in the past 12 months were considered to be food insecure. The 2025 NHAS target for hunger/food insecurity is approximately 11%.
- **Unemployment**: Unemployed persons included those who reported being unemployed at the time of interview, excluding persons who are unable to work, calculated among all adults with HIV. The 2025 NHAS target for unemployment is approximately 7%.
- **Unstable housing or homelessness**: Persons were considered to have experienced unstable housing if they reported moving in with others due to financial issues, moving 2 or more times, or being evicted at any time during the past 12 months. Persons were considered to have experienced homelessness if they reported living on the street, in a shelter, in a single-room-occupancy hotel, or in a car during the past 12 months. Persons were considered to have experienced unstable housing or homelessness if they reported any form of unstable housing or homelessness during the past 12 months. The 2025 NHAS target for unstable housing or homelessness is approximately 11%.
- **HIV stigma**: Defined as the weighted median score on a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures 4 dimensions of HIV stigma: personalized stigma during the past 12 months, current disclosure concerns, current negative self-image, and current perceived public attitudes about persons living with HIV, measured among persons aged ≥18 years with diagnosed HIV infection living in the United States and Puerto Rico. The HIV stigma scale used for this indicator is discussed in Wright, et al [7]. The 2025 NHAS target for the median HIV stigma score is approximately 16.

Demographic characteristics and additional social determinants of health

- **Gender**: Categories were cisgender men, cisgender women, and transgender. Respondents were classified as cisgender if sex at birth and gender reported by the person were the same. Respondents were classified as transgender if reported sex at birth and current gender as reported by the respondent were not the same or if the respondent answered “transgender” to the interview question regarding self-identified gender.
- **Race/ethnicity**: Respondents were asked about whether they considered themselves as being of Hispanic, Latino/a, or Spanish origin. They were also asked about racial groups they identified as; respondents could check all categories that applied to them. These data were used to create the following analytic racial/ethnic categories: American Indian/Alaska Native, Asian, Black/African American, Hispanic/Latino, Native Hawaiian/other Pacific Islander, White, and multiple races. Hispanic/Latino persons could be of any race.

NHAS priority populations

- **Gay, bisexual, or other men who had sex with men (MSM)**: Included cisgender men with diagnosed HIV who reported having sex with ≥1 cisgender men in the past 12 months (among persons who had sex during the past 12 months) and cisgender men with diagnosed HIV who reported identifying as gay or bisexual (among those who did not have sex during the past 12 months).
- **Black/African American MSM**: Included MSM with diagnosed HIV who identified as non-Hispanic/Latino Black/African American race/ethnicity.

- **Hispanic/Latino MSM**: Included MSM with diagnosed HIV who identified as Hispanic/Latino race/ethnicity. Hispanic or Latino MSM could be of any race.
- **American Indian/Alaska Native MSM**: Included MSM with diagnosed HIV who identified as American Indian/Alaska Native race/ethnicity.
- **Black/African American cisgender women**: Included cisgender women with diagnosed HIV who identified as non-Hispanic Black/African American race/ethnicity.
- **Transgender women**: Persons with diagnosed HIV were classified as transgender women if the person reported that their sex assigned at birth was male but identified as female or transgender.
- **Persons aged 18–24 years**: Priority population for youths includes persons with diagnosed HIV aged 13–24 years; however, data from MMP are only available and presented for persons aged 18–24 years.
- **Persons who inject drugs**: Included persons with diagnosed HIV who reported injecting drugs for nonmedical purposes during the past 12 months.

Other factors related to social determinants of health

- **Federal poverty guidelines**: Respondents were asked about their combined monthly or yearly household income (in U.S.$) from all sources during the calendar year prior to the interview date. The number of persons meeting the current federal poverty threshold was determined by using the U.S. Department of Health and Human Services poverty guidelines that corresponded to the calendar year for which income was asked. These guidelines are issued yearly for the 48 contiguous states and Washington, D.C., and are an indicator used for determining eligibility for many federal and state programs. The 2021 guidelines were used for respondents interviewed in 2022, and the 2022 guidelines were used for persons interviewed in 2023 [8]. Because the poverty guidelines are not defined for the territory of Puerto Rico, the guidelines for the contiguous states and Washington, D.C., were used for this jurisdiction. Respondents were asked to specify their income range, and household income was assumed to be the midpoint of the income range.
- **Health insurance or coverage (including receipt of Ryan White HIV/AIDS Program [RWHAP] assistance)**: Respondents were asked whether they had health insurance or coverage during the 12 months before interview—including assistance through the RWHAP, a federally-funded comprehensive care program that provides HIV primary care, medications, and essential support services for low-income persons with HIV [9]. Respondents could select more than 1 response for health insurance or coverage. Responses to these questions were combined and categorized as having any private health insurance; having public insurance only; and being uninsured or being covered through RWHAP only. Private insurance included receipt of health insurance through a person's employer or family member's employer, or health insurance purchased through the Health Insurance Marketplace or directly from a health insurance company. Public insurance included Medicaid, Medicare, TRICARE/CHAMPUS, Veterans Administration insurance, and other public health insurance plans. Those who only received RWHAP assistance were considered to not have health insurance.
- **Disability**: Defined as having a physical, mental, and/or emotional disability. Respondents were considered to have a disability if they reported being deaf or having serious difficulty hearing; being blind or having serious difficulty seeing, even when wearing glasses; having serious difficulty concentrating, remembering, or making decisions because of a physical, mental, or emotional condition; having serious difficulty walking or climbing stairs; having difficulty dressing or bathing; or having difficulty completing errands alone such as visiting a doctor's office or shopping because of a physical, mental, or emotional condition.

Clinical outcomes

- **Outpatient HIV medical care**: Defined as documentation of any of the following at the most frequent source of HIV care: encounter with an HIV care provider, viral load test result, CD4 test result, HIV resistance test or tropism assay, ART prescription, pneumocystis pneumonia (PCP) prophylaxis, or

Mycobacterium avium complex (MAC) prophylaxis. All were measured through documentation in the person's medical record; an encounter with an HIV care provider was also measured based on interview self-report.

- **Retention in HIV care**: Persons were considered to be retained in care if they had 2 or more elements of outpatient HIV care at least 90 days apart in each 12-month period reviewed.
- **ART dose adherence**: Respondents were asked about how many days they missed at least 1 dose of their HIV medicines during the 30 days before interview as part of a 3-item ART adherence scale developed by Wilson and colleagues [10]. Respondents were considered ART dose adherent if they reported not missing any doses of their HIV medicines during the 30 days before interview.
- **Viral suppression**: Viral loads were abstracted from medical records from the facility where respondents most frequently received HIV care. Lack of viral suppression was assessed based on two measures. Lack of viral suppression at last test was defined as having the viral load measurement at last test documented as detectable or ≥200 copies/mL. Lack of sustained viral suppression was defined as having any viral load measurement during the past 12 months documented as detectable or ≥200 copies/mL. Those with no viral load tests were considered to be unsuppressed.
- **Unmet needs for ancillary services**: Ancillary services were defined as services that support retention in routine HIV medical care and viral suppression, such as HIV case management, dental care, and mental health services [11]. Ancillary services include services that support HIV medical care more directly, or those that support a person's general health through other types of services. Ancillary services included: HIV case management; medicine through the AIDS Drug Assistance Program (ADAP); adherence support services; HIV peer group support; and patient navigation services (patient navigation services could have been for HIV medical care or other types of care); dental care; mental health services; drug or alcohol counseling or treatment; and domestic violence services; Supplemental Nutrition Assistance Program (SNAP) or Special Supplemental Nutrition Program for Women, Infants, and Children (WIC); transportation assistance; meal or food services; and shelter or housing services. Needs for SSI, SSDI, interpreter services, and lawyer/legal services were dropped after the 2017 cycle and could not be incorporated in estimates for unmet needs for ≥1 ancillary services from 2018 cycle onwards. For this reason, estimates for unmet needs for ≥1 ancillary services were not reported from 2015–2017.

COMMENTARY

The Ryan White HIV/AIDS Program (RWHAP) supports direct health care and support services for more than half a million people with HIV—more than half of all people with diagnosed HIV in the United States [1]. The RWHAP funds and coordinates with cities, counties, states, and local community-based organizations to deliver efficient and effective HIV care, treatment, and support services for people with HIV who have lower incomes. Since it was established, the RWHAP has developed a comprehensive system of safety net services within a network of providers who deliver high-quality, direct health care and support services. The RWHAP is critical to ensuring that individuals with HIV are linked to and retained in care, adhere to medication schedules, and remain virally suppressed. People with HIV who take HIV medication as prescribed and reach and maintain viral suppression cannot sexually transmit the virus to their partner (also known as “U=U” for “Undetectable = Untransmittable”) and can live longer and healthier lives. RWHAP services are crucial for attaining optimal HIV health outcomes among people with HIV, preventing further transmission of the virus, and—ultimately—ending the HIV epidemic in the United States.

Background

The U.S. Department of Health and Human Services (HHS), Health Resources and Services Administration (HRSA), HIV/AIDS Bureau (HAB) administers the RWHAP. In 1990, Congress passed the Ryan White Comprehensive AIDS Resources Emergency (CARE) Act to address the crisis of the HIV epidemic in the United States. This statute was amended and reauthorized in 1996, 2000, 2006, and, most recently, in 2009 as the Ryan White HIV/AIDS Treatment Extension Act of 2009.

The RWHAP was funded at $2.49 billion in fiscal year (FY) 2022 and is the largest federal program focused exclusively on HIV care, treatment, and support services. The RWHAP leverages other funding sources and health care coverage opportunities for people with HIV (e.g., state and/or local funds, program income, pharmaceutical rebates).

The RWHAP has five statutorily defined Parts that provide funding for medical and support services, technical assistance, clinical training, and the development of innovative models of care to meet the needs of different communities and populations affected by HIV:

- **Part A** provides funding to Eligible Metropolitan Areas (EMAs) and Transitional Grant Areas (TGAs) severely affected by the HIV epidemic. Grant funds assist eligible jurisdictions to develop or enhance access to a comprehensive continuum of high-quality, community-based care for people with HIV who have lower incomes through the provision of formula, supplemental, and Minority AIDS Initiative funds. Eligibility for RWHAP Part A grants is based, in part, on the number of confirmed Stage 3 HIV (AIDS) cases within a statutorily specified “metropolitan area.” HHS uses the Office of Management and Budget (OMB) census-based definitions of a metropolitan statistical area (MSA) to determine the geographic boundaries of an RWHAP metropolitan area, based on the boundaries in effect when a jurisdiction initially received RWHAP Part A funding. For all newly eligible areas, HHS bases the boundaries on current OMB MSA boundary definitions. To qualify for EMA status, an area must have reported more than 2,000 AIDS cases in the most recent five years and have a population of at least 50,000. To be eligible for TGA status, an area must have reported 1,000 to 1,999 AIDS cases in the most recent five years and have a population of at least 50,000. EMAs and TGAs range in size from one city or county to more than 26 different geographic entities; 11 EMAs or TGAs have service areas that cross state lines.

- **Part B** provides funding to all 50 states, the District of Columbia, the Commonwealth of Puerto Rico (hereafter referred to as Puerto Rico), the Northern Mariana Islands, American Samoa, Guam, the U.S. Virgin Islands, the Federated States of Micronesia, the Republic of the Marshall Islands, and the Republic of Palau—hereafter referred to collectively as state(s)/territory(ies)—to support HIV care and treatment services for people with HIV who have lower incomes.
  - The RWHAP Part B grants include funding for the AIDS Drug Assistance Program (ADAP) to fund medication and health care coverage.
- **Part C** provides funding to local community-based organizations, community health centers, health departments, academic medical centers, and hospitals in 49 states, the District of Columbia, Puerto Rico, and the U.S. Virgin Islands to provide comprehensive primary medical care and support services in an outpatient setting for people with HIV who have lower incomes. The RWHAP Part C funds also support capacity development grants to strengthen organizational infrastructure and develop, enhance, or expand access to high-quality primary medical care for people with HIV.
- **Part D** provides funding to local community-based organizations, community health centers, health departments, academic medical centers, and hospitals in 39 states and Puerto Rico to support family-centered HIV primary medical care and support services in an outpatient setting (directly or through contracts or memoranda of understanding) for women, infants, children, and youth with HIV who have lower incomes and their affected family members.
- **Part F** provides funds for the following programs:
  - The Special Projects of National Significance (SPNS) Program supports the development, implementation, and evaluation of evidence-based, evidence-informed, and emerging interventions to improve and enhance HIV care and effective service delivery systems for people with HIV. The RWHAP SPNS Program also supports the dissemination of successful interventions and supports the adaptation, replication, and integration of these interventions by RWHAP-funded recipients.
  - The AIDS Education and Training Center (AETC) Program works to increase the number of health care providers who can counsel, diagnose, treat, and medically manage individuals with HIV by providing education, training, consultation, and clinical decision support to health care professionals at the local and regional levels.
  - The Dental Programs provide funding for oral health care for people with HIV and support training dental and dental hygiene providers.
  - The Minority AIDS Initiative provides funding to evaluate and address the disproportionate impact of HIV on racial and ethnic minority populations.

Together, the Parts of the RWHAP provide the public health infrastructure needed to ensure access to a wide range of core medical services (e.g., outpatient/ambulatory health services, medical case management, mental health services, outpatient care for substance use) and support services (e.g., non-medical case management, housing, transportation, food bank/home delivered meals) aimed at early diagnosis of HIV, linkage to care, retention in care, medically appropriate treatment, and sustained viral suppression.

Ending the HIV Epidemic in the U.S.

The RWHAP goals align with two complementary national efforts to reduce new HIV infections: the *Ending the HIV Epidemic in the U.S. (EHE)* initiative [2] and the *National HIV/AIDS Strategy (NHAS)*

2022–2025 [3]. The EHE initiative focuses on increased linkage to, reengagement in, and retention in HIV care and treatment. Reducing new infections to this level essentially would mean that HIV transmissions would be rare and would meet the definition of ending the epidemic. In 2021, HAB EHE-funded providers served 22,413 people with HIV who were new to care and 15,318 people who were estimated to be re-engaged in care [4,5]. Correspondingly, *NHAS 2022–2025*, which was released in December 2021, aims to prevent new HIV infections, improve HIV-related health outcomes for those with HIV, reduce HIV-related disparities and health inequities, and achieve integrated and coordinated efforts to address the HIV epidemic. HRSA's RWHAP plays a key role in providing care and treatment to people with new HIV diagnoses, people with HIV who are re-engaged in care, and people with HIV who are in care but not virally suppressed, as well as continued care for the more than half a million people served by the RWHAP annually.

2022 Ryan White HIV/AIDS Program Annual Data Report Overview

This report is HRSA HAB's annual publication of national RWHAP client-level data from the RWHAP Services Report (RSR). The RSR data are HRSA HAB's primary source of annual, client-level data reported by more than 2,000 funded grant recipients and subrecipients.

Client-level RSR data collection began in 2010, and the data are used to assess the numbers and demographics of clients receiving RWHAP services, understand client HIV-related outcomes, and identify and address HIV-related disparities. This information is a crucial component of data-driven program decision-making and for informing action to advance health equity. Project officers at HRSA HAB discuss the data with recipients to monitor and support their progress to improve HIV care and treatment for people with HIV. It is through the dedicated work of RWHAP recipients, subrecipients, and the RWHAP community that clients receive HIV services every day.

This report includes data submitted to HRSA HAB through the RSR system for all clients served by RWHAP Parts A, B, C, and D during calendar years 2018 through 2022, regardless of the source of RWHAP funding. The data presented are not specific to any one Part, regardless of geographic area presented (e.g., state-level, EMA/TGA-level). RSR data do not include information about ADAP; all ADAP-related information is reported through the RWHAP ADAP Data Report and is disseminated in another publication [6]. Although data presented here are "non-ADAP," many clients also receive ADAP services.

The RSR data presented in this report highlight the state of the RWHAP and include the demographic composition of clients served; socioeconomic factors, such as federal poverty level (FPL), health care coverage, and housing status; and the results of focused analyses to measure progress toward achieving select HIV-related clinical outcome indicators [7,8]. The data are inclusive of the overall RWHAP client population and priority populations. This report does not include the specific services provided to individuals. All tables include all clients served, regardless of the RWHAP services rendered (unless otherwise noted, e.g., viral suppression tables) or source of RWHAP funding (i.e., data from Parts A, B, C, and D are included in all tables).

Tables displaying demographic and socioeconomic data (Table 1a, Tables 2 through 8, and Tables 20a through 26b) include all RWHAP clients, regardless of HIV serostatus[1] (hereafter referred to as *HIV status)*. The data include people with HIV, as well as clients missing HIV status information (e.g., clients who receive services that do not require HIV status to be reported, such as medical transportation services) and clients who do not have HIV (i.e., the families of people with HIV are able to receive certain RWHAP services). In 2022, people with HIV represented 98.3% of all clients. Table 1b and tables displaying retention in care and viral suppression data (Tables 9 through 19b and

[1] "The state of either having or not having detectable antibodies against a specific antigen, as measured by a blood test (serologic test). For example, *HIV seropositive* means that a person has detectable antibodies to HIV; *HIV seronegative* means that a person does not have detectable HIV antibodies" (https://clinicalinfo.hiv.gov/en/glossary/serostatus*)*.

Tables 27a through 36b) include only people with HIV who meet the criteria for the specified analysis (see Technical Notes). The tables include data reported from 50 states, the District of Columbia, Guam, Puerto Rico, and the U.S. Virgin Islands. However, due to reporting challenges during the coronavirus disease 2019 (COVID-19) pandemic, Guam's 2019 and 2020 RSR data are unavailable. Tables 20a through 36b display data by state and EMA/TGA. Readers are encouraged to review all table titles and footnotes carefully to ensure a complete understanding of the data presented.

Readers should interpret RWHAP retention in care and viral suppression data carefully. RWHAP recipients and subrecipients report RSR client-level data annually, and the data are de-identified when reported. As a result, it is not possible to link client-level data across years, which affects how HIV-related outcomes are calculated in this report (i.e., outcomes are calculated separately for each calendar year and compared across years). Specifically, HRSA HAB measures retention in care among RWHAP clients with HIV who received at least one Outpatient Ambulatory Health Services (OAHS) visit before September 1 of the calendar year (i.e., January 1 through August 31), thereby allowing a second care visit to occur at least 90 days later during that calendar year. HRSA HAB measures viral suppression among RWHAP clients who received at least one OAHS visit any time during the calendar year and who had at least one viral load test result reported; that is, viral suppression is measured among people with HIV who received medical care from RWHAP providers during the year and had at least one viral load test.

As a result of the above specifications about the retention in care and viral suppression calculations, the numbers of people with HIV included in these analyses are not equal to the total number of people with HIV served by the RWHAP; the subset of clients for retention in care analyses is 63% of the total RWHAP client population with HIV, and the subset for viral suppression is 66%. Clients not included in retention in care or viral suppression calculations may have received any other RWHAP service (e.g., medical or non-medical case management, housing, transportation, food bank/home delivered meals). It is also important to note that many of the clients not included in calculations for retention in care and viral suppression (i.e., those who did not receive RWHAP OAHS services) receive medical care at RWHAP-supported organizations, where primary medical care services are covered using non-RWHAP funding sources (e.g., private, public, or other health care coverage types), or receive care from providers outside the RWHAP system; these clients should not be presumed to be "out of care" [9].

Monitoring HIV-Related Health Outcomes

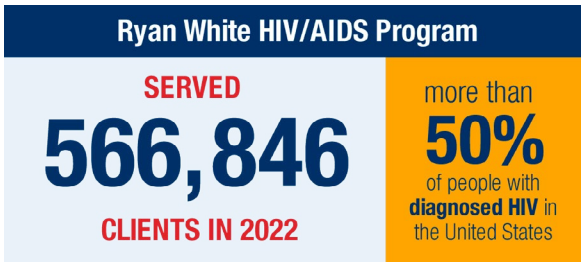
RWHAP recipients and subrecipients submit select client-level HIV-related clinical data (e.g., OAHS visit dates and viral load test results) to HRSA HAB that monitors progress toward achieving the goals of the EHE initiative and NHAS. HRSA HAB uses these data to calculate retention in HIV medical care and viral suppression among clients receiving RWHAP OAHS. This report displays these data for the RWHAP client population of people with HIV who are receiving OAHS by demographics, state, and EMA or TGA (Tables 9, 10, and 27a through 36b).

Because of notable disparities, HRSA HAB enhanced its efforts to improve HIV-related health outcomes among several priority populations, as detailed in Tables 11a through 19b. These tables also display retention in care ("a" tables) and viral suppression ("b" tables) for priority populations (except for Tables 12a–d, where retention in care for men and gay, bisexual, and other men who have sex with men are displayed in the "a" and "b" tables, respectively, and viral suppression in the "c" and "d" tables, respectively).

Report Considerations

HRSA HAB periodically updates the RSR to measure the full investment of the RWHAP more precisely and demonstrate its impact at the state and local levels. As a payor of last resort, RWHAP funds cannot be used to pay for services that have been or reasonably can be expected to be

covered by another payment source. However, more recipients have been funding services with RWHAP-related funding (i.e., program income, pharmaceutical rebates) to be used for specified allowable costs. To fully measure RWHAP investments and their impact, beginning with the 2019 data, HRSA HAB encourages recipients and subrecipients to include RSR data on clients receiving services provided using RWHAP-related funding; this became a reporting requirement for all RWHAP recipients and subrecipients beginning with the 2021 data submission. It is important to note that this new reporting requirement does not replace the previous eligible scope reporting requirement, but rather expands on the previous requirement.



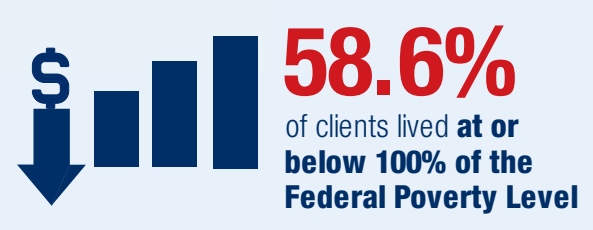
Client-level data for people with HIV who received HAB EHE–funded services and RWHAP FY 2020 Coronavirus Aid, Relief, and Economic Security (CARES) Act–funded services were included in the RSR data submission for 2020–2021 (EHE- and CARES Act–funded services) and 2022 (EHE-funded services only). Collectively, these reporting changes may explain some fluctuations in the numbers of clients since 2019.

Because of reporting challenges, data for the state of Indiana are not included in the state-level data tables ("a" tables from 20a to 36a). Additionally, race/ethnicity data for the states of Maryland and Texas and the Baltimore, MD, and Dallas, TX, EMAs are not included in this report because of data quality issues (Tables 22a–22b, Tables 31a–31b, and Tables 32a–32b).

Ryan White HIV/AIDS Program Client Highlights

Client Demographics

The RWHAP serves more than half a million people each year. In 2022, 566,846 clients received services from RWHAP-funded providers (Table 1a). Among all RWHAP clients served in 2022, 98.3% (557,394) were people with HIV (Table 1b), which has been relatively consistent since 2018.



Nearly half of RWHAP clients are aged 50 years and older. In 2022, people aged 50 years and older accounted for 48.2% of all RWHAP clients, an increase from 46.1% of clients in 2018. People aged 65 years and older accounted for 11.6% of all RWHAP clients, an increase from 7.6% of clients in 2018.

Nearly three-quarters of RWHAP clients are from racial and ethnic minority groups. The percentage distribution of client race and ethnicity populations has remained consistent since 2018. In 2022, 44.5% of clients self-identified as Black/African American, 25.8% as White, 25.3% as Hispanic/Latino, and less than 2% each as American Indian/Alaska Native, Asian, Native Hawaiian/Pacific Islander, or people of multiple races (Table 1a).

The majority of RWHAP clients are male. In 2022, 72.1% of clients were cisgender male (hereafter referred to as *male*), 25.2% were cisgender female (hereafter referred to as *female*), and 2.8% identified as transgender (2.3% transgender female; 0.3% transgender male; 0.2% clients with another gender identity; Table 1a). The gender distribution of RWHAP clients has remained largely consistent since 2018. However, the gender distribution differs by race and ethnicity (Table 2) and by age group (Table 3). See Technical Notes for additional information about gender categories.

Socioeconomic Factors and Health Care Coverage

More than half of RWHAP clients are living at or below 100% FPL. In 2022, 58.6% of clients were living at or below 100% FPL, a slight decrease from 61.3% in 2018 (Table 1a).

The percentages of clients living below 100% FPL differ by race/ethnicity. The percentages of Black/African American, American Indian/Alaska Native, Hispanic/Latino, and multiracial clients living at or below 100% FPL (63.2%, 62.5%, 61.1%, and 59.1%, respectively) were higher than those among clients of other races (Native Hawaiian/Pacific Islander, 53.6%; Asian, 52.1%; White, 48.7%; Table 5, percentages presented in the table are column percentages, and those presented here are row percentages).

Higher percentages of female and transgender female clients are living below 100% FPL compared to male clients. In 2022, 66.8% of female clients and 72.5% of transgender female clients were living at or below 100% FPL (Table 3). Comparatively, 55.2% of male clients were living at or below 100% FPL.

Approximately 18% of RWHAP clients lack health care coverage and nearly 50% are covered by Medicare and/or Medicaid. Among all RWHAP clients in 2022, 31.4% were covered by Medicaid, 10.3% were covered by Medicare, 10.4% had multiple forms of coverage, 10.2% had private employer coverage, and 9.4% had private individual coverage (Table 1a); multiple coverages include any combination of health care coverage types, *except* those who had Medicaid *and* Medicare (dual eligibility), which is displayed separately (7.6% of clients). See Technical Notes for additional information. Nearly one-fifth (18.2%) of RWHAP clients had no health care coverage in 2022, which is lower than in 2018 (20.1%).

Approximately 7% of RWHAP clients have temporary housing and approximately 5% have unstable housing. The distribution of RWHAP clients by housing status has remained relatively stable since 2018 (Table 1a). Nearly 90% of RWHAP clients had stable housing in 2022.

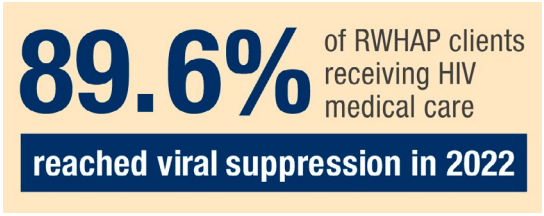
In 2022, the highest proportions of clients with temporary or unstable housing were among those aged 20–24 years (9.6% and 5.7%, respectively), 25–29 years (9.6% and 6.9%), 30–34 years (9.1% and 7.3%), 35–39 years (8.7% and 7.1%), and 40–44 years (8.0% and 6.4%) (Table 6; percentages presented in the table are column percentages, and those presented here and below are row percentages). In addition, a relatively high proportion of youth aged 15–19 years had temporary housing in 2022 (7.9%).

Retention in Care and Viral Suppression Highlights

Retention in HIV Medical Care

HRSA HAB calculates retention in care among RWHAP patients with HIV who had at least one OAHS visit by September 1 of the measurement calendar year; patients are considered retained in care if they had a second visit at least 90 days after.

Retention in care remained relatively stable at approximately 80% year-to-year during 2018 through 2022. In 2022, 77.5% of 352,115 OAHS patients were retained in HIV care (Table 9), a slight decrease (0.8 percentage points) compared to 2021. These data do not delineate the factors contributing to this decrease, and similar minor fluctuations occurred in years prior.



Across subpopulations, retention in care was generally consistent with the overall average (Table 9). However, a few subpopulations had lower retention in care percentages (lower than the national RWHAP average of 77.5% by at least 5 percentage points): patients in each 5-year age group aged 25–34 years (71.1% and 71.9%, respectively), patients with a race/ethnicity of Native Hawaiian/Pacific Islander (70.1%), transgender male patients (70.6%), patients with another gender identity (61.5%), patients with Veterans Administration (72.5%) or Indian Health Service (63.8%) health care coverage, and patients with unstable housing (71.8%).

When examining retention in care among subpopulations from 2018 through 2022, the percentage of patients retained in care by 5-year age groups forms a reverse bell curve, with older and younger populations more likely to be retained and the lowest percentage occurring among those aged 25–29 years.

Viral Suppression

Viral suppression was calculated among people with HIV who had at least one OAHS visit and at least one viral load test during the measurement calendar year. Viral suppression was defined as a most recent viral load test result of <200 copies/mL.

Nearly 90% of RWHAP OAHS patients reached viral suppression in 2022. In 2022, 89.6% of 367,846 OAHS patients had a suppressed viral load at their most recent test (Table 10). From 2018 through 2022, viral suppression increased nearly 3 percentage points, from 87.1% in 2018 to 89.6% in 2022.

Young people aged 15−24 years made great progress improving viral suppression from 2018 through 2022. In 2022, viral suppression was 83.6% among patients aged 15–19 years and 83.7% among those aged 20–24 years (Table 10). Although these percentages are the lowest by age group, they reflect approximately 7 percentage point increases each for these groups from 2018 through 2022.

The percentage of transgender women (aged >13 years) reaching viral suppression continues to increase. In 2022, 86.0% of transgender women reached viral suppression, which reflects a 4.9 percentage point increase from 2018 (81.1%; Table 10).

Viral suppression improved for OAHS patients with unstable housing. In 2022, 77.9% of patients with unstable housing reached viral suppression, compared with 72.4% in 2018 (Table 10). There were also small gains in viral suppression from 2018 through 2022 for patients with temporary housing (from 80.7% to 84.1%) and for patients with stable housing (from 88.4% to 90.6%). Patients with unstable and temporary housing continue to have disparately lower levels of viral suppression than those with stable housing.

Retention in Care and Viral Suppression Among Priority Populations

This section reviews overall retention in care and viral suppression in 2022 for each priority population and highlights the subpopulations with the lowest percentages. Generally, this includes subpopulations with outcomes at least 5 percentage points lower than that of the overall priority population. Data for subpopulations with less than 100 patients are not included in the highlights because of the variability in percentages resulting from small numbers.

Black/African American women (Tables 11a/b): Overall, the percentages of Black/African American women retained in care (79.0%) and virally suppressed (89.1%) were relatively consistent with the national RWHAP averages (77.5% and 89.6%, respectively).

Among Black/African American women, retention in care was lowest among those aged 25–29 and 30–34 years (72.4% and 72.4%, respectively), those with unstable housing (73.0%), and those in HHS Regions 5 and 8 (71.9% and 71.0%, respectively; see Technical Notes for states and territories included in each region).

Viral suppression among Black/African American women was lowest among those in each 5-year age group from 15 to 39 years (range: 79.9%–84.1%), those with perinatal HIV (77.1%), and those with unstable housing (77.5%). In most subpopulations of women, viral suppression was lower among Black/African American women than among women overall in that subpopulation.

Black/African American men (Tables 12a/c): The overall percentage of Black/African American men who were retained in care (75.3%) was relatively consistent with the national RWHAP average (77.5%) and the average among all men (76.8%). The percentage of those who achieved viral suppression (86.2%) was lower than the RWHAP average (89.6%) and the average among men overall (89.6%).

Retention in care was lowest among those aged 25–29 years (69.3%); those with health care coverage though the Veterans Administration (66.7%); those with unstable housing (66.5%); and those in HHS Regions 5, 7, and 10 (68.7%, 70.0%, and 69.6%, respectively).

Viral suppression was lowest among Black/African American men aged 25–29 years (81.1%), those with perinatal HIV (77.2%), those with no health care coverage (79.6%), and those with temporary (80.1%) or unstable (74.2%) housing.

The proportions of Black/African American men who were virally suppressed (86.2%) were lower than those of Hispanic/Latino (91.3%) and White men (92.9%). This gap was the widest among those aged 25–39 years, those with perinatal HIV or male-to-male sexual contact transmission categories; those living at or below 100% FPL; those with Medicaid, other plan, and no health care coverage; and those with temporary housing.

Hispanic/Latina women (Tables 11a/b): Overall, larger percentages of Hispanic/Latina women were retained in care (84.5%) and virally suppressed (91.6%) than the national RWHAP averages (77.5% and 89.6%, respectively).

Among Hispanic/Latina women, retention in care was lowest among each 5-year age group from 20–39 years (range: 76.4%–79.5%); those living at greater than 400% FPL (74.5%); those with temporary housing (79.3%); and those in HHS Regions 7 and 10 (75.8% and 76.1%, respectively).

The lowest percentages of viral suppression were among Hispanic/Latina women aged 20–24 (83.3%), 25–29 (82.3%), and 35–39 (85.6%) years; those with perinatal HIV (78.5%); and those with unstable housing (85.1%).

Hispanic/Latino men (Tables 12a/c): Overall, retention in care (80.5%) and viral suppression (91.3%) among Hispanic/Latino men were higher than the national RWHAP averages (77.5% and 89.6%, respectively).

Retention in care was lowest among Hispanic/Latino men in each 5-year age group from 20 to 34 years (range: 74.3%–75.1%); those with temporary housing (75.3%); and those in HHS Regions 5 and 10 (73.9% and 73.2%, respectively).

Viral suppression was lowest among Hispanic/Latino men aged 15–19 and 20–24 years (82.8% and 85.8%, respectively), those with perinatal HIV (83.4%), and those with unstable housing (83.7%).

Gay, bisexual, and other men who have sex with men (Tables 12b/d): Overall, retention in care (76.9%) and viral suppression (90.2%) for males with HIV attributed to male-to-male sexual contact (i.e., gay, bisexual, and other men who have sex with men) were relatively consistent with the national

RWHAP averages (77.5% and 89.6%, respectively). It is important to note that data presented for gay, bisexual, and other men who have sex with men are based on the reported risk factor most likely to have been responsible for the original transmission of HIV (i.e., male-to-male sexual contact).

Retention in care among gay, bisexual, and other men who have sex with men by race/ethnicity was lowest among American Indian/Alaska Native patients (72.3%), Black/African American patients (74.5%), and Native Hawaiian/Pacific Islander patients (71.6%).

The lowest percentage of viral suppression among gay, bisexual, and other men who have sex with men by race/ethnicity was among Black/African American patients (85.7%), particularly among those aged 15–19 years (80.6%), those with no health care coverage (78.9%), and those with temporary (79.3%) or unstable (73.6%) housing. Viral suppression also was lower than the overall average among American Indian/Alaska Native patients aged 30–34 years (85.0%) and those with no health care coverage (83.2%). Among all gay, bisexual, and other men who have sex with men, regardless of race/ethnicity, viral suppression was consistently lowest among those with temporary (84.6%) or unstable (79.7%) housing.

Transgender adults and adolescents (Tables 13a/b): Overall, retention in care (73.5%) and viral suppression (86.4%) for transgender adults and adolescents were lower than the national RWHAP averages (77.5% and 89.6%, respectively).

Among transgender patients, retention in care was lowest among those with HIV attributed at diagnosis to sexual contact and injection drug use (64.9%), those with private employer health care coverage (68.1%), those with temporary (68.3%) or unstable (67.5%) housing, and those in HHS Regions 5 and 8 (67.3% and 46.0%, respectively).

Viral suppression was lowest among patients with unstable housing (73.6%). Generally, Black/African American transgender patients had lower percentages of viral suppression (overall 83.3%) across demographic subgroups than Hispanic/Latino (88.4%) and White (91.8%) transgender patients.

Given the low numbers within the various subpopulations for transgender people, caution should be used in interpreting the percentages in Tables 13a/b.

Older adults aged 50 years and older (14a/b): Overall, retention in care (81.1%) and viral suppression (92.9%) for older adults with HIV were higher than the national RWHAP averages (77.5% and 89.6%, respectively).

Retention in care among older adults by race/ethnicity was lowest among American Indian/Alaska Native patients (77.6%), Native Hawaiian/Pacific Islander patients (72.7%), and White patients (78.6%). Regardless of race/ethnicity, retention in care was lowest among those with health care coverage through the Veterans Administration (74.8%) and those with temporary (77.0%) or unstable (76.2%) housing.

Viral suppression was lower among transgender older adults with HIV attributed to sexual contact and injection drug use (88.1%), compared to older adults overall. In addition, viral suppression was lower among older adults with temporary (88.0%) or unstable (82.1%) housing, particularly for Black/African American older adults (86.2% and 79.5%, respectively), and was low among White older adults with unstable housing (81.1%).

Given the low numbers within various subpopulations for older adults, caution should be used in interpreting the percentages in Tables 14a/b.

Youth aged 13–24 years (Tables 15a/b): Among youth overall, retention in care (74.6%) and viral suppression (83.8%) were lower than the national RWHAP averages (77.5% and 89.6%, respectively).

The lowest percentages of retention in care were among transgender youth (68.5%), transgender youth with HIV attributed at diagnosis to sexual contact (69.9%), and youth with unstable housing (69.1%).

Viral suppression was lowest among transgender youth (81.0%), transgender youth with HIV attributed at diagnosis to sexual contact (79.7%), and youth with unstable housing (75.3%).

Given the low numbers within the various subpopulations for youth, caution should be used in interpreting the percentages in Tables 15a/b.

Young Black/African American gay, bisexual, and other men who have sex with men, aged 13–24 years (Tables 16a/b): Overall, retention in care for young Black/African American gay, bisexual, and other men who have sex with men (73.3%) was lower than the national RWHAP average (77.5%), but consistent with the average for young gay, bisexual, and other men who have sex with men overall (74.2%). Viral suppression for young Black/African American gay, bisexual, and other men who have sex with men (83.0%) was lower than the national RWHAP average (89.6%) by a considerable difference of 6.6 percentage points, but slightly lower than the average for young gay, bisexual, and other men who have sex with men overall (84.8%).

For young Black/African American gay, bisexual, and other men who have sex with men, the lowest percentage of retention in care was among those with unstable housing (61.6%), and viral suppression was lowest among those with no health care coverage (77.4%) or unstable housing (77.0%).

Young Black/African American gay, bisexual, and other men who have sex with men living at or below 100% FPL had notably lower viral suppression compared with other racial/ethnic groups. Specifically, viral suppression among young Black/African American gay, bisexual, and other men who have sex with men living at or below 100% FPL (81.2%) was 3.6 percentage points lower than that among young Hispanic/Latino gay, bisexual, and other men who have sex with men (84.8%) and 8.7 percentage points lower than that among young White gay, bisexual, and other men who have sex with men (89.9%).

Given the low numbers within the various subpopulations of young gay, bisexual, and other men who have sex with men and young Black/African American gay, bisexual, and other men who have sex with men, caution should be used in interpreting the percentages in Tables 16a/b.

Young Black/African American women, aged 13–24 years (Tables 17a/b): Overall, retention in care for young Black/African American women (79.4%) was consistent with the national RWHAP average (77.5%) and slightly higher than the average for young women overall (78.9%). Viral suppression for young Black/African American women (81.8%) was considerably lower than the national RWHAP average (89.6%) and lower than the average for young women overall (82.8%).

Given the low numbers within the various subpopulations of young women and young Black/African American women, caution should be used in interpreting the percentages in Tables 17a/b.

Patients with HIV attributed at diagnosis to injection drug use (Tables 18a/b): Overall, for patients with HIV attributed at diagnosis to injection drug use, retention in care (77.4%) and viral suppression (88.5%) were consistent with the national RWHAP averages (77.5% and 89.6%, respectively).

Among all patients with HIV attributed at diagnosis to injection drug use, retention in care was lower among patients in each 5-year age group from 20 to 44 years (range: 54.7%–69.6%), those with “other plan” health care coverage (70.2%) or no health care coverage (68.7%), and those with temporary (69.5%) or unstable (64.0%) housing. By race/ethnicity, retention in care was lowest among White patients (72.4%) and American Indian/Alaska Native patients (71.6%).

Viral suppression was lower than the overall average for patients with HIV attributed at diagnosis to injection drug use (88.5%) among American Indian/Alaska Native (82.6%) and White patients (86.7%). Regardless of race/ethnicity, low viral suppression was seen among patients in each 5-year age group from 20 to 49 years (range: 75.0%–82.9%), those with no health care coverage (80.0%), and those with temporary (82.0%) or unstable (73.1%) housing. By race/ethnicity, patients with temporary or unstable housing had lower viral suppression than patients in that population overall. Viral suppression for those with temporary housing was 81.0% among White patients, 82.6% among Black/African American patients, and 83.1% among Hispanic/Latino patients; viral suppression among those with unstable housing was 70.5% among White patients, 76.4% among Black/African American patients, and 74.5% among Hispanic/Latino patients.

Data for patients with HIV attributed at diagnosis to injection drug use are based on patients who reported “injection drug use” as their transmission category at diagnosis and may not reflect current behavior.

Housing status (Tables 19a/b): Among RWHAP patients, those with temporary or unstable housing consistently have lower retention in care and viral suppression than those with stable housing.

Overall, retention in care was higher among patients with stable housing (78.4%) than among those with temporary (72.6%) or unstable (71.8%) housing. Among patients with temporary housing, retention in care was lowest among patients aged 25–29 years (66.8%) and 30–34 years (67.6%), male patients with HIV attributed at diagnosis to male-to-male sexual contact and injection drug use (66.9%), and male patients with HIV attributed at diagnosis to perinatal transmission (68.8%). Among patients with unstable housing, retention in care was lowest among patients aged 25–29 years (63.4%), patients of multiple races (63.4%), and male and female patients with HIV attributed at diagnosis to injection drug use (62.6% and 66.6%, respectively).

Overall, the highest percentage of viral suppression was among patients with stable housing (90.6%), while percentages among patients with temporary (84.1%) or unstable (77.9%) housing were substantially lower. Among patients with temporary housing, viral suppression was lowest among male and female patients with perinatal HIV (70.5% and 76.4%, respectively). Among patients with unstable housing, viral suppression was lowest among patients aged 25–29 years (72.2%), patients of multiple races (72.8%), and male patients with HIV attributed at diagnosis to injection drug use (72.9%).

Across all genders, a substantially greater proportion of patients with stable housing reached viral suppression compared with those who had temporary or unstable housing. For example, viral suppression among transgender females with stable housing (87.7%) was 5.9 percentage points higher than that among transgender females with temporary housing (81.8%) and 14.3 percentage points higher than that among those with unstable housing (73.4%). There were similar percentage point differences for male and female patients.

TECHNICAL NOTES

Ryan White HIV/AIDS Program Data

The Ryan White HIV/AIDS Program (RWHAP) Services Report (RSR) is the U.S. Department of Health and Human Services (HHS), Health Resources and Services Administration (HRSA), HIV/AIDS Bureau's (HAB) primary source of annual, client-level data reported by more than 2,000 grant recipients and subrecipients. These data allow HRSA HAB and its stakeholders to assess the numbers and demographics of clients receiving services, understand client HIV-related outcomes, and identify and address HIV-related disparities. Client-level RSR data have been used since 2010. Each year, HRSA HAB requires grant recipients and subrecipients that use RWHAP funds to provide core medical or support services during the reporting period to submit data in a specified format [10].

This report includes data reported to the RSR for all clients served by the RWHAP Parts A through D during calendar years 2018 through 2022. Beginning with the 2016 calendar year data collection period, recipients and subrecipients reported data for all clients who met the recipient's eligibility requirements for RWHAP participation (which varies by recipient and is based on such criteria as HIV status, income, and residency) and received at least one of the core medical or support services for which the recipient or subrecipient received RWHAP funding. The data are reported regardless of the actual funding used to pay for the services (i.e., some services may have been paid for by sources other than the RWHAP). Because more recipients have been moving toward funding services with RWHAP-related funding (i.e., program income; pharmaceutical rebates), beginning with the 2019 data, HRSA HAB encourages recipients and subrecipients to include RSR data on clients receiving services provided using RWHAP-related funding; this became a reporting requirement for all RWHAP recipients and subrecipients beginning with the 2021 data submission. This reporting requirement did not replace the previous eligible scope reporting requirement, but rather expanded on the previous requirement.

In addition to the expanded scope of reporting clients served using RWHAP-related funds, recent RSR data include information for people with HIV receiving RWHAP fiscal year 2020 Coronavirus Aid, Relief, and Economic Security (CARES) Act–funded services (2020 and 2021) and HAB *Ending the HIV Epidemic in the U.S. (EHE)* initiative–funded services (2020–2022).

RSR data do not include information about the AIDS Drug Assistance Program (ADAP), which is reported through another data system. Although data presented in this report are "non-ADAP," many clients included in the RSR data also receive ADAP services.

After removing personally identifying information, recipients and subrecipients submit data to HRSA HAB. Data are reported by RWHAP grant recipients and subrecipients in 50 states, the District of Columbia, and three territories—Guam, Puerto Rico, and the U.S. Virgin Islands. Of the six U.S. Pacific territories, only Guam submits client-level data; only Guam, therefore, is included in this report.

Presentation of Data

The data in this report include information received by HRSA HAB for clients served during calendar years 2018 through 2022. Data are organized into four sections:

- Section 1 (Tables 1–8): National-level numbers and percentages of clients served by the RWHAP (non-ADAP), presented by selected demographics.

- Section 2 (Tables 9–19b): National-level retention in care and viral suppression among patients receiving outpatient ambulatory health services (OAHS), presented by selected demographics and priority populations.
- Section 3 (Tables 20a–26b): State- and Eligible Metropolitan Area or Transitional Grant Area (EMA/TGA)–level numbers and percentages of clients served by the RWHAP (non-ADAP), presented by selected demographics.
- Section 4 (Tables 27a–36b): State- and EMA/TGA-level retention in care and viral suppression among patients receiving OAHS, presented by selected demographics.

Tables 1–3 and 5–8 display subtotals for each subpopulation, as well as the overall total. Subtotals are displayed to reflect the denominator used for the percentage calculation of each subpopulation. Because of missing data, the values in each column may not sum to the column total.

HIV Status

RSR data include de-identified client-level information about people who received services from RWHAP-funded providers. RWHAP clients include people with HIV, as well as people who are affected by HIV (e.g., families and partners of people with HIV served by the RWHAP). Families of people with HIV can receive certain services through RWHAP Part D. The data presented in Table 1a, Tables 2 through 8, and Tables 20a through 26b include all RWHAP clients, regardless of HIV status. Table 1b and tables displaying retention in care and viral suppression (Tables 9 through 19b and Tables 27a through 36b) include only people with HIV.

Presumed HIV-positive status

Table 1b displays demographic data only about clients with HIV; however, many clients receive services that do not require HIV status to be reported (e.g., Medical Transportation) and, therefore, may be missing HIV status information. HRSA HAB applied an algorithm to estimate a “presumed HIV positive” status for Table 1b. That is, only six RWHAP-funded service categories are available to clients without HIV (i.e., Child Care Services, Early Intervention Services, Food Bank/Home-Delivered Meals, Other Professional Services, Outreach Services, and Psychosocial Support Services) [11]. Clients aged 13 years and older who received only one or a combination of these six services, without receiving another service available to only people with HIV, were presumed to be HIV negative. All other clients (aged 13 years and older) were presumed to have HIV and were included in Table 1b. Clients younger than 13 years were not included in the algorithm because of an inconsistency in data reporting between 2014 and later years; however, testing the algorithm for 2017 and 2018 for the <13 age group produced effectively no difference from the number of clients with a reported HIV status. Therefore, the HIV status variable was used for clients aged <13 years across all years.

Age Group

RWHAP grant recipients and subrecipients report client birth year, which is used to calculate the client’s age during the designated year as a discrete variable. For tables displaying age groups (Tables 1a–14b and 18a–19b), client ages were categorized to align with the Centers for Disease Control and Prevention (CDC) National HIV Surveillance System (NHSS) age group delineations: <13 years (if applicable), 13–14, 15–19, 20–24, 25–29, 30–34, 35–39, 40–44, 45–49, 50–54, 55–59, 60–64, and ≥65 years [1].

In Tables 21a/b (state and EMA/TGA by age group), data are displayed using broader age group delineations: <13 years, 13–24, 25–34, 35–44, 45–54, 55–64, and ≥65 years.

Tables displaying retention in care and viral suppression for priority populations (Tables 11a–19b) include only clients aged 13 years and older. Tables 14a–14b focus on older adults (aged 50 years and older), and Tables 15a–17b focus on youth and young adults aged 13–24 years.

Race/Ethnicity

Recipients and subrecipients report race/ethnicity information for RWHAP clients according to Office of Management and Budget (OMB) standards [12]. The OMB standards have five categories for race: American Indian or Alaska Native; Asian; Black or African American; Native Hawaiian or Other Pacific Islander; and White. The data on ethnicity have two categories: (1) Hispanic or Latino and (2) not Hispanic or Latino. Race and ethnicity are submitted as separate variables and combined for analysis.

The race/ethnicity variable is categorized as American Indian or Alaska Native, Asian, Black or African American, Hispanic or Latino, Native Hawaiian or other Pacific Islander, White, and multiple races (two or more categories of race reported).

In this report, clients categorized as Hispanic/Latino may have had race reported as well. Clients categorized by race (e.g., Black/African American) are non-Hispanic/Latino; however, the number of clients reported in each “non-Hispanic/Latino” race category may include clients with missing data for Hispanic/Latino ethnicity.

HRSA HAB expects RWHAP grant recipients and subrecipients to make every effort to obtain and report race and ethnicity based on each client’s self-report. Self-identification is the preferred means of obtaining this information.

Gender

Gender designations in this report are cisgender (non-transgender) male, cisgender female, or transgender. Transgender is a term for people whose gender identity and/or expression is different from their sex assigned at birth. Because of the unique health needs of transgender people with HIV, they are discussed separately from cisgender people and are specifically identified as being transgender. HRSA HAB collaborated with the transgender community and other experts in sexual orientation and gender identity data collection methods to successfully designate transgender people receiving HIV care and treatment from RWHAP providers, to best inform program decisions.

Reporting and analysis to determine transgender identity

Transgender variable options for RSR data reporting include transgender female-to-male, transgender male-to-female, or transgender other, which includes people who do not identify with the provided transgender variable options and/or who do not identify with the binary options of male/female (e.g., nonbinary, two-spirit, genderqueer). Self-identification is the preferred means of obtaining this information.

During the period 2010 through 2013, RSR variables for gender included *current gender,* with the options of male, female, and transgender, and a subsequent variable for *transgender identity* (this variable captured transgender female-to-male, transgender male-to-female, and transgender unknown). In 2014, HRSA HAB began requiring recipients and subrecipients report gender using a multistep method: *sex assigned at birth (*male or female) was added, and the *current gender* variable was replaced with *current gender identity* (male, female, transgender); the *transgender identity* variable remained intact. Beginning with 2017 reporting, HRSA HAB further refined the *current gender identity* variable to include the options of male, female, transgender female-to-male, transgender male-to-female, and transgender other (previously *transgender unknown*); the transgender identity variable was removed, thus creating a two-step method for reporting and determining gender (i.e., sex assigned at birth and current gender identity).

Gender data in this report use the two-step method (i.e., the 2017 method); when the reported *current gender identity* is different from the *sex assigned at birth*, the analysis determines gender using an algorithm designed specifically for this purpose.

Language used in this report

In this report and in the accompanying data tables, for analyses that include clients of all ages, cisgender male clients are referred to as *male*, cisgender female clients as *female*, transgender female-to-male clients as *transgender male*, and transgender male-to-female clients as *transgender female*. For analyses that include only clients aged 13 years and older, clients are referred to as *men, women, transgender men,* and *transgender women,* respectively.

Clients designated under the *transgender other* variable option are referred throughout as *clients with another gender identity,* or in the data tables as *other gender identity.*

Transmission Category

Transmission category is the term for the classification that summarizes a client's possible HIV risk factor(s) at the time of HIV acquisition; the summary classification results from selecting—from a presumed hierarchical order of probability—the single risk factor most likely to have been responsible for transmission.

It is important to note that data by transmission category presented in this report are based on the reported risk factor *most likely to have been responsible for the original transmission of HIV;* data may not reflect current behavior (e.g., injection drug use).

For tables displaying data for all clients served by the RWHAP (Table 1a, Tables 2 through 8, and Tables 20a through 26b), transmission category data include clients with known positive HIV status and those who have unknown HIV status (e.g., children with indeterminate status and clients with transmission category information but missing HIV status data).

Transmission categories are presented separately by gender (i.e., male, female, transgender).

- For male clients, transmission categories include male-to-male sexual contact, injection drug use, male-to-male sexual contact *and* injection drug use, heterosexual contact, perinatal, and other.
- For female clients, transmission categories include heterosexual contact, injection drug use, perinatal, and other.
- For transgender clients, transmission categories have been modified to better reflect the transgender experience of transmission risk while continuing to follow a relative hierarchy of likelihood for transmission. That is, transmission category data for transgender clients are presented as sexual contact, injection drug use, sexual contact *and* injection drug use, perinatal, and other.

HRSA HAB adapted the definitions of transmission risk categories from the CDC's NHSS definitions for transmission categories [1]. Clients with more than one reported risk factor are classified in the transmission category listed first in the hierarchy. The only exceptions are (1) men who had sexual contact with other men and who injected drugs and (2) perinatal; these groups make up separate transmission categories. The transmission categories are defined, in order of the hierarchy, as follows:

- *Male-to-male sexual contact:* Male clients who report sexual contact with other men and males who report sexual contact with both men and women.

- *Injection drug use:* Clients who report use of drugs intravenously or through skin popping.
- *Male-to-male sexual contact and injection drug use:* Male clients who report sexual contact with other men or sexual contact with both men and women *and* report the use of drugs intravenously or through skin popping.
- *Heterosexual contact:* Clients who report specific heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
- *Perinatal:* This category is exclusively for clients with perinatally acquired HIV. This category includes clients born after 1980 who are known to have HIV and whose HIV is attributed to perinatal transmission at diagnosis, as well as infants with indeterminate HIV status.
- *Other:* Clients who report transmission from the receipt of transfusion of blood, blood components, or tissue and clients who report hemophilia/coagulation disorder. Beginning with 2014 data collection, unknown risk factor was no longer included in the classification of *other* transmission risk, nor was it collected as a separate category for the RSR. All analyses in this report include only blood transfusion or hemophilia/coagulation disorder in the *other* transmission category.

For transgender clients, the following transmission category hierarchy is used:

- *Sexual contact:* Transgender clients who report any sexual transmission risk.
- Injection drug use: Transgender clients who report use of drugs intravenously or through skin popping.
- *Sexual contact and injection drug use:* Transgender clients who report sexual contact *and* report the use of drugs intravenously or through skin popping.
- *Perinatal:* As above.
- *Other:* As above.

Tables 12b/d and 16a/b display retention in care and viral suppression among gay, bisexual, and other men who have sex with men aged 13 years and older and among young gay, bisexual, and other men who have sex with men aged 13–24 years, respectively. These tables include only those clients with infection attributed at diagnosis to male-to-male sexual contact and exclude male-to-male sexual contact *and* injection drug use. Tables 18a and 18b display retention in care and viral suppression among people with HIV attributed at diagnosis to injection drug use, respectively. These tables include only those clients whose reported transmission category is injection drug use; male clients with male-to-male sexual contact *and* injection drug use and transgender clients with sexual contact *and* injection drug use as their transmission category are not included.

Federal Poverty Level

Federal poverty level (FPL) characterizes the client's income as a percentage of the FPL [13] at the end of the reporting period. In this report, FPL categories are 0–100% FPL, 101–138% FPL, 139–250% FPL, 251–400% FPL, and >400% FPL.

Health Care Coverage

RWHAP grant recipients and subrecipients report all sources of health care coverage that each client had for any part of the reporting period. These data are categorized further for analysis. Health care coverage was categorized as private employer, private individual, Medicare, Medicaid, Medicare and

Medicaid (dual eligibility), Veterans Administration, Indian Health Service, other plan, no coverage, and multiple coverages. The Medicaid classification also includes the Children's Health Insurance Program (CHIP) and other public state health care coverage programs.

Housing Status

The housing status variable captures the client's housing status at the end of the reporting period and is categorized as stable (e.g., permanent) housing, temporary housing, or unstable housing. The definitions for each of these categories are based on the Housing Opportunities for Persons with AIDS Program Annual Progress Report Measuring Performance Outcomes: form HUD-40110C and the McKinney-Vento Act, Title 42 US Code, Sec. 11302, General definition of homeless individual [14,15].

Region

HHS uses 10 geographic designations for classifying regions of the United States, which encompass all states and territories. The classification of states and territories within these regions is as follows:

- **Region 1:** Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, Vermont
- **Region 2:** New Jersey, New York, Puerto Rico, U.S. Virgin Islands
- **Region 3:** Delaware, District of Columbia, Maryland, Pennsylvania, Virginia, West Virginia
- **Region 4:** Alabama, Florida, Georgia, Kentucky, Mississippi, North Carolina, South Carolina, Tennessee
- **Region 5:** Illinois, Indiana, Michigan, Minnesota, Ohio, Wisconsin
- **Region 6:** Arkansas, Louisiana, New Mexico, Oklahoma, Texas
- **Region 7:** Iowa, Kansas, Missouri, Nebraska
- **Region 8:** Colorado, Montana, North Dakota, South Dakota, Utah, Wyoming
- **Region 9:** Arizona, California, Guam, Hawaii, Nevada
- **Region 10:** Alaska, Idaho, Oregon, Washington

The six U.S. Pacific territories are included in HHS Region 9. However, only Guam submits client-level data; only Guam, therefore, is included in this report.

It is important to note that the COVID-19 pandemic emerged during the 2019 RSR data submission period and continued through the 2021 period, shifting the priorities for RWHAP recipients and subrecipients. Because of these challenges, the U.S. territory of Guam was unable to submit data by the deadline needed for data processing in 2019 and 2020. Therefore, the 2019 and 2020 data do not include Guam's data; in addition, these data are not shown for state/territory-specific tables that show these data years (i.e., Tables 20a, 27a, and 28a).

State

State data are displayed in "a" tables from 20a through 36a. State-level delineation of data is based on provider location rather than client location. Clients receiving services in multiple states are not included in state-specific totals; these clients make up less than 2% of the total RWHAP population.

In addition, state-level analyses include data submitted for all Parts of the RWHAP. That is, data presented by state are not limited to entities receiving RWHAP Part B funding; all tables include data for all clients served by RWHAP providers in the state, regardless of the source of RWHAP funding (i.e., data from Parts A, B, C, and D are included).

Eligible Metropolitan Areas (EMAs) and Transitional Grant Areas (TGAs)

Part A of the RWHAP provides emergency assistance to EMAs and TGAs that are most severely affected by the HIV epidemic. To qualify for EMA status, an area must have reported at least 2,000 Stage 3 HIV (AIDS) cases in the most recent five years and have a population of at least 50,000. To be eligible for TGA status, an area must have reported 1,000–1,999 AIDS cases in the most recent five years and have a population of at least 50,000.

EMAs and TGAs range in size from one city or county to more than 26 different geographic entities; 11 include parts of more than one state.

The boundaries of EMAs and TGAs are based on the U.S. Census Bureau delineation of the metropolitan statistical area at the time of first eligibility. Client-level data are reported based on provider location, rather than client location.

EMA and TGA data are displayed in “b” tables from 20b through 36b. It is important to note that data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and TGAs. In addition, data presented for EMAs and TGAs are not limited to entities receiving RWHAP Part A funding; all tables include data for all clients served by RWHAP providers in the EMA or TGA, regardless of the source of RWHAP funding (i.e., Parts A, B, C, and D data are included).

Tables 22b, 31b, and 32b display EMA and TGA data by race/ethnicity. To protect the confidentiality of clients, values less than five (5) were suppressed. In addition, to ensure values less than 5 cannot be calculated, all data on clients of multiple races have been suppressed. In Table 22b, the “Total” column on which percentages were based includes all clients with reported race/ethnicity information.

Similarly, Table 23b displays data by gender. To protect the confidentiality of clients, values less than 5 were suppressed and all data on clients whose gender is “other gender identity” have been suppressed. The Total column on which percentages were based includes all clients with reported gender information.

Retention in Care and Viral Suppression

Retention in HIV medical care was defined as people with HIV having at least two medical visits that were at least 90 days apart in the measurement year. Because the data sets are restricted to one calendar year of data each, the first of these HIV medical care visits in the year must have occurred before September 1 of the measurement year, thus giving the client an opportunity to meet the retention criteria by December 31.

Viral suppression was based on data for people with HIV who had at least one OAHS visit and at least one viral load test during the measurement year. Viral suppression was defined as the most recently reported HIV RNA test result of <200 copies/mL.

Priority Populations

Although anyone can have HIV, all people and communities are not impacted equally. HRSA HAB has enhanced its efforts to focus on communities where HIV is most concentrated. These priority populations include women; transgender women; gay, bisexual, and other men who have sex with men; Blacks/African Americans; Hispanics/Latinos; adults aged 50 years and older; youth; young

Black/African American gay, bisexual, and other men who have sex with men; young Black/African American women; people with HIV attributed at diagnosis to injection drug use; and people with unstable or temporary housing. Tables 11a through 19b display retention in care (“a” tables) and viral suppression (“b” tables) for these priority populations (except for Tables 12a–d, where retention in care for men and for gay, bisexual, and other men who have sex with men are displayed in the “a” and “b” tables, respectively, and viral suppression in the “c” and “d” tables, respectively).

[a] Hispanics/Latinos can be of any race.
[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[c] Includes hemophilia and blood transfusion.
[d] Subtotals are reflective of available gender and transmission category information. The values may not sum to the subtotals for gender overall.
[e] Includes any sexual transmission category reported by transgender clients.
[f] Subtotals for each subpopulation are displayed to reflect the denominator used for the percentage calculation of each subpopulation; due to missing data, the values in each column may not sum to the column total.

[a] Hispanics/Latinos can be of any race.
[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[c] Includes hemophilia and blood transfusion.
[d] Subtotals are reflective of available gender and transmission category information. The values may not sum to the subtotals for gender overall.
[e] Includes any sexual transmission category reported by transgender clients.
[f] Subtotals for each subpopulation are displayed to reflect the denominator used for the percentage calculation of each subpopulation; due to missing data, the values in each column may not sum to the column total.

Abbreviation: FPL, federal poverty level.
[a] Hispanics/Latinos can be of any race.
[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[c] Includes hemophilia and blood transfusion.
[d] Subtotals are reflective of available gender and transmission category information. The values may not sum to the subtotals for gender overall.
[e] Includes any sexual transmission category reported by transgender clients.
[f] Subtotals for each subpopulation are displayed to reflect the denominator used for the percentage calculation of each subpopulation; due to missing data, the values in each column may not sum to the column total.

[a] Hispanics/Latinos can be of any race.
[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[c] Includes hemophilia and blood transfusion.
[d] Subtotals are reflective of available gender and transmission category information. The values may not sum to the subtotals for gender overall.
[e] Includes any sexual transmission category reported by transgender clients.
[f] Subtotals for each subpopulation are displayed to reflect the denominator used for the percentage calculation of each subpopulation; due to missing data, the values in each column may not sum to the column total.

Note: See Technical Notes for the states/territories included in each region.
[a] Hispanics/Latinos can be of any race.
[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[c] Includes hemophilia and blood transfusion.
[d] Subtotals are reflective of available gender and transmission category information. The values may not sum to the subtotals for gender overall.
[e] Includes any sexual transmission category reported by transgender clients.
[f] Subtotals for each subpopulation are displayed to reflect the denominator used for the percentage calculation of each subpopulation; due to missing data, the values in each column may not sum to the column total.

Section 2.

National-Level Data: Retention in Care and Viral Suppression

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
[a] Hispanics/Latinos can be of any race.
[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[c] Includes hemophilia and blood transfusion.
[d] Includes any sexual transmission category reported by transgender clients.
[e] See Technical Notes for the states/territories in each region.
[f] Because column totals were calculated independently of the values for the subpopulations, the values in each column may not sum to the column total.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.

[a] Hispanics/Latinos can be of any race.

[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[c] Includes hemophilia and blood transfusion.

[d] Includes any sexual transmission category reported by transgender clients.

[e] See Technical Notes for the states/territories in each region.

[f] Because column totals were calculated independently of the values for the subpopulations, the values in each column may not sum to the column total.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.

[a] Hispanics/Latinas can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.

[a] Hispanics/Latinos can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Note: Data are included only for males with the transmission category male-to-male sexual contact; data do not include male clients who reported male-to-male sexual contact *and* injection drug use.
[a] Hispanics/Latinos can be of any race.
[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.
[c] See Technical Notes for the states/territories in each region.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.

[a] Hispanics/Latinos can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] See Technical Notes for the states/territories in each region.

Table 12d. Viral suppression among gay, bisexual, and other men who have sex with men (aged 13 years and older) served by the Ryan White HIV/AIDS Program (non-ADAP), by race/ethnicity and selected characteristics, 2022—United States and 3 territories

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
* To ensure confidentiality, data have been suppressed.
[a] Hispanics/Latinos can be of any race.
[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.
[c] Includes any sexual transmission category reported by transgender clients.
[d] Includes hemophilia and blood transfusion.
[e] See Technical Notes for the states/territories in each region.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
* To ensure confidentiality, data have been suppressed.
[a] Hispanics/Latinos can be of any race.
[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.
[c] Includes any sexual transmission category reported by transgender clients.
[d] Includes hemophilia and blood transfusion.
[e] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.

[a] Hispanics/Latinos can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] Includes any sexual transmission category reported by transgender clients.

[f] See Technical Notes for the states/territories in each region.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.

[a] Hispanics/Latinos can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] Includes any sexual transmission category reported by transgender clients.

[f] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.

[a] Hispanics/Latinos can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] Includes any sexual transmission category reported by transgender clients.

[f] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Note: Data are included only for males with the transmission category male-to-male sexual contact; data do not include male clients who reported male-to-male sexual contact and injection drug use.
[a] Hispanics/Latinos can be of any race.
[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.
[c] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.

[a] Hispanics/Latinas can be of any race.

[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.

[c] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[d] Includes hemophilia and blood transfusion.

[e] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: Data presented in this table represent clients who reported injection drug use as their transmission category; data may not be reflective of current injection drug use behavior.
Data are included only for clients with the transmission category injection drug use; data do not include male clients who reported male-to-male sexual contact and injection drug use or transgender clients who reported sexual contact and injection drug use.
[a] Hispanics/Latinos can be of any race.
[b] Because totals were calculated independently of the values for the subpopulations, the values in each column and row may not sum to the column and row totals.
[c] See Technical Notes for the states/territories in each region.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.

[a] Hispanics/Latinos can be of any race.

[b] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).

[c] Includes hemophilia and blood transfusion.

[d] Includes any sexual transmission category reported by transgender clients.

[e] See Technical Notes for the states/territories in each region.

[f] Because column totals were calculated independently of the values for the subpopulations, the values in each column may not sum to the column total.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location. Data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Notes: Percentages shown are based on the row total.
EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Notes: Percentages shown are based on the row total.
EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
* To ensure confidentiality, values less than (<) 5 have been suppressed; in addition, all data for clients of multiple races have been suppressed. Therefore, the numbers for each subpopulation may not sum to the row total.
[a] Hispanics/Latinos can be of any race.
[b] Includes all clients with reported race/ethnicity information.
[c] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.
[d] 2022 race/ethnicity data for Baltimore, MD, and Dallas, TX, EMAs are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Notes: Percentages shown are based on the row total.
EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
* To ensure confidentiality, values less than (<) 5 have been suppressed; in addition, data in the *Other gender identity* category are not included. Therefore, the numbers for each subpopulation may not sum to the row total.
[a] Includes all clients with reported gender information.
[b] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Notes: Percentages shown are based on the row total.
EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] Heterosexual contact with an individual with HIV or posing increased risk for HIV transmission (e.g., a person who injects drugs).
[b] Includes hemophilia and blood transfusion.
[c] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Notes: Percentages shown are based on the row total.
EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] Includes any sexual transmission category reported by transgender clients.
[b] Includes hemophilia and blood transfusion.
[c] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable. 2019 and 2020 data for Guam are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable. 2019 and 2020 data for Guam are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] Hispanics/Latinos can be of any race.
[b] 2022 data for Indiana are unavailable. 2022 race/ethnicity data for Maryland and Texas are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
* To ensure confidentiality, values less than (<) 5 have been suppressed; in addition, all data for clients of multiple races have been suppressed.
[a] Hispanics/Latinos can be of any race.
[b] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.
[c] 2022 race/ethnicity data for the Baltimore, MD, and Dallas, TX, EMAs are unavailable.

Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] Hispanics/Latinos can be of any race.
[b] 2022 data for Indiana are unavailable. 2022 race/ethnicity data for Maryland and Texas are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
* To ensure confidentiality, values less than (<) 5 have been suppressed; in addition, all data for clients of multiple races have been suppressed.
[a] Hispanics/Latinos can be of any race.
[b] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.
[c] 2022 race/ethnicity data for the Baltimore, MD, and Dallas, TX, EMAs are unavailable.

Abbreviation: FPL, federal poverty level.
Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable.

Abbreviations: EMA, eligible metropolitan area; FPL, federal poverty level; TGA, transitional grant area.
Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Abbreviation: FPL, federal poverty level.
Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable.

Abbreviations: EMA, eligible metropolitan area; FPL, federal poverty level; TGA, transitional grant area.
Viral suppression was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit during the measurement year and whose most recent viral load test result was <200 copies/mL.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Note: Data are based on provider location. Clients receiving services in multiple states were not included in state-specific totals or column subtotals and totals.
[a] 2022 data for Indiana are unavailable.

Abbreviations: EMA, eligible metropolitan area; TGA, transitional grant area.
Retention in care was based on data for people with HIV who had at least 1 outpatient ambulatory health services visit by September 1 of the measurement year, with a second visit at least 90 days after.
Notes: EMAs/TGAs are listed according to the primary state in which the jurisdiction resides. EMA/TGA delineations are based on provider location.
Data shown for individual EMAs and TGAs are not mutually exclusive; clients may have received services from providers in multiple EMAs and/or TGAs.
[a] The EMA/TGA service area crosses state boundaries. See Technical Notes for more information.

Abstract

This study examines perceived source credibility of health information in a moment of TGD health disinformation. Through thematic analysis of in-depth interviews with thirty transgender and gender diverse (TGD) individuals, findings suggest health information is marred by anti-TGD legislation, a sociopolitical force that bleeds into health information spaces. Disinformation and TGD health communication are intertwined in complex ways, whereby disinformation can undermine trust in healthcare institutions, lead to harmful behaviors, and contribute to the spread of diseases. Health communication practitioners need to center the safety and humanity of TGD people, addressing TGD health disinformation.

Keywords

transgender; gender diverse; health information seeking; source credibility; disinformation

Introduction

Health communication plays a crucial role in ensuring transgender and gender diverse (TGD) populations have access to accurate, inclusive, and affirming information about their health needs, rights, and available resources. Transgender is a term used to describe individuals whose gender identity differs from the sex they were assigned at birth. Transgender individuals may undergo social, medical, or legal transition to align their gender expression with their gender identity. Gender diverse is a broader term that encompasses individuals whose gender identity or expression differs from societal expectations or norms associated with their assigned sex at birth. This includes transgender individuals as well as individuals who identify as non-binary, genderqueer, genderfluid, or any other non-conforming gender identity. The purpose of this research is to examine health information seeking and perceived source credibility among TGD populations.

Health disparities in TGD communities are largely attributed to structural and social barriers individuals face in accessing health information and resources (Augustaitis et al., 2021). Health information for TGD populations is scarce because of a systematic erasure of TGD health data (Nolan et al., 2019), avoidance of non-gender-transition-related medicine and health by TGD people due to the perception of discrimination (Kcomt et al., 2020), and broader institutional limitations of healthcare access for TGD people (Feldman et al., 2021). Extant research underscores that TGD populations often avoid visiting healthcare facilities citing reasons such as hostile environments (Kcomt et al., 2021), traumatic experiences at the medical facility (Jaffee et al., 2016), as well as structural barriers such as medical costs and insurance issues (Bakko & Kattari, 2020). Furthermore, social and institutional stigma against TGD individuals has led to the exclusion of TGD care in medical training, which contributes to limited knowledge and experience in the TGD health domain (Meyer et al., 2020), resulting in provider ambivalence and uncertainty when interacting with TGD patients (Dolan et al., 2020; Marshall-Paquin et al., 2023).

TGD individuals may face challenges in accessing comprehensive and accurate health information tailored to their specific needs. Much of the available health information may not address their unique healthcare requirements (Pohjanen & Kortelainen, 2016), leading to gaps in knowledge and understanding about TGD health issues (Korpaisarn & Safer, 2018). Health information resources often lack cultural competence, meaning they may not be sensitive to the needs, identities, and experiences of TGD individuals. This can result in misunderstandings, miscommunication, and ultimately, inadequate care. Without access to accurate health information, TGD individuals may be more vulnerable to misinformation and harmful practices (Billard, 2024; Lepore et al., 2022). Misinformation and a lack of accurate and affirming health information (Augustaitis et al., 2021) can contribute to mental health disparities within TGD communities (Scheim et al., 2020), and feelings of isolation, anxiety, and depression can arise when individuals feel that their health needs are not understood or supported (Hughto et al., 2021).

Addressing health disparities in TGD communities requires efforts to ensure that health messages are inclusive, accurate, and readily accessible. Health messages are conveyed through a variety of communication methods including traditional media (e.g., television,

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

radio, print media), digital media (e.g., websites, social media, blogs and email newsletters), mobile applications, community outreach and events (e.g., health fairs, workshops, seminars), interpersonal communication (e.g., peer-to-peer communication, consultations with practitioners) and campaigns (e.g., public service announcements, pharmaceutical advertising). Research in health communication has generated evidence that demonstrates strategic health communication can reduce health risks and incidence of disease and improve quality of life (Kreps & Neuhauser, 2015). While health communication is an important component of addressing TGD health inequities, there is a dearth of research attending to the experiences and perspectives of TGD populations (Combs et al., 2018), and a lack of research on health information seeking and source credibility among priority populations (Jackson et al., 2019). Source credibility and health information seeking are vital to ensure TGD populations receive accurate, safe, empowering, and affirming healthcare that meets their unique needs and identities.Top of Form Therefore, through in-depth interviews with 30 TGD people, we examine health information seeking and source credibility pertaining among TGD populations.

Literature Review

Health Information Seeking—Health information seeking has been long studied among non-TGD populations, and research has examined health information needs (Chiet et al., 2020; Shi & Luo, 2020; Pian et al., 2020) and the influencers of health information seeking behavior (Chang & Huang, 2020; Rowley et al., 2017) and source selection process (Zhang, 2014; Song et al., 2021). Populations may seek health information online via search engines, provider websites, and online health communities, and by utilizing online networks through social media platforms (Wang et al., 2021) Online health communities can fill information gaps, which may be useful for individuals isolated from others. Among TGD populations, health information is frequently exchanged in online communities, and users post and/or consume health information on social media platforms and user-generated information sites (see Evans et al., 2017; Hawkins & Gieseking, 2017; Karami et al., 2018; Selkie et al., 2019). Importantly, despite the wealth of health information online for TGD people, individuals must vet content on social media channels for relevance and quality (Morse et al., 2023).

Health information seeking behavior is influenced by a variety of factors, many of which have been studied extensively among non-TGD populations. Demographics play a role in how individuals seek health information. For example, younger people may be more likely to use the internet for health information, while older adults may rely more on traditional sources like healthcare providers (Miller & Bell, 2012). Perceived health status may impact online health information seeking, whereby individuals who perceive themselves as being in poor health are more likely to seek health information to address their concerns (Alwi & Murad, 2018). Availability of resources such as internet access, libraries, healthcare providers, and health insurance can influence health information seeking behavior. Lack of access to these resources may limit an individual's ability to seek out information (Kang et al., 2022). Additionally, trust in the source of health information is critical (Rowley et al., 2017). Non-TGD individuals are more likely to seek information from sources they perceive as credible, such as healthcare providers, government agencies, and

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

reputable websites. However, health information seeking and source credibility among TGD populations remains underexamined.

Source Credibility—Source credibility is crucial when seeking and evaluating health information, and several factors influence perceptions of credibility. Individuals are more likely to perceive information as credible if it comes from sources perceived as knowledgeable or expert in the field (Eastin, 2001). For health information, this often includes healthcare professionals, researchers, and reputable health organizations (Kivits, 2006). The reputation of the source significantly affects credibility and perceptions; therefore, established institutions, organizations, and well-known experts are generally considered more credible than unfamiliar or obscure sources (Metzger & Flanagin, 2015). Over time, consistency of information may enhance credibility with sources that provide accurate, evidence-based information may be perceived as more credible than those that frequently make errors or contradict themselves (Stella, 2003). Recommendations from healthcare professionals or reputable institutions lend credibility to health information sources (Zhao et al., 2024). While scholars have long been examining factors that influence source credibility of health information among non-TGD populations, sexual and gender minority populations have historically not been studied.

A growing body of research analyzes the factors influencing LGBTQ+ individuals' health information seeking. Certain demographic factors are associated with online health information seeking. For example, LGBTQ participants identifying as Hispanic/Latina were less likely to seek health information online than whites (Gerke et al., 2020). Psychological factors may influence health information seeking among LGBTQ+ individuals, including sexual self-efficacy, the perceived bias of health care providers, and perceived control, with sexual health information from significant others as the best predictor of one's sexual self-efficacy (Charest et al., 2016). LGBQ individuals who perceived provider bias were significantly more likely to seek health information on the internet and from friends and family members who were not medical professionals (Jabson et al., 2017). Physical and behavioral health information related to STDs was reported to be the most frequently sought information, with STI/STD-related topics as the principal focus of LGBTQ+ health information seeking literature (Jia et al., 2022), leading underexamined source credibility of preventive health information among this population. We understand preventive health information as knowledge intended to prevent illness, disease, or injury rather than treating them once they occur. This information contains proactive steps aimed at maintaining or improving health and well-being that can encompass a variety of activities, including screenings, vaccinations, and education about risk factors. Therefore, this study is guided by the following inquiry: How do TGD individuals perceive source credibility of health information pertaining to preventive health?

Method

Thirty semi-structured interviews were conducted online via Zoom meeting software with TGD individuals between February 21, 2023 and July 31, 2023. The interviews were conducted online to eliminate geographic barriers to participation. The inclusion criteria were that the participants had to be 19 years of age or older, identify as gender diverse

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

(e.g., transgender, gender queer, non-binary), and live in the United States. Participants were recruited via convenience sampling. A distribution list of 32 community-based organizations and coalitions working with TGD populations was created using a Google search. Recruitment messages with attached flyers were sent through the established list. Additional recruitment was done via social media sites and publicly accessible interest groups with a TGD focus on WhatsApp, Instagram, and Facebook. Recruitment materials included a QR code and a link to a webpage with information about the study, including inclusion criteria. Interested individuals completed an online, self-administered screener survey. Eligible and interested participants provided an online informed consent form prior to continuing registration. After consent, participants completed a demographic form and selected an interview time through the online scheduling platform. Inclusion criteria were validated by self-report. Participants were provided a password-protected Zoom link upon scheduling.

Thirty (30) interviews were included in the analysis. The interviews were conducted by two interviewers trained in qualitative interviewing techniques. A short TGD-responsive resource guide for referral was created and available to interviewees as a resource during or after the interviews. Interviews lasted approximately sixty (60) minutes each (range: 41–94 minutes) and were recorded to a secure cloud online server. An interview guide was followed, including open-ended questions and probes. The script was piloted with two TGD individuals, and adjustments were made to the script based on feedback. Questions regarding source credibility included: "*When it comes to your health, tell me about your trusted sources of health information"* and *"Tell me about why you trust these sources of information*." Participants were provided with operational definitions of key concepts such as "health communications campaigns." Participants were given examples of health communications campaigns and clarified how these differed from direct patient communication, as needed to ensure understanding of the concepts.

Upon completion of the interview, recordings were transcribed using Otter.ai and then matched to audio recordings for quality control. Participants were provided a $100 electronic gift card as an incentive for participation. Study protocols were approved by the Institutional Review Board at The University of Texas at Austin.

Data Analysis

Audio recordings of the interviews were transcribed, and participants were de-identified. Interview transcripts were coded using NVivo software for Mac. Thematic analysis was done using inductive coding, allowing themes to emerge organically using open coding. Coding procedures and theme development were completed by two members of the research team (Creswell & Poth, 2016). The research team collectively reviewed and discussed coding and revised themes as needed. The research team developed a codebook that was used in thematic development and assessment, a process that ensured validity of the study and its analysis. The following section presents the findings of the analysis, starting with the demographic characteristics of participants.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Findings

Participant Demographics

Of the sample, 27% (n = 8) were young adults ages 19 – 24, 43% (n = 13) were ages 25 – 34, 23% (n = 7) were ages 35 – 59, and 7% (n = 2) were over 60 years old. Participants' ages ranged from 19 to 75 years of age. Half of the sample identified as White (n = 15), 20% Native American (n = 6), 13% African American/Black (n = 4), 10% Latinx (n = 3), 3% Asian (n = 1), and 3% Multiracial (n = 1). Gender identity was relatively evenly distributed with 30% identifying as a transgender woman (n = 9), 37% identifying as a transgender man (n = 11), and 33% identifying as non-binary (n = 10). For sexual orientation, 47% of the sample identified as queer (n = 14), 13% as bisexual (n = 4), 13% as pansexual (n = 4), 10% as asexual (n = 3), 7% as gay (n = 2), 7% as lesbian (n = 2), and 3% as straight (n = 1).

Category	Sub-category	Percentage (%)	Number (n)
Age Group	19 – 24	27	8
	25 – 34	43	13
	35 – 59	23	7
	60+	7	2
Race/Ethnicity	White	50	15
	Native American	20	6
	African American/Black	13	4
	Latinx	10	3
	Asian	3	1
	Multiracial	3	1
Gender Identity	Transgender Woman	30	9
	Transgender Man	37	11
	Non-binary	33	10
Sexual Orientation	Queer	47	14
	Bisexual	13	4
	Pansexual	13	4
	Asexual	10	3
	Gay	7	2
	Lesbian	7	2
	Straight	3	1

The following themes emerged from the data: 1) perilous socio-political climate; 2) precarious mass media landscape; and 3) benevolent community-based organizations.

Perilous socio-political climate

Although participants are largely distrustful of government, when asked about general health information, federal institutions were commonly cited as sources of credible health information due to providing scientific, peer-reviewed information. Health information from

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

federal institutions such as the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH), were most often referenced as being credible, due to their reliance on evidence-based research. However, data point to source credibility as influenced by the broader socio-political climate. Political parties in power, influence of interest groups, and elected officials in leadership play a crucial role in shaping participants' perceptions of source credibility of health information. Many participants expressed diminishing trust and credibility in health information coming from both federal and local health agencies because of the interplay between federal agencies and government, a sentiment encapsulated by one participant:

> I don't like the government. If I'm gonna be honest, I have a lot of mistrust of the government or any authoritative like figures in that way. I mean, like, I did look at like CDC guidelines, and I do in general, like, trust the CDC. But if the governor puts out something, especially during COVID, I would always go and double check those things because I just genuinely didn't like trust it.

Participants perceive federal institutions like the National Institutes of Health as empirically driven institutions that are like the engine driving medical breakthroughs and advancements, aiming to make life better for everyone by tackling health challenges head-on. Findings illuminate that TGD individuals do not trust state and local government officials, but they do have faith in federally funded institutions, like health research organizations and federal or state university hospitals. Several participants expressed a deep distrust of the government, uncertain about health information disseminated from state-level entities. One participant noted:

Lord, Texas is a hot mess right now. I'm just gonna be blunt. Our key officials like the Governor and the Attorney General tried having the Department of Family Services go after parents who are helping their trans youth access gender affirming services…There's a ton of bills right now targeting the trans community, but especially youth. So, right now, the state government [is] very firmly on my distrust list.

Participants like this individual chronicled the ways anti-TGD legislation by state government officials erodes trust in government sources of health information. Another participant noted that in their home state of North Dakota, the governor signed a bill into law that restricts transgender health care in the state, making it a crime to provide gender-affirming care to people younger than 18, a ruling that goes against international health guidelines pertaining to TGD health. The participant recounted an attempt by government officials to enact a law that would require any government entity in North Dakota to use an individual's pronouns based on their assigned sex at birth. Because of this proposed legislation, he stopped going to the government-funded public health clinic for his medication and was forced to find another provider that would use his correct pronouns and name. He expressed a complete lack of trust in health information grounded in the larger bureaucratic influence government has on health and medical institutions. Other participants noted a broader skepticism of government resources of health information, because of the historical disregard and erasure of queer people, indigenous populations, and communities of color. One participant noted:

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

> A lot of people are very skeptical of government resources in terms of health information. I still exercise a healthy skepticism, even for government resources, because historically governments have not had the needs of queer people and indigenous people, people of color in mind.

Participants' feelings of skepticism are rooted in a deep historical violence and erasure of queer lives in health and medicine, as well as erasure and epistemological violence that has dominated mainstream media.

Precarious mass media landscape

News media were frequently referenced as lacking credibility, and journalists' coverage of issues pertaining to TGD people was gravely impacted by the tone of state and local level legislation on TGD communities. Journalists were referenced as not reliable, often changing their messages to gain advertising or ratings, and exhibiting bias and polarizing TGD people in their reporting. One participant shared his longstanding distrust of news media: "I've always been skeptical of the news, because there's always an angle. There's always a bias. So, I prefer unbiased sources." For participants like him, a biased source is an uncredible source. Amidst the backdrop of the COVID-19 pandemic, a climate of misinformation shapes participants perceived source credibility of health information. One participant noted:

> I'm looking at health stuff through the news. I'm finding it's better to look at a couple different newspapers or online newspapers and compare what they're saying. [For] example, Fox News is very right leaning. They were very much spreading misinformation about masking or vaccination at one point, or very dismissive of it. CNN can be I guess, a little more left leaning, or it's considered more left leaning. I find they sometimes sensationalize certain things… So, I like to hop around to see how much I trust that particular statistic or recommendation before just jumping with it. In terms of anything relating to being trans, I tend to be really cautious with the news.

Participants tend to filter through health information content, making sense of messages and sources based on attitudes and beliefs they hold about media outlets.

Benevolent community-based organizations

Most participants pointed to community-based organizations (CBOs) as the most trusted source of health information. Describing her local CBO, one participant noted, "I absolutely love community-based organizations. Specifically, things like the Transformation Project here in South Dakota is something that I really trust for health information, especially regarding transgender people and healthcare specifically targeted for us." Participants expressed a benevolence embodied by these agencies, and this perception was paired with perceived health information credibility attributable to geographic proximity and a hyper-local focus of a CBO to TGD communities served. Participants conveyed trust in the health communication information provided by these agencies, as they often employed people with TGD identities and lived experiences.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Discussion

Data from this research illuminate the complexity of perceived source credibility of health information among TGD individuals. On the one hand, TGD populations may only trust empirical, peer-reviewed health information. On the other hand, TGD populations demonstrate a distrust of any non-TGD community-based organizations. Because of the current legislative landscape in the United States, feelings about the anti-TGD political landscape creep into state and local health information sources. Based on the anti-TGD legislation in their regions, TGD populations operate from a place of deep distrust of governmental entities. Participants' responses to questions about health information conveyed a sense of uncertainty amid the broader sociopolitical landscape and climate of health misinformation.

Misinformation refers to information sent to media consumers that subject experts have determined to be incorrect (Vraga & Bode, 2020) without an intent to deceive (Hameleers et al., 2021; Wardle, 2017). Conversely, disinformation involves the dissemination of deliberately false information, and it is thereby intentional manipulation, fabrication, or decontextualization of information to attain a particular political goal (Hameleers et al., 2021). Findings from this study point to political disinformation about TGD people that impacts source credibility of health information.

Health misinformation is a core element of contemporary public discourse on transgender rights that has been mobilized to advance state and federal policies that limit and/or prohibit transition-related health care (Billard, 2024). Findings from this study suggest health information is marred by anti-TGD legislation, a sociopolitical force that bleeds into health information spaces. While perceptions of health information sources are implicated in misinformation, a deeper understanding of the concept is needed. The concepts of misinformation and disinformation are often interconnected and conflated, but they have significant conceptual distinctions. These distinctions manifest in the findings from this study.

The relationship between source credibility and trust in health communication is pivotal in shaping TGD individuals' perceptions, decisions, and behaviors related to their health. Most importantly, addressing disinformation is essential for health communication practitioners to effectively convey accurate and evidence-based information and promote positive health outcomes among TGD populations. Importantly, health institutions and health communication practitioners may not be aware of and comprehend the feelings TGD people have about their lives and their health. When making sense of health information, TGD people may rely on various cognitive schemas that affect how individuals perceive, interpret, and respond to health information from various messengers and media outlets. Findings suggest TGD people may seek out and interpret information in ways that confirm their pre-existing beliefs and attitudes toward health information sources, suggesting a confirmation bias. They may be more inclined to trust and accept health information sources that align with their existing worldview. TGD individuals may categorize health information sources based on generalizations about the source's political affiliation, credibility, or biases. For example, someone might dismiss a campaign about colon cancer and colorectal screening

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

from a local government because they perceive it as biased or untrustworthy. Health disinformation can have significant implications for TGD populations, exacerbating existing health disparities and posing risks to individual well-being. Disinformation about health can lead to confusion and distrust among TGD individuals, potentially delaying or preventing them from accessing healthcare services. Health disinformation may contribute to increased risk of adverse health outcomes, such as increased risk of gynecological cancers among TGD people with cervixes (World Health Organization, 2018) and increased risk of venous thromboembolism among TGD people who use estrogen and androgen-lowering hormone therapies (Van Bunderen et al., 2022). Future research is needed that empirically examines confirmation bias, stereotyping, and authority bias in health information seeking and source credibility among TGD populations.

Health disinformation can impede TGD individuals' ability to make informed decisions about their own healthcare and well-being. When disinformation is widespread or presented as credible, it can be difficult for individuals to discern accurate information from falsehoods, undermining their autonomy and agency in making decisions about their bodies and identities. Health communication practitioners need to center the safety and humanity of TGD people. To address the implications of health misinformation for TGD populations, health communication practitioners need to prioritize accurate, evidence-based information within TGD populations and communities. This includes providing accessible, affirming resources and support services, increasing cultural competency among healthcare providers, combating stigma and discrimination, and fostering critical thinking skills to evaluate health information critically. Additionally, efforts to regulate and counteract misinformation through media literacy initiatives (Bulger & Davison, 2018), community education campaigns, and advocacy for policies that protect transgender rights and access to affirming healthcare (Alstott et al., 2024) are crucial for promoting the health and well-being of TGD individuals. Most importantly, the onus should not be placed on TGD populations to combat health misinformation. Political leaders and government need to be held accountable for health misinformation and the violence enacted on TGD people. Scientific misinformation has been used to uphold legislative actions in the United States, resulting in laws that threaten the health and safety of TGD people but also require health workers to practice care that is against evidence-based guidelines or face career-ending retribution (Lepore et al., 2022). However, research suggests that political accountability in the contemporary informational environment is particularly difficult (Schiff et al., 2023).

The implications of this research will be useful to health communication practitioners who can adapt messages to better address the health information needs of TGD populations. Researchers and practitioners with funding and support from governmental agencies (e.g., NIH, CDC) shouldn't assume this affiliation is a source of credibility to their audiences. Rather, disseminating health information should begin with community-based partnerships in TGD communities. Additionally, practitioners need to translate and disseminate empirical research by way of white papers co-written with trusted TGD-affirming community health organizations.

The strong support for CBOs as credible sources of health information among participants has several implications for scholars and practitioners of health communication. Participants

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

perceive CBOs as trustworthy sources of health information; therefore, scholars and practitioners should recognize the importance of trusted messengers within communities and the potential impact they can have on health communication efforts. Understanding who community members view as credible sources can inform the development of effective communication strategies and interventions. Scholars and practitioners should prioritize partnerships with CBOs and community leaders to ensure that health messages are culturally relevant, linguistically appropriate, and resonate with the target audience. Collaborating with CBOs can facilitate access to diverse communities, build rapport and trust, and enhance the reach and effectiveness of health communication efforts.

Our research is not without limitations. This research employed convenience sampling, and participants were recruited through social media of community-based organizations and coalitions, which could have introduced bias. These audiences may have already had interaction and rapport with social service organizations and may be more inclined to prefer online communication. The study may not have captured the responses from those with limited resources or limited access to computers and technology. The sample size was limited to only 30 individuals and is not representative of the diversity of TGD populations.

Additional research is needed that focuses on identifying, examining, and solving health inequities faced by TGD individuals by way of communication problems, specifically research that develops a deeper understanding of social media and social networks, exploring the effectiveness of partnerships with TGD content creators to lead message delivery. Additionally, a content analysis of health communications campaigns currently in rotation, including social media campaigns, is needed to confirm the communications gap in a systematic manner. Research is also needed related to the long-term effects of health communications campaigns. Additionally, while there is a growing corpus of research on health information seeking among TGD populations, this research points to the need to distinguish the experiences of non-binary populations.

Conclusion

TGD health communication involves the dissemination of accurate and understandable health information, aiming to promote health, prevent disease, and improve healthcare outcomes. In addition to policy implications, TGD health disinformation can undermine trust in health institutions, lead to harmful behaviors, and contribute to the spread of diseases among gender diverse populations. Health communication efforts can counteract TGD health disinformation by providing evidence-based, accurate, and easily understandable information to policy makers and federal institutional stakeholders. Health communication practitioners can monitor channels where disinformation spreads and address false claims with accurate information, engaging with communities, fact-checking organizations, and social media platforms to correct misinformation and prevent further dissemination.

Abstract

Introduction

Transgender individuals are at risk for HIV. HIV risks are dynamic and there have been substantial changes in HIV prevention (e.g., pre-exposure prophylaxis [PrEP]). It is thus time to revisit HIV prevalence and burden among transgender individuals. The objective of this systematic review and meta-analysis was thus to examine worldwide prevalence and burden of HIV over the course of the epidemic among trans feminine and trans masculine individuals.

Methods

We conducted an updated systematic review by searching PsycINFO, PubMed, Web of Science, and Google Scholar, for studies of any research design published in in a peer-reviewed journal in any language that reported HIV prevalence among transgender individuals published between January 2000 and January 2019. Two independent reviewers extracted the data and assessed methodological quality. We then conducted a meta-analysis, using random-effects modelling, to ascertain standardized prevalence and the relative burden of HIV carried by transgender individuals by country and year of data collection, and then by geographic region. We additionally explored the impact of sampling methods and pre-exposure prophylaxis (PrEP).

Results

Based on 98 studies, overall standardized HIV prevalence over the course of the epidemic, based on weights from each country by year, was 19.9% (95% CI 14.7% - 25.1%) for trans feminine individuals (n = 48,604) and 2.56% (95% CI 0.0% - 5.9%) for trans masculine individuals (n = 6460). Overall OR for HIV infection, compared with individuals over age 15, was 66.0 (95% CI 51.4–84.8) for trans feminine individuals and 6.8 (95% CI 3.6–13.1) for trans masculine individuals. Prevalence varied by geographic region (13.5% - 29.9%) and sampling method (5.4% - 37.8%). Lastly, PrEP effects on prevalence could not be established.

Funding: This systematic review and meta-analysis was funded by AIDSFonds (P-30805). See https://aidsfonds.nl. SS & KJ received the funding. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Competing interests: The authors have declared that no competing interests exist.

Conclusion

Trans feminine and trans masculine individuals are disproportionately burdened by HIV. Their unique prevention and care needs should be comprehensively addressed. Future research should further investigate the impact of sampling methods on HIV prevalence, and monitor the potential impact of PrEP.

Introduction

Transgender individuals, defined as individuals who experience a misalignment between the sex they were assigned at birth and their gender identity or whose gender identity is incongruent with gender norms, [1, 2] are at significant risk for an HIV infection [3]. Individual level risk factors include condomless sex, particularly receptive anal sex, coinfection with other sexually transmitted infections, transactional sex, and the shared use of needles for hormone and/or silicon injections [4–8]. Individual level risk factors do not stand alone; they result from, and intersect with, other factors such as mental health difficulties, substance use, and many forms of marginalization and stigmatization that limit, among other things, educational and work opportunities, as well as legal recognition of one's chosen gender [6, 9–14]. Given that HIV risk among transgender individuals is a dynamic phenomenon, it is important to regularly monitor and update our knowledge of HIV prevalence and burden, such that we can identify trends that can inform policy-making and interventions. Here, we present a comprehensive updated systematic review of HIV prevalence over the course of the epidemic and a meta-analyses of HIV burden among transgender individuals covering literature from 2000 until 2019.

Previous systematic reviews and meta-analyses

Since 2008, a series of systematic reviews and meta-analyses have been published [1, 4, 5, 11, 15–17]. The first, by Herbst and colleagues, [15] investigated HIV prevalence among trans individuals in the United States, covering literature from 1988 until early 2007, and included laboratory-confirmed and self-reported prevalence. Pooled HIV prevalence based upon studies reporting laboratory-confirmed HIV status was, for trans women, 27.7%. HIV prevalence among trans women based upon self-reported HIV status was 11.8%. Among trans men, only one study reported laboratory confirmed prevalence (2%) and self-reported prevalence rates ranged from 0% to 3%. The second systematic review and meta-analysis by Operario et al. [16] set out to assess whether transgender female sex workers (FSW) experienced higher HIV infection rates than cis-gender sex workers and transgender women who do not engage in sex work, using both laboratory-confirmed and self-reported HIV prevalence rates published between 1998 and 2006. HIV prevalence was 27.3% in transgender FSW and 14.7% in trans women who did not engage in sex work. Operario et al.'s meta-analysis further showed that transgender FSW are at significantly higher risk for HIV than cis-gender sex workers and trans women who do not engage in sex work [16]. In 2013, Baral and colleagues [4] published a systematic review and meta-analysis of HIV prevalence among transgender women, covering literature from 2000 to November 2011 and using only laboratory-confirmed HIV prevalence rates. Pooled prevalence was 19.1% and the meta-analytical findings showed that, compared to all adults of reproductive age, the odds ratio for HIV infection in trans women was 49 across the 15 countries included, thus demonstrating that transgender women carry a high burden of HIV [4]. Poteat and colleagues [5] followed up on Baral et al.'s work with a systematic review, but not a meta-analysis, of HIV

prevalence literature published between 2012 and 2015, looking now at both trans feminine and trans masculine populations. Prevalence rates varied substantially based on locale but Poteat et al. [5] concluded, in line with the previous reviews, that HIV prevalence was high in trans feminine populations. They also concluded that data on HIV among trans masculine individuals is still very limited. Almost simultaneously, Reisner and Murchison [1] published a global research synthesis of HIV and STI risks in adult trans men, but not trans women, using 25 studies. They found HIV prevalence rates for trans men ranging from 0% to 4.3% for laboratory-confirmed HIV status and 0% to 10% for self-reported HIV, suggesting that trans masculine individuals may also be more vulnerable to HIV than cis-gender adults. Additionally, in 2017, MacCarthy and colleagues [11] published a global systematic review of HIV and sexually transmitted infections among transgender individuals. They reported HIV prevalence rates ranging from 0% to 17.6% for self-reported HIV status and 0.6% to 34.1% for laboratory-confirmed HIV status. However, given their focus on HIV and STI co-infection, the HIV prevalence rates reported in that review were derived only from studies that also reported STI prevalence rates. The reported prevalence rates were thus based on a mere 6 studies for self-reported HIV status and 13 studies for laboratory-confirmed HIV status. Recently, Becasen et al. [17] published a systematic review and meta-analysis of HIV prevalence among transgender individuals in the United States only using literature published in the United States between 2006 and May 2017. They established that laboratory-confirmed HIV prevalence was 14.1% for trans women and 3.2% for trans men; self-reported prevalence was 16.1% and 1.2% for trans women and trans men, respectively.

Current concerns

Overall, the various systematic reviews and meta-analyses demonstrate that transgender individuals, particularly trans feminine individuals, are disproportionately burdened with HIV but none of the more recent systematic reviews have comprehensively updated Baral et al.'s worldwide systematic review and meta-analysis with both transfeminine and transmasculine individuals. Furthermore, from a methodological perspective, more fine-grained analyses (e.g. by country and year of data collection) are being called for, rather than only pooled analyses by country or region, as has been the methodological approach in previous meta-analyses. Additionally, critique about reported prevalence rates has been levied, with the claim that many studies have relied on convenience samples of, often, transgender women who engage in sex work, which may inflate prevalence rates [18, 19]. Also, previous meta-analyses have not differentiated between various sampling strategies and this may impact meta-analytical findings. Further, there have been substantial and fundamental changes in HIV prevention in recent years. One is the emergence of pre-exposure prophylaxis (PrEP) as a powerful tool for HIV prevention for at risk groups like transgender individuals [5, 8, 20–23]. With these considerations in mind, we feel it is time to revisit worldwide HIV prevalence and burden among transgender individuals. We therefore systematically reviewed literature published between 2000 and 2019 on HIV prevalence among transgender individuals and then conducted a meta-analysis 1) to establish prevalence rates for both trans feminine and trans masculine individuals; and 2) to compare the burden of HIV infection among transgender individuals to individuals over 15 years of age in the countries and regions from which samples were derived, taking year of data collection into account. We then explored the possible impact of sampling methods and of PrEP on prevalence rates and the burden of HIV infection.

Methods

Search strategies and eligibility

We searched, in November 2017 and again in January 2019, PsycINFO, PubMed, Web of Science, and Google Scholar®, for studies in all languages published between January 1st, 2000

and January 28th, 2019. We selected this timeframe in order to gain a complete, comprehensive, and nuanced understanding of worldwide prevalence over and burden of HIV among transgender individuals. We also reviewed the studies included in Baral et al. [4] and in Poteat et al. [5] to ensure that they were covered in our analysis as well. We explicitly overlapped the timeframe in our meta-analysis with those of previous meta-analyses in order to generate comprehensive and robust meta-analytical findings. It also allowed us to explore the impact of applying more refined methodology (standardized vs. pooled prevalence rates) in the meta-analysis, and compare findings delivered by the different meta-analytical approaches. Articles and citations were downloaded and managed in the reference software Mendeley®.

We searched for articles on (the treatment of) HIV and transgender individuals using the following search terms: HIV OR AIDS OR "PrEP" OR "Pre-Exposure Prophylaxis" OR "TasP" OR "treatment as prevention" AND *transgender* OR "MTF" or "male to female transgender" OR "FTM" OR "female to male transgender" OR *transsexual* OR "travesty" OR "cross dresser" OR "koti" OR "hijra" OR "mahuvahine" OR "mahu" OR "waria" OR "katoey" OR "bantut" OR "nadleehi" OR "berdache" OR "xanith". These terms are in line with the terms previously used by Baral et al. [4].

Studies of any research design published in peer-reviewed journals that reported laboratory- confirmed prevalence of HIV among transgender individuals were included. When prevalence rates were pooled across trans feminine and trans masculine individuals or when prevalence was pooled across trans feminine individuals and men who have sex with men (MSM), we contacted the authors and requested separate prevalence rates for the populations included.

Study selection and data extraction

Titles and abstracts were screened by two independent reviewers and articles that clearly did not include HIV prevalence data were excluded, as were duplicates. All articles that met the inclusion criteria and articles that needed further review to ascertain whether they met the criteria were subsequently downloaded. When one reviewer deemed the title and/or abstract potentially relevant and the other did not, the full-text for that article was nonetheless downloaded. Subsequently, the full texts were reviewed. When studies reported duplicate data, the study with the smallest sample size was excluded. If sample sizes were identical, the later publication was excluded. Any conflicts over study inclusion were resolved by project leads (KJ and SS) in conjunction with the researchers running the meta-analysis (MvD and HW). The PRISMA reporting checklist was used to guide the reporting of this study. No protocol was registered for this review.

Data were extracted by two trained coders using a standardized extraction form that included details about sample size, sampling method, sample description, recruitment location, time period of study, age range, transgender type (trans masculine/trans feminine/both), HIV measure (self-reported/laboratory testing), and HIV prevalence or incidence.

Methodological quality assessment

Given the lack of consensus on fitting quality assessment tools for epidemiological studies, [24] we developed criteria specifically for this systematic review and meta-analysis. In doing so, we used and adapted appropriate criteria from the JBI Critical Appraisal Checklist for Studies Reporting Prevalence Data [25]. Studies were deemed of sufficient quality if: 1) biological testing (rather than self-reported HIV status) was used to establish HIV diagnoses, as was done in Baral et al. [4]; 2) study participants were described in sufficient detail, meaning that prevalence was reported, or subsequently obtained directly from the authors, specifically for

trans feminine and/or trans masculine individuals (rather than transgender individuals as a whole group); 3) if the study setting/location was sufficiently detailed; 4) if the data collection timeframe was reported; 5) if prevalence or frequency of HIV diagnosis within the total sample were reported; and 6) if sample size was at least 40 for trans feminine individuals. We did not apply a minimum sample size for studies reporting prevalence among trans masculine individuals as the majority of studies had small sample sizes, and a minimum sample size would have led to the exclusion of most studies reporting HIV prevalence among trans masculine individuals. Additionally, we did not exclude studies based on sampling method as investigating the impact of sampling methods was one of the objectives of this meta-analysis.

Data analyses

First, we used analogous methodology to prior meta-analyses [4, 26, 27]. We grouped studies by country, weighted by sample size. We calculated pooled HIV prevalence and 95% confidence intervals (CIs) per country. We did this separately for trans feminine and trans masculine samples. In line with previous meta-analyses, we then calculated odds ratios per country by dividing the HIV prevalence among transgender individuals (numerator) by the HIV prevalence rate among individuals over 15 years of age in the general population in the country from which the sample was derived (denominator), as reported by the 2017 UNAIDS reports (where prevalence estimates for adults are from 15 years of age onward) [28] and estimations of adult population size from the US Census Bureau International Division [29]. These results are reported in S1 Appendix.

Then, to achieve a more refined methodological analysis, we standardized rather than pooled prevalence rates, and ran the meta-analysis again, this time matching country-level prevalence rates to year(s) of data collection for the included studies. When data were collected over multiple years in the original studies, the median year of the year-span was chosen for the country by year analysis. If HIV prevalence in the sample was 0, we calculated confidence intervals using the Wilson interval [30]. Then, we grouped countries by geographic region (Africa, Latin America, Asia, and Global North) and calculated, per geographic region, the standardized HIV prevalence among trans feminine individuals as well as odds ratios based on weights from each country-year.

Subsequently, given recent discussions about the impact of sampling methods on findings pertaining to HIV prevalence among trans feminine individuals, [18] we grouped studies by sampling method, and calculated standardized HIV prevalence by sampling method. We delineated ten sampling methods, namely cluster sampling, convenience sampling, purposive sampling, respondent driven sampling, snowball sampling, sampling from database health plan, as well as sampling via STI clinic, via hospital, via NGO, and via surveillance. Overlap in categories may exist as some studies used multiple sampling methods. In such cases, we categorized the study under its primary sampling method.

Lastly, we explored possible effects of the introduction of PrEP on HIV prevalence among trans feminine individuals. We focused on US studies only as PrEP has been available in the US since 2012, which is longer than in any other country. We conducted subgroup analyses, with data being collected either prior to the introduction of PrEP (1997–2011), or after the introduction of PrEP (2012–2017).

The meta-analysis was conducted with the statistical software R [31] using the metafor package [32]. We used a random-effects model and the DerSimonian-Laird method to estimate the model. The DerSimonian-Laird Q test and I^2 values were used to assess heterogeneity, with low, moderate, and high heterogeneity corresponding to I^2 values of 25%, 50%, and 75%. [33] We investigated publication bias by inspecting funnel plots [34].

Results

The study selection process is presented in Fig 1. We included 98 studies from a total of 34 countries, of which 78 studies described HIV prevalence in trans feminine individuals, 4 described prevalence in trans masculine individuals, and 16 described both. In total, we included 48,604 trans feminine individuals from 34 countries and 6460 trans masculine individuals from 5 countries. The included studies and relevant characteristics of those studies are reflected in Table 1.

The overall standardized HIV prevalence over the course of the epidemic, based on weights from each country by year, was 19.9% (95% CI 14.7% - 25.1% Table 2) for trans feminine individuals and 2.56% (95% CI 0.0% - 5.9%; Table 3) for trans masculine individuals. The overall OR for HIV infection, compared with individuals over 15 years of age, was 66.0 (95% CI 51.4–84.8; Table 2 and Fig 2) for trans feminine individuals and 6.8 (95% CI 3.6–13.1, Table 3 and Fig 3) for trans masculine individuals. Tables 2 and 3 also show the overall standardized prevalence rates and overall odds ratios per country by year for trans feminine individuals and trans masculine individuals, respectively.

Standardized prevalence rates and overall odd ratios (based on weights from each country by year) according to geographic region are presented in Table 4. In sub-Saharan Africa (n = 1192), standardized HIV prevalence among trans feminine individuals was 29.9% (95% CI 22.5% - 37.3%) and the overall OR for HIV infection, compared to individuals over 15

TF = trans feminine; TM = trans masculine.

https://doi.org/10.1371/journal.pone.0260063.t001

years of age in the countries from which we had prevalence data for trans feminine individuals, matched to year of data collection, was 21.5 (95% CI 6.3–73.7). In Latin America (n = 7917), standardized prevalence was 25.9% (95% CI 20.0% - 31.8%) and the overall OR for HIV infection, compared to individuals over 15 years of age, was 95.6 (95% CI 73.7–122.7). In Asia (n = 14,798), the standardized HIV prevalence was 13.5% (95% CI 2.3% - 17.7%) and the overall OR was 68.0 (95% CI 42.9–107.8). Lastly, in the Global North, thus in Australia, Europe, and North America (n = 24,697), the standardized HIV prevalence was 17.1% (95% CI 13.1% - 21.1%) and the overall OR for HIV infection was 48.4 (95% CI 28.2–83.9).

The standardized HIV prevalence by sampling method is reported in Table 5. The standardized HIV prevalence among transgender individuals when respondent driven sampling was employed (33 studies) was 23.3% (95% CI 18.0% - 28.4%). When prevalence rates were ascertained via STI clinic visits (26 studies), standardized prevalence was 17.4% (95% CI 12.2% - 22.7%). When convenience sampling was employed (14 studies), standardized prevalence was 19.7% (95% CI 14.8% - 24.5%) and when cluster sampling was employed (11 studies), the standardized prevalence was 19.6% (95% CI 14.4% - 24.9%). The remaining sampling methods were relatively infrequently employed (i.e., employed in 5 or fewer studies).

Next, we looked at the potential role of PrEP in reducing HIV prevalence among trans feminine individuals. Prior to the introduction of PrEP (1997–2011), the standardized HIV prevalence in US-based studies was 18.4% (95% CI 14.8% - 22.0%; Table 6) and the overall OR for HIV infection, compared to individuals over 15 years of age in the USA, was 53.5 (95% CI 29.7–96.5). After the introduction of PrEP (2012–2017), the standardized HIV prevalence in

Table 2. Meta-analysis of HIV prevalence in trans feminine individuals compared to all adults (age 15+).

Country	Year of data collection	Number of samples	Sample size	Frequency of HIV among TF in the samples	Prevalence (95% CI)*	Odds Ratio (95%CI)	HIV prevalence in adults (95% CI)

*Overall prevalence was calculated by direct standardization based on country-year weights used in meta-analysis.

https://doi.org/10.1371/journal.pone.0260063.t003

US-based studies was 23.7% (95% CI 20.2% - 27.2%) and the OR for HIV infection, compared to individuals over 15 years of age, was 58.0 (95% CI 12.3–275.9). The forest plot of this analysis is presented in Fig 4.

Heterogeneity was high across the studies that included trans feminine individuals ($Q = 6327.25$, $df = 86$, $p < .0001$, $I^2 = 98.63\%$). This may be because the studies were conducted in different countries using different methodologies. Heterogeneity was moderate for the studies that included trans masculine individuals ($Q = 102.06$, $df = 15$, $p<0.0001$, $I^2 = 72.17\%$). The funnel plots showed an asymmetrical distribution of studies and may therefore indicate publication bias (S2 Appendix in Fig A2.1 and Fig A2.2).

Discussion

This systematic review and meta-analysis affirms that transgender individuals are disproportionately burdened by HIV, and that this is the case for not only trans feminine individuals, but also for trans masculine individuals. Using a larger pooled sample than ever compiled before, we ascertained that trans masculine individuals almost seven times more likely to have HIV, and trans feminine individuals are 66 times more likely to have HIV, than other individuals over 15 years of age. Additionally, based on data from 34 countries across major geographic regions, we found support for the contention that the disproportionate burden for HIV carried by transgender individuals is a worldwide phenomenon, and that some regions, such as Africa and Latin America, may be impacted more than others. Further, we established that sampling methods are likely to impact prevalence rates and that, to date, PrEP prevention effects on HIV prevalence cannot be established.

To our knowledge, no previous study has estimated the HIV burden carried by trans masculine individuals worldwide. Reisner and Murchinson [1] did conduct a research synthesis of

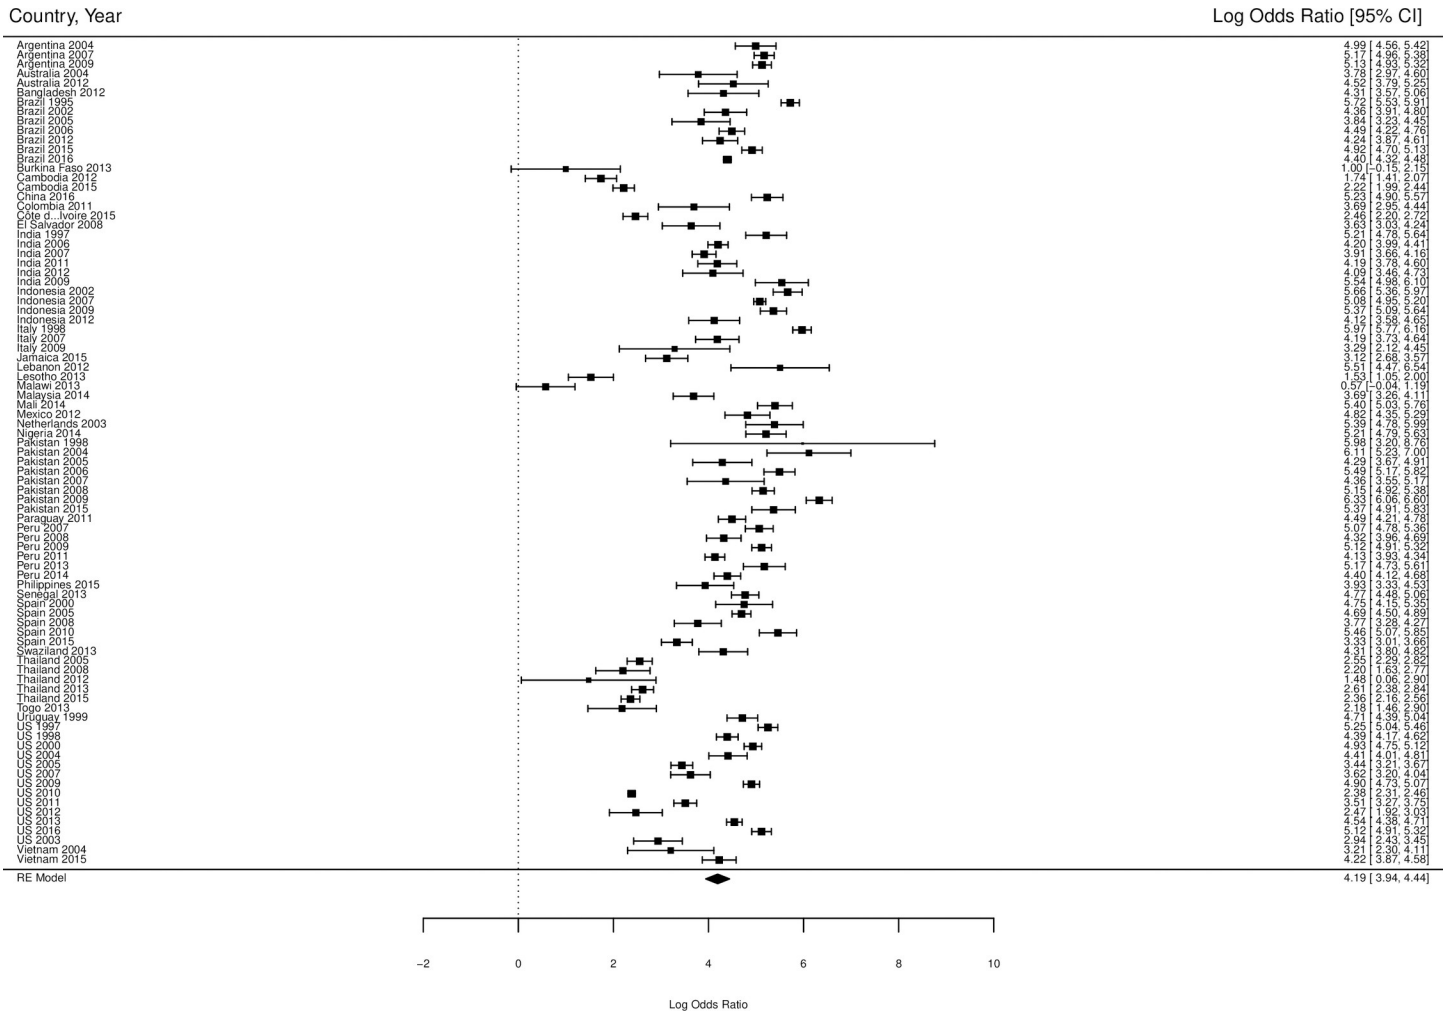

Fig 2. Forest plot of HIV prevalence in trans feminine individuals compared to all adults (age 15+). The scale on the x-axis is log odds ratio. The percentages indicate the weight of each country by year within the meta-analysis. The numbers in the right column are the log odds ratios including their confidence intervals. We converted these log odds ratios into odds ratios, as described in *Table 2*.

https://doi.org/10.1371/journal.pone.0260063.g002

HIV risks in trans masculine individuals where laboratory-confirmed prevalence ranged from 0% to 4.3% and Becasen and colleagues [17] established a laboratory-confirmed estimated prevalence rate of 3.2% but, in both studies, no odds ratios were calculated to ascertain the relative burden of HIV carried by trans masculine individuals. Our finding that trans masculine individuals are almost seven times more likely to have HIV than other individuals over 15 years of age indicates that many trans masculine individuals are indeed at risk for HIV. The presumption that trans masculine individuals almost exclusively have sex with cis-gender women and are therefore not at risk for HIV is thus incorrect [1]. As indicated by Reisner and Murchinson, there is a diverse range of bio-anatomies represented among trans masculine individuals and their partners in sexual encounters, and these should be considered in HIV prevention efforts [1].

Our finding that trans feminine individuals are 66 times more likely to have HIV than other individuals over 15 years of age is a higher estimate that the estimate generated in Baral and colleagues' meta-analysis, [4] where the odds ratio for HIV infection among transgender women was 49.1. We believe that the odds ratio and prevalence rates established in our

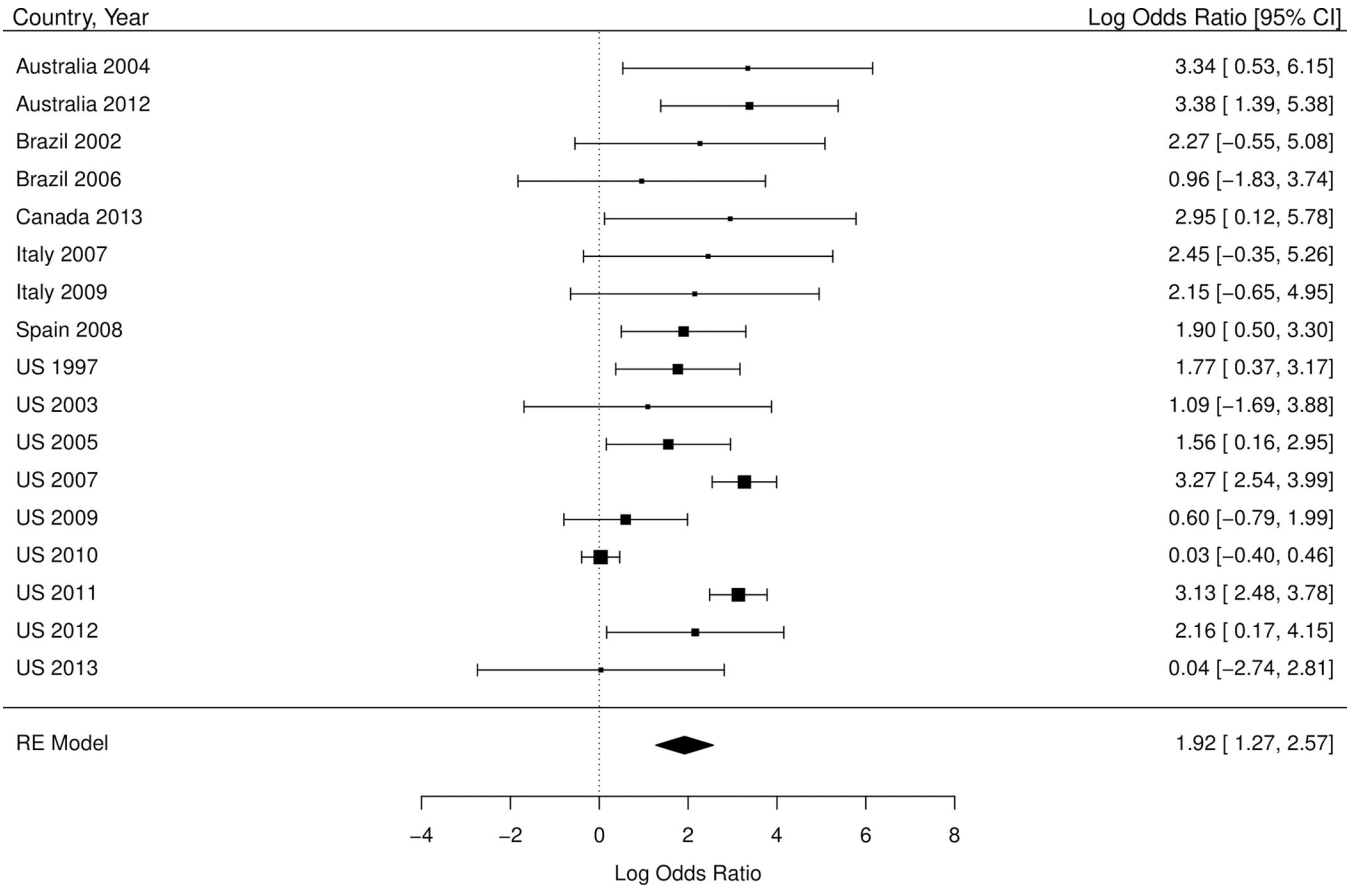

Fig 3. Forest plot of HIV prevalence in trans masculine individuals compared to all adults (age 15+). The scale on the x-axis is log odds ratio. The percentages indicate the weight of each country by year within the meta-analysis. The numbers in the right column are the log odds ratios including their confidence intervals. We converted these log odds ratios into odds ratios, as described in *Table 3*.

https://doi.org/10.1371/journal.pone.0260063.g003

systematic review and meta-analysis are likely more realistic estimations for two reasons. First, our methodological approach used standardized rather than pooled prevalence and took into account not only country but also year of data collection. In a pooled estimate, the total study population and total HIV cases are summed, and then a crude proportion is calculated. This does not take heterogeneity and variation among the included studies into account. Our standardization approach entailed taking the weights from each country-year into account. Without the weighted standardization, a country-year combination that contains large or small

Table 4. HIV prevalence and odds ratios for trans feminine individuals compared to all adults (age 15+), separated by geographic region.

Region	Number of countries	Number of Samples	Sample size	Prevalence (95% CI) *	Odds Ratio (95% CI) *	HIV prevalence in adults (95% CI)*
Africa	9	9	1192	29.9 (22.5–37.3)	21.5 (6.3–73.7)	4.69 (4.67–4.71)
Asia	11	35	14798	13.5 (2.3–17.7)	68.0 (42.9–107.8)	0.344 (0.343–0.345)
Global North	5	35	24697	17.1 (13.1–21.1)	48.4 (28.2–83.9)	0.297 (0.296–0.298)
Latin America	9	23	7917	25.9 (20.0–31.8)	95.6 (73.7–122.7)	0.391 (0.388–0.394)

Note. The HIV prevalence in adults of the population (last column) is the weighted prevalence of the countries included in this meta-analysis, not overall prevalence in the region.

* Results were calculated by direct standardisation of country-year sample size instead of pooling.

Table 5. HIV prevalence in trans feminine individuals, separated by sampling method.

Sampling method	Number of samples	Sample size	HIV prevalence (95% CI)*
Respondent driven sampling	33	12202	23.3 (18.0–28.4)
STI clinic visit	26	19360	17.4 (12.2–22.7)
Convenience sampling	14	3733	19.7 (14.8–24.5)
Cluster sampling	11	4273	19.6 (14.4–24.9)
Hospital	5	827	15.0 (9.8–20.4)
Snowball	4	1203	11.8 (8.0–15.6)
Surveillance	4	2339	9.1 (6.1–12.0)
NGO	2	213	37.8 (31.5–44.2)
Database health plan	1	3475	5.4 (4.6–6.1)
Purposive sampling	1	538	29.9 (26.1–33.8)

Note. For one study, the sampling method was unknown and is not included in this table.

*: Results were calculated by direct standardisation of country-year sample size instead of pooling.

https://doi.org/10.1371/journal.pone.0260063.t005

study samples is likely to deliver misleading pooled results. The standardized approach thus delivers a more robust estimation than a pooled approach. Second, due to recent increases in the number of studies reporting HIV prevalence among transgender individuals, the total sample of transgender individuals in our meta-analysis was almost four and a half times larger than the pooled sample in Baral et al. [4] Third, the data reviewed in Baral et al. was derived from 15 countries, all of which have male-dominant epidemics, while the data in the meta-analysis reported here was derived from 34 countries, thus lending additional support to the contention that the high burden of HIV among transgender individuals is a worldwide phenomenon.

Our finding that HIV prevalence among transgender individuals appears to be, over the course of the epidemic, higher in African and Latin American regions may point to greater disapproval of gender fluidity and the accompanying marginalization that puts transgender individuals more at risk for HIV in these regions, although we recognize that overall prevalence rates for HIV are higher in Sub-Saharan Africa than in many other regions. Nonetheless, this was the first systematic review and meta-analysis to include samples from Sub-Saharan Africa, and the findings from Sub-Saharan Africa point to a significant burden of HIV among transgender individuals. However, given that, in our analyses, the sample sizes for African regions and Latin America were smaller than the sample sizes for other regions, more research is needed to confirm that transgender individuals in these regions do indeed have higher prevalence rates and carry an even greater burden of HIV. Additionally, future research should also seek to establish HIV prevalence rates and burdens in other understudied regions such as Eastern Europe.

This meta-analysis also demonstrated that sampling methods are likely to impact prevalence rates. This is in line with critiques of sampling methods that were levied in earlier

Table 6. HIV prevalence and odds ratios for trans feminine individuals compared to all adults (age 15+) in US-based studies, according to whether data was collected before or after the introduction of PrEP (2012).

	Number of studies	Sample size	Frequency of HIV among TF in the samples	Prevalence (95%CI)*	Odds Ratio (95%CI)
Before PrEP	18	21022	1475	18.4 (14.8–22.0)	53.5 (29.7–96.5)
After PrEP	6	1401	358	23.7 (20.2–27.2)	58.0 (12.3–275.9)

Note. *Overall prevalence was calculated by direct standardization based on country-year weights used in meta-analysis.

https://doi.org/10.1371/journal.pone.0260063.t006

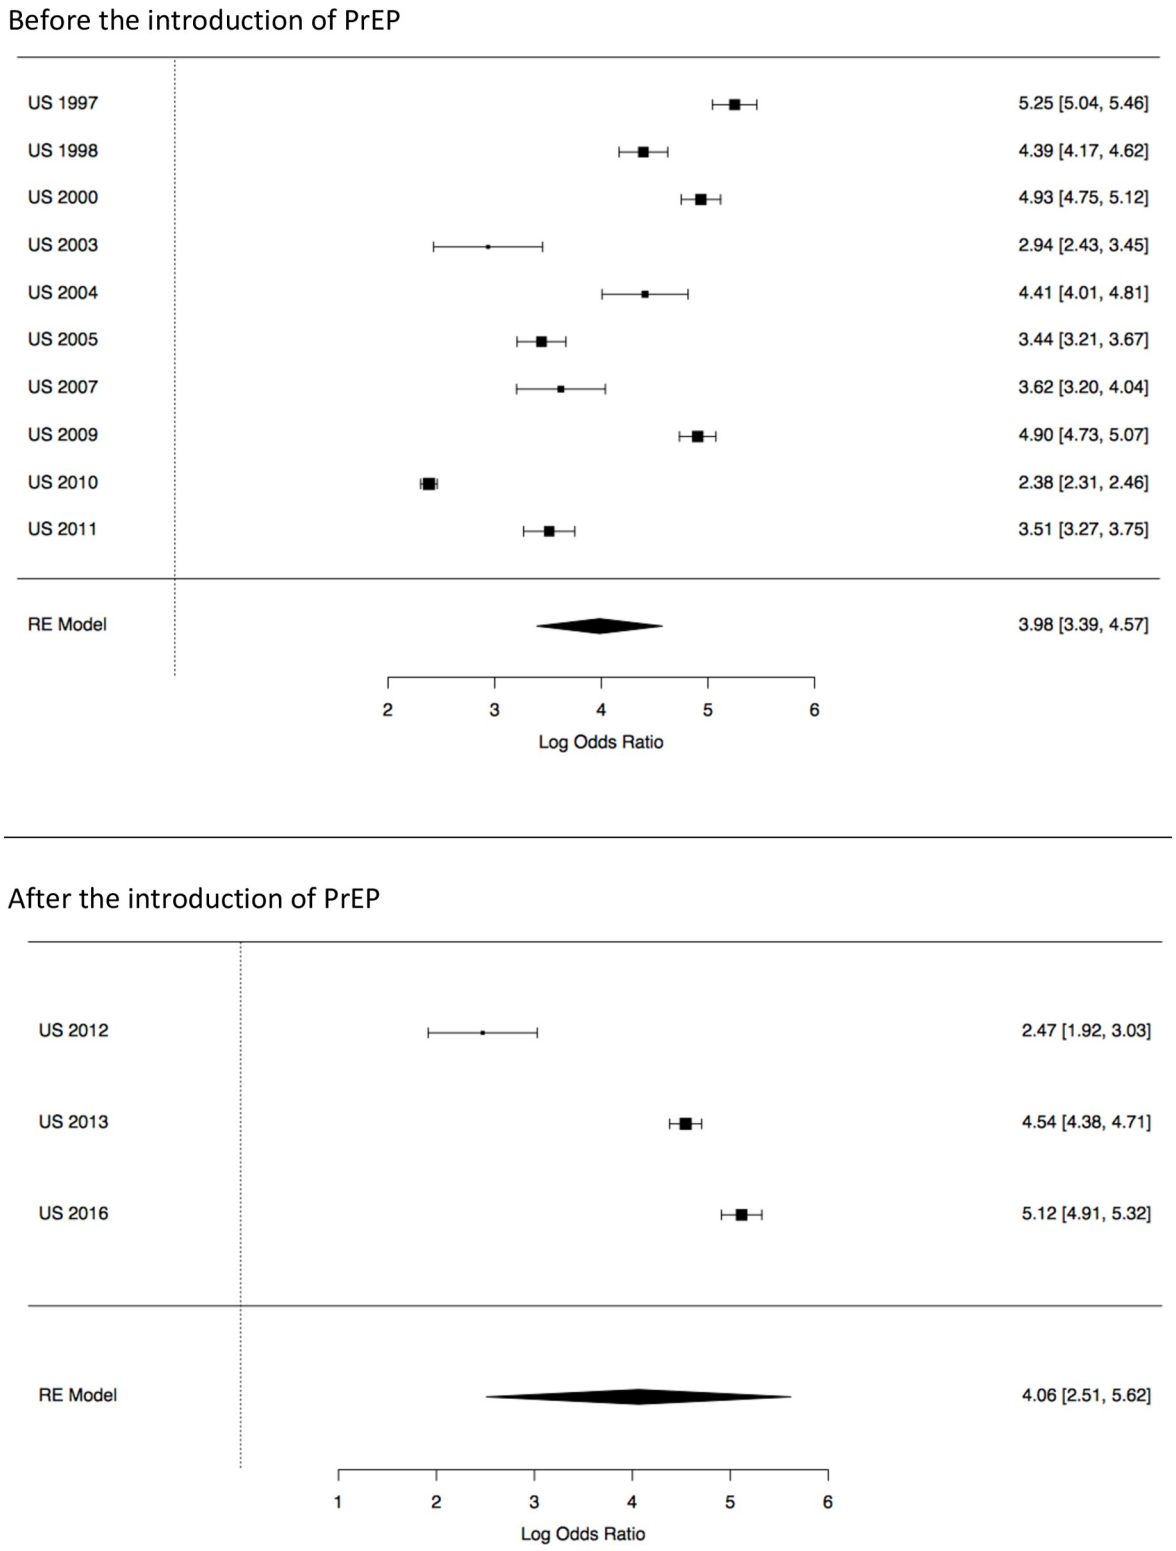

Fig 4. Forest plot of HIV prevalence in trans feminine individuals in the USA compared to all adults (age 15+) in the USA. The 10 country-year including 18 studies above the line are studies where data were collected prior to the introduction of PrEP (2012). The 3 country-year including 6 studies below the line are studies where data were collected after the introduction of PrEP. The scale on the x-axis is log odds ratio. The percentages indicate the weight of each sample within the meta-analysis. The numbers in the right column are the log odds ratios including their confidence intervals.

https://doi.org/10.1371/journal.pone.0260063.g004

commentaries on Baral et al. [4] and in other studies [11, 18, 134]. In our study, the various sampling methods generated very different prevalence rates for HIV in trans feminine individuals ranging from 5.4% to 37.8%. However, the four most frequently used sampling methods, namely respondent-driven sampling, sampling via STI clinics, convenience sampling, and cluster sampling had similar ranges (17.4% to 23.3%). We believe that the impact of sampling methods on prevalence rates is in need of further investigation. In our analyses, unambiguous classification was not always possible and the prevalence rates generated for less common sampling methods may be less reliable. We therefore recommend more comprehensive investigations of the impact of sampling methods in transgender studies.

In our meta-analyses, we also explored the potential role of PrEP availability by comparing studies conducted in the US where data was collected prior to and after the introduction of PrEP. No effect of PrEP could be established yet in our analyses. In fact, we found a higher HIV prevalence rate following the introduction of PrEP. This may be because there were only six studies done following the introduction of PrEP and the total sample after PrEP introduction was smaller and possibly less representative than the 18 studies conducted before PrEP was introduced. It is possible that no reduction in prevalence due to PrEP is the result of PrEP not yet reaching trans individuals. The inclusion of transgender individuals in PrEP trials has been low and access to PrEP for transgender individuals has been limited.[20, 21, 135] However, a qualitative study on PrEP acceptability among transgender women in San Francisco showed that interest was relatively high once participants were informed about the possibilities, thus suggesting that transgender individuals at high risk for HIV need to be informed about PrEP [20]. By the same bio-medical token, future meta-analytic studies should also include Treatment-as-prevention (TasP) effects in their analysis, once sufficiently robust primary data is available.

This systematic review and meta-analysis should be interpreted in light of possible limitations. One is potential sample size biases for studies originating from countries other than the USA, and those of trans masculine individuals. To be able to present a comprehensive, global picture, we set a lower bound for trans feminine individuals, excluding sample sizes of trans feminine individuals less than 40. Yet, we did not apply a minimum sample size for studies among trans masculine individuals as this would have resulted in the exclusion of most studies reporting HIV prevalence among trans masculine individuals. Further, we were not in a position to conduct city-level comparisons and thus acknowledge that our country-level analyses may provide a less precise estimation of the odds ratios, as these do not take into account that, in some countries, the HIV epidemic is more concentrated in certain areas. A third possible limitation is related to our classification of sampling methods. Unambiguous classification was not always feasible and it is possible that the prevalence rates generated for less common sampling methods were less reliable. Fourth, in our meta-analysis, the sample sizes for African regions and Latin America were smaller than the sample sizes for other regions, and this may have impacted the prevalence rates. Additionally, no prevalence rates from Eastern Europe were available. Fifth, our analysis did not account for sexual orientation or the presence or absence of gender reassignment surgery, both of which can impact HIV risk. It is also did not separately ascertain prevalence rates for trans feminine individuals who engage in sex work versus those who do not as primary level data on this is not available on a global scale. We recommend that future research take these potential shortcomings into consideration. Specifically, we recommend that future research explicitly investigate prevalence among subpopulations within the transgender community, and that new studies also take changes in HIV treatment (TasP) and sampling strategies, as well as their interactions, into account, as this will provide an even more comprehensive picture of HIV prevalence and burden among transgender individuals.

Summary and recommendations

That transgender individuals, both trans feminine and trans masculine, are, worldwide, disproportionately burdened by HIV points to the need to pay explicit attention to the unique HIV prevention and care needs of transgender individuals. HIV surveillance and research has traditionally grouped transgender individuals, particularly trans feminine individuals, with men who have sex with men (MSM), thus conflating gender with anatomy. This obscures the unique situation and vulnerabilities to HIV of transgender people [100]. It is therefore necessary to abandon the aggregation of data across MSM and trans feminine women [100, 136]. Additionally, and in line with MacCarthy et al., [11] we also propose disaggregating data across trans feminine and trans masculine individuals [106]. Although some individual and structural risk factors for HIV may be shared by transgender individuals, trans feminine and trans masculine individuals have unique needs [106].

Ascertaining that transgender individuals continue to be disproportionately burdened by HIV is important as it can serve as an impetus for efforts to change this burden. Although transgender individuals in certain regions may more affected by HIV and knowing that transgender processes are diverse across the world, we contend that it is important to, in all regions, target multiple levels of HIV risk, as well as their antecedents and their intersections, while being cognizant of the local context. Targeting individual level risk factors, such as unprotected sex, STI co-infection, and needle sharing, must occur alongside broader efforts to support transgender individuals and reduce stigmatization and marginalization [9, 137, 138].

Paramount to HIV risk reduction is gender affirmation, and in the context of HIV, gender affirmation is particularly important in health care [139–141]. Discrimination, judgment, insensitivity, and a lack of understanding from health care providers prevents many transgender individuals from accessing HIV prevention, testing, treatment, and care services [142]. Gender affirming care is not simply the provision of hormones and gender-affirming surgeries; it also includes using patients' preferred names and pronouns, respecting diversity in gender identities and expressions, employing inclusive intake forms, displaying images that are welcoming to transgender individuals, and creating safe spaces where transgender individuals can be themselves [135, 143]. We recommend integrating HIV prevention and care services in broader gender-affirming care services [6, 135, 142]. This includes actively making PrEP available to transgender individuals [141, 144, 145].

Conclusion

In sum, this systematic review and meta-analyses have served to update our understanding of HIV prevalence over the course of the epidemic as well as HIV burden in both trans feminine and trans masculine individuals using a larger sample than ever before, and has shown that, worldwide, both carry a substantially higher burden of HIV than other individuals over 15 years of age. It has further demonstrated that a by country and year analysis is recommended, that prevalence rates are higher in African and Latin American regions, that sampling methods may impact prevalence rates, and that, at this point in time, the evidence does not suggest that PrEP has played a role in reducing HIV among transgender individuals.

What's New in the Guidelines

Updated: September 12, 2024
Reviewed: September 12, 2024

These guidelines were updated by the U.S. Department of Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) based on key new clinical evidence on the use of antiretroviral therapy (ART) for the treatment of people with HIV.

New Section Added to the Guidelines

Transplantation in People With HIV

This new section has been added to provide guidance on ART management in people with HIV who are candidates or recipients of solid organ and hematopoietic cell transplants. The Panel emphasizes the importance of maintaining HIV viral suppression before and after a transplant. The addition of immunosuppressive therapy and prophylaxis against opportunistic infections to ART increases pill burden and the potential for drug–drug interactions and adverse effects. Because of the complexities of medical management, the Panel recommends that people with HIV who require transplantation be managed by a multidisciplinary team before, during, and after transplant **(AIII).**

Key Revisions to the Guidelines

What to Start: Initial Combination Antiretroviral Regimens for People With HIV

Several changes have been made to the Panel's recommendations for initial ART regimens for people with HIV. The regimens recommended by the Panel as initial ART for people with HIV include those that have demonstrated clinical efficacy, have a high barrier to resistance, are well tolerated, and can be given as once-daily therapy. The Panel made the following changes to the recommended initial ART regimens:

- Dolutegravir (DTG)/abacavir/lamivudine (3TC) has been changed from one of the Recommended Initial Regimens for Most People With HIV (Table 6a) to a regimen recommended as part of Other Initial Antiretroviral Regimens for Certain Clinical Scenarios (Table 6b) due to the need for HLA-B*5701 testing before initiating therapy, the potential increase in the risk of cardiovascular events, and the availability of other options for initial therapy.
- Several antiretroviral (ARV) regimens are no longer recommended as initial therapy due to higher pill burdens, more adverse effects, or a lower barrier to resistance than other ART regimens recommended by the Panel. These regimens include the following:
  - Elvitegravir/cobicistat and raltegravir-based regimens
  - Boosted atazanavir-based regimens
  - Efavirenz-based regimens
  - Rilpivirine (RPV)/tenofovir disoproxil fumarate/emtricitabine (FTC) regimens

Virologic Failure

Updates made to the Virologic Failure section include the following:

- For people who experience virologic failure while on their first ARV regimen of a non-nucleoside reverse transcriptase inhibitor (NNRTI) plus two nucleoside reverse transcriptase inhibitors (NRTIs), a salvage regimen of DTG plus boosted darunavir can be used **(AI)**. This recommendation is based on data from the D^2EFT trial, a large randomized controlled trial comparing this regimen to a regimen of DTG plus two NRTIs.
- Some people with HIV cannot reach or maintain viral suppression on oral ART despite intensive adherence support. A complete regimen of long-acting injectable cabotegravir and rilpivirine (LA CAB/RPV) has been used in this population with some success, although long-term efficacy data are limited. Based on very limited data, the Panel recommends the use of LA CAB/RPV on a case-by-case basis in select individuals with persistent virologic failure despite intensive adherence support on oral ART, who have no evidence of resistance to CAB or RPV, and with shared decision-making between providers and people with HIV **(CIII).** The Panel notes that people with HIV and their providers must be aware of the significant risk of developing resistance to NNRTIs, and particularly integrase strand transfer inhibitors (INSTIs) if virologic failure occurs on LA CAB/RPV. Such resistance may limit future treatment options and may also lead to HIV transmission.

Optimizing Antiretroviral Therapy in the Setting of Viral Suppression

Updates made to the Optimizing Antiretroviral Therapy in the Setting of Viral Suppression section include the following:

- Because more people with HIV are switched to regimens that do not include NRTIs or only include 3TC, the Panel has expanded the guidance to emphasize the importance of keeping regimens that contain hepatitis B virus (HBV)–active drugs for people with HBV/HIV coinfection. For people with no known history of HBV infection, the Panel noted the need to screen for HBV before initiating NRTI-sparing (or limited) regimens.
- The discussion of LA CAB/RPV as a switch strategy with data from additional clinical trials and information on the use of this regimen in people who have challenges with adherence to oral ART.
- The Panel expanded on the discussion of clinical trial data on switch strategies in people with limited or extensive drug resistance.

HIV and the Older Person

Updates made to the HIV and the Older Person section include the following:

- A new subsection on HIV and Immunologic Aging.
- Expanded discussions on non-AIDS complications among older people with HIV.
- A discussion on atherosclerotic cardiovascular disease in older people with HIV and the recent recommendation for the use of statins in people with HIV (see Statin Therapy in People With HIV).

Substance Use Disorders and HIV

Updates made to the Substance Use Disorders and HIV section include the following:

- A new subsection on Substance Use and Unstable Housing that includes discussion of the impact of unstable housing on the HIV care continuum and adherence to ART.

- An expanded discussion on considerations when using LA CAB/RPV in people with HIV and substance use disorder.
- A new subsection that includes a discussion on xylazine, an adulterant that may be added to opioids, such as fentanyl. The Panel notes that xylazine is a cytochrome P450 (CYP) 3A4 substrate; thus, its half-life may be prolonged in the presence of CYP3A4 inhibitors, such as ritonavir or cobicistat, further increasing the risk of overdose.

Transgender People With HIV

Updates made to the Transgender People With HIV section include the following:

- An update on the epidemiology of transgender people with HIV based on recent data from national surveys and Centers for Disease Control and Prevention (CDC) surveillance reports.
- An expanded discussion on barriers that transgender adults and adolescents with HIV may face in accessing care and maintaining HIV suppression.
- A new table that lists the most commonly used gender-affirming hormone therapies (GAHT).
- Updates to the drug–drug interaction table for interactions between GAHT and ARV drugs to include newer ARV drugs used in clinical practice.
- The Panel expanded discussion on cardiovascular disease risk in transgender people with HIV who use GAHT.

Hepatitis B Virus/HIV Coinfection

Updates made to the Hepatitis B Virus/HIV Coinfection section include the following:

- The Panel no longer recommends pegylated interferon as a therapy for the treatment of HBV in people with HIV **(AIII).** Pegylated interferon should only be considered in rare cases and with consultation with an expert in HBV**.**
- The Panel noted that approximately 4% of people with HBV/HIV coinfection are also found to have hepatitis D virus (HDV) in serologic testing. Because HBV/HDV coinfection is associated with serious liver complications, experts recommend screening for HDV in people with HBV/HIV coinfection.
- The Panel emphasizes that for people with HBV/HIV coinfection who are planning to switch to an NRTI-sparing regimen, ARV drugs that are active against HIV should be continued **(AII)** or another anti-HBV drug (i.e., entecavir) should be initiated **(AII).**
- Due to increased interest in switching people to NRTI-sparing or NRTI-limiting ARV regimens, this section stresses the importance of screening for HBV before switching to NRTI-sparing or NRTI-limiting regimens in people who are not known to have HBV infection. The Panel recommends vaccination for those found to be nonimmune to HBV and provides guidance for monitoring and managing people with prior exposure to HBV.

Tuberculosis/HIV Coinfection

Updates made to the Tuberculosis/HIV Coinfection section include the following:

- The Panel previously did not recommend the use of a DTG-based regimen for people with HIV who use a once-daily isoniazid plus rifapentine regimen for the treatment of latent tuberculosis infection. Based on data from a recently published pharmacokinetics (PK) study, the Panel now recommends that—
    - For a person with virologic suppression while on a once-daily DTG 50 mg regimen, the DTG dose should be increased to 50 mg twice daily throughout the course of once-daily isoniazid plus rifapentine for 1 month (1HP), continuing DTG twice daily for 14 days after 1HP completion before switching back to once-daily DTG dosing **(AII).**
- The subsection on Drug Interaction Considerations has been updated to indicate that rifamycins are not recommended for use with the long-acting injectable drugs CAB, RPV, or lenacapavir.

Adherence to the Continuum of Care Section

Updates made to the Adherence to the Continuum of Care section include the following:

- The section emphasizes that addressing social determinants of health is essential for enhancing adherence throughout the HIV continuum of care.
- A new subsection has been added to discuss the importance of guiding individuals with HIV through transitions between different health care systems to ensure continuity of care.
- The subsection on the use of LA CAB/RPV in people with viremia and ongoing challenges to oral ART adherence or retention in care has been expanded to incorporate recommendations from the Virologic Failure section of the guidelines.

Drug–Drug Interactions

Tables 24a through 24g have been updated with new PK data on interactions between ARV drugs and other drugs, including drugs that were approved by the U.S. Food and Drug Administration in the past 3 years and that may have interactions with ARV drugs.

Other Updates

Minor updates have been made to the following sections of the guidelines:

- Drug-Resistance Testing
- Early (Acute and Recent) HIV Infection
- Women With HIV
- Cost Considerations and Antiretroviral Therapy
- Appendix B, Table 12

Sections Removed From the Guidelines

- Antiretroviral Components or Regimens Not Recommended as Initial Therapy
- What Not to Use

Panel Roster

Introduction

Updated: September 21, 2022
Reviewed: September 21, 2022

Antiretroviral therapy (ART) for the treatment of HIV infection has improved steadily since the advent of potent combination therapy in 1996. ART has dramatically reduced HIV-associated morbidity and mortality and has transformed HIV infection into a manageable chronic condition, with life expectancy approaching that for people without HIV.[1,2] ART is also highly effective at preventing sexual transmission of HIV in patients who have adequately suppressed viral loads.[3-5] Lack of viral load suppression is mostly due to undiagnosed HIV infection and failure to link or retain patients with HIV in care.

The U.S. Department of Health and Human Services (HHS) Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) is a working group of the Office of AIDS Research Advisory Council (OARAC). The Panel's primary goal is to provide HIV care practitioners with recommendations that are based on current knowledge of the antiretroviral (ARV) drugs that are used to treat adults and adolescents with HIV in the United States. The Panel reviews new evidence and updates recommendations when needed. These guidelines include recommendations on baseline laboratory evaluations, treatment goals, benefits of ART and considerations when initiating therapy, choice of the initial regimen for ART-naive people with HIV, ARV drugs or combinations to avoid, management of treatment failure, optimizing ARV regimens, management of adverse effects and drug interactions, and special ART-related considerations in specific populations. This Panel works closely with the HHS Panel on Antiretroviral Therapy and Medical Management of Children Living with HIV to provide recommendations for adolescents at different stages of growth and development. Recommendations for ARV regimens in these guidelines are most appropriate for postpubertal adolescents (i.e., those with sexual maturity ratings [SMR] of 4 and 5). Clinicians should follow recommendations in the Pediatric Antiretroviral Guidelines when initiating ART in adolescents with an SMR of 3 or lower. For recommendations related to pre-exposure prophylaxis (PrEP) and post-exposure prophylaxis (PEP) for people who do not have HIV, clinicians should consult recommendations from the Centers for Disease Control and Prevention.[6]

These guidelines represent current knowledge regarding the use of ARV drugs. Because the science of HIV evolves rapidly, the availability of new agents and new clinical data may change therapeutic options and preferences. Information included in these guidelines may not always be consistent with approved labeling for the specific drugs or indications, and the use of the terms "safe" and "effective" may not be synonymous with the U.S. Food and Drug Administration–defined legal standards for drug approval. The Panel frequently updates the guidelines (current and archived versions of the guidelines are available on the Clinical Info website). However, updates to the guidelines may not keep pace with the release of new data, and the guidelines cannot offer guidance on care for all patients. Patient management decisions should be based on clinical judgement and attention to unique patient circumstances.

The Panel recognizes the importance of clinical research in generating evidence to address unanswered questions related to the optimal safety and efficacy of ART and encourages both the development of protocols and patient participation in well-designed Institutional Review Board–approved clinical trials.

HIV Expertise in Clinical Care

Several studies have demonstrated that overall outcomes in patients with HIV are better when care is delivered by clinicians with HIV expertise (e.g., those who have cared for a large group of patients with HIV),[7-11] reflecting the complexity of HIV transmission and its treatment. Appropriate training, continuing education, and clinical experience are all components of optimal care. Providers who do not have this requisite training and experience should consult HIV experts when needed.

Guidelines Development Process

Table 1. Outline of the Guidelines Development Process

Topic	Comment
Goal of the guidelines	Provide guidance to HIV care practitioners on the optimal use of antiretroviral (ARV) agents for the treatment of HIV in adults and adolescents in the United States.
Panel members	The Panel is composed of approximately 50 voting members who have expertise in HIV care and research and includes at least one representative from each of the following U.S. Department of Health and Human Services (HHS) agencies: Centers for Disease Control and Prevention (CDC), U.S. Food and Drug Administration (FDA), Health Resource and Services Administration (HRSA), and National Institutes of Health (NIH). Approximately two-thirds of the Panel members are nongovernmental scientific members. The Panel also includes four to five community members with knowledge of HIV treatment and care. The U.S. government representatives are appointed by their respective agencies; other Panel members are selected after an open call for nominations. Each member serves on the Panel for a 4-year term, with an option for reappointment for an additional term. See the Panel Roster for a list of current Panel members.
Financial disclosure	All members of the Panel submit a written financial disclosure annually, reporting any association with manufacturers of ARV drugs or diagnostics used to manage HIV infection. The latest version of the Financial Disclosure list is available on the Clinical Info website.
Users of the guidelines	HIV treatment providers
Developer	Panel on Antiretroviral Guidelines for Adults and Adolescents—a working group of the Office of AIDS Research Advisory Council (OARAC)
Funding source	Office of AIDS Research, NIH
Evidence collection	The recommendations in the guidelines are based on studies published in peer-reviewed journals or data available in FDA drug labels. On some occasions, particularly when new information may affect patient safety, unpublished data presented at major conferences or prepared by the FDA and/or manufacturers as warnings to the public may be used as evidence to revise the guidelines.
Recommendation grading	As described in Table 2 below
Method of synthesizing data	Each section of the guidelines is assigned to a working group of Panel members with expertise in the section's area of interest. The working groups synthesize available data and propose recommendations to the Panel. The Panel discusses all proposals during monthly teleconferences. Recommendations endorsed by the Panel are included in the guidelines.

Table 1. Outline of the Guidelines Development Process

Topic	Comment
Other guidelines	These guidelines focus on antiretroviral therapy (ART) for adults and adolescents with HIV. For a more detailed discussion on the use of ART in children and prepubertal adolescents (those with sexual maturity ratings of 1 to 3), clinicians should refer to the Pediatric Antiretroviral Guidelines. These guidelines also include a brief discussion on the management of persons of childbearing potential and pregnant persons. For more details on the use of ARV drugs during pregnancy, see the Perinatal Guidelines.
Update plan	The Panel meets monthly by teleconference to review data that may warrant modification of the guidelines. Updates may be prompted by new drug approvals (or new indications, dosing formulations, or frequency of dosing), new safety or efficacy data, or other information relating to ARV drugs that may have an impact on the clinical care of people with HIV. In the event of new data of clinical importance, the Panel may post an interim announcement with recommendations on the Clinical Info website until the guidelines can be updated with the appropriate changes. Updated guidelines are available on the Clinical Info website.
Public comments	A 2-week public comment period follows the release of the updated guidelines on the Clinical Info website. The Panel reviews comments to determine whether additional revisions to the guidelines are indicated. The public also may submit comments to the Panel at any time at HIVinfo@NIH.gov.

Basis for Recommendations

Recommendations in these guidelines are based on scientific evidence and expert opinion. Each recommendation statement includes a letter **(A**, **B**, or **C)** that represents the strength of the recommendation and a Roman numeral **(I**, **II**, or **III)** that represents the quality of the evidence that supports the recommendation (see Table 2 below).

Table 2. Rating Scheme for Recommendations

Strength of Recommendation	Quality of Evidence for Recommendation
A: Strong recommendation for the statement **B:** Moderate recommendation for the statement **C:** Weak recommendation for the statement	**I:** One or more randomized trials with clinical outcomes and/or validated laboratory endpoints **II:** One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes **III:** Expert opinion

Baseline Evaluation

Updated: September 21, 2022
Reviewed: September 21, 2022

Every patient with HIV entering into care should have a complete medical history, physical examination, and laboratory evaluation and should be counseled regarding the implications of HIV infection. The goals of this initial evaluation are to confirm the diagnosis of HIV infection, obtain appropriate baseline historical and laboratory data, ensure patient understanding about HIV infection and its transmission, and initiate care as recommended in the HIV Medicine Association of the Infectious Diseases Society of America's (HIVMA/IDSA) Primary Care Guidance for Persons with HIV[1] and the Adult and Adolescent Opportunistic Infections Guidelines.[2] The initial evaluation also should include discussion of the benefits of antiretroviral therapy (ART) for the patient's health and to prevent HIV transmission, as well as strategies to optimize care engagement and treatment adherence **(AIII).** Information obtained in this baseline evaluation then can be used to define treatment management goals and plans. The Panel on Antiretroviral Guidelines for Adults and Adolescents recommends initiating ART at the time of diagnosis (when possible) or as soon as possible afterward to increase the uptake of ART, decrease the time required to achieve linkage to care and virologic suppression, improve the rate of virologic suppression, and reduce HIV transmission **(AII).**

The following laboratory tests performed during initial patient visits can be used to stage HIV progression and to assist in the selection of antiretroviral (ARV) drug regimens:

- HIV antigen/antibody testing (if prior documentation is not available or if HIV RNA is below the assay's limit of detection) **(AI)**
- CD4 T lymphocyte (CD4) cell count **(AI)**
- Plasma HIV RNA (viral load) **(AI)**
- Complete blood count; chemistry profile, including glucose, blood urea nitrogen and creatinine, liver enzymes and bilirubin, urinalysis, and serologies for hepatitis A, B, and C viruses **(AIII)**
  - If random blood glucose level is abnormal, repeat fasting
- Serum lipids (if random levels are abnormal, fasting lipids should be obtained)
- HLA-B*5701 test (if abacavir is being considered) **(AI)**
- Genotypic drug-resistance testing **(AII).** Based on current rates of transmitted drug resistance to different ARV medications, standard genotypic drug-resistance testing in ARV-naive people should focus on testing for mutations in the reverse transcriptase (RT) and protease (PR) genes. If transmitted integrase strand transfer inhibitor (INSTI) resistance is a concern in people with newly diagnosed HIV or in people who acquired HIV after receipt of long-acting cabotegravir (CAB-LA) as pre-exposure prophylaxis (PrEP), testing for mutations in the integrase gene also should be performed.
- For patients who have HIV RNA levels <1,000 copies/mL, viral amplification for drug-resistance testing should still be performed; however, it may not always be successful **(BII)** (see Drug-Resistance Testing).

In addition, other tests (including screening tests for sexually transmitted infections, opportunistic infections, and cancer) should be performed as recommended in the HIVMA/IDSA's Primary Care Guidance for Persons with HIV[1] and the Adult and Adolescent Opportunistic Infections Guidelines.[2]

Many clinics have adopted a rapid start policy to initiate ART on the day of HIV diagnosis in order to increase ART uptake and engagement in care and to accelerate the time to viral suppression. Rapid ART initiation also reduces the time during which people with newly diagnosed HIV can transmit HIV. Prior to ART initiation, HIV infection should be confirmed. HIV RNA and CD4 count also should be obtained, but results need not be available before starting ART. CD4 count will determine the need for prophylaxis for certain opportunistic infections.

- If available, results of safety testing—such as complete blood count, renal function tests, and liver enzymes—should be reviewed. If safety test results are not available, ART can still be started, but a clinician should review the results as soon as possible.
- Genotypic resistance testing for RT and PR (and INSTI resistance testing if patient has a history of CAB PrEP use or if INSTI transmission is suspected) should be obtained before ART initiation. It is not necessary to delay ART until results are available, but results should be reviewed as soon as possible in order to make adjustments to the regimen, if needed.
- Screening for viral hepatitis should be done before starting ART, and if ART initiation occurs before results are available, a regimen that has activity against hepatitis B virus should be selected.
- In patients who do not have reliable methods of contact, rapid ART may be initiated, with a plan for a return clinic visit soon after ART initiation to review test results.
- Screening for sexually transmitted infections should, ideally, occur at the initial visit, but results do not need to be available before starting ART.

For previously treated patients who present for an initial evaluation with a new health care provider, it is critical to obtain a complete ARV history (including drug-resistance testing results, if available), preferably through the review of past medical records. A complete immunization history (including for SARS-CoV-2) also should be obtained. Newly diagnosed patients also should be asked about any prior use of ARV agents for prevention of HIV infection.

People with HIV often must cope with many social, psychiatric, and medical issues that are best addressed through a patient-centered, multidisciplinary approach. The baseline evaluation should include consideration of the patient's readiness for ART, including an assessment of substance use (including tobacco use), social support, mental health, medical comorbidities, economic factors (e.g., unstable housing, food instability), medical insurance status and adequacy of coverage, and other factors that are known to impair adherence to ART and increase the risk of HIV transmission. Once evaluated, these factors should be managed accordingly. The baseline evaluation also should include a discussion of risk reduction and disclosure to sexual and/or needle-sharing partners, especially with untreated patients who are still at high risk of HIV transmission. People with HIV should be informed that maintaining a plasma HIV RNA of <200 copies/mL, including any measurable value below this threshold, with ART prevents sexual transmission of HIV to their partners **(AII).** Patients may recognize this concept as Undetectable = Untransmittable or U=U.

Laboratory Testing

Laboratory Testing for Initial Assessment and Monitoring of People With HIV Receiving Antiretroviral Therapy

Updated: September 21, 2022
Reviewed: September 21, 2022

Several laboratory tests are important for initial evaluation of people with HIV upon entry into care. Some tests should be performed before and after initiation or modification of antiretroviral therapy (ART) to assess the virologic and immunologic efficacy of ART and to monitor for laboratory abnormalities that may be associated with antiretroviral (ARV) drugs. Table 3 below outlines recommendations from the Panel on Antiretroviral Guidelines for Adults and Adolescents on the frequency of testing. As noted in the table, some tests may be repeated more frequently if clinically indicated.

Two surrogate markers are used to monitor people with HIV: plasma HIV RNA (viral load) to assess level of HIV viremia and CD4+ T lymphocyte cell count (or CD4 count) to assess immune function. Standard (reverse transcriptase and protease) genotypic drug-resistance testing should be used to guide selection of an ARV regimen; if transmitted integrase strand transfer inhibitor (INSTI) resistance is a concern or for people who acquired HIV after taking long-acting cabotegravir as pre-exposure prophylaxis, testing also should include the integrase gene (see Drug-Resistance Testing). For guidance on the choice of ARV regimens before drug-resistance testing results become available, clinicians should consult the What to Start section. A viral tropism assay should be performed before initiation of a CCR5 antagonist or at the time of virologic failure that occurs while a patient is receiving a CCR5 antagonist. HLA-B*5701 testing should be performed before initiation of abacavir (ABC) to reduce the risk of hypersensitivity reaction, and HLA-B*5701-positive patients should not be prescribed ABC. Patients should be screened for hepatitis B and hepatitis C virus infections before initiating ART and, if indicated, periodically after ART initiation, because treatment of these coinfections may affect the choice of ART and likelihood of drug-induced hepatotoxicity. The rationale for and utility of some of these laboratory tests are discussed in the corresponding sections of the guidelines.

Table 3. Laboratory Testing Schedule for Monitoring People With HIV Before and After Initiation of Antiretroviral Therapy[a]

Laboratory Test	Timepoint or Frequency of Testing								
	Entry Into Care	ART Initiation[b] or Modification	4 to 8 Weeks After ART Initiation or Modification	Every 3 Months	Every 6 Months	Every 12 Months	Treatment Failure	Clinically Indicated	If ART Initiation Is Delayed[c]

[a] This table pertains to laboratory tests done to select an ARV regimen and monitor for treatment responses or ART toxicities. Please refer to the HIV Medicine Association of the Infectious Diseases Society of America's (HIVMA/IDSA) Primary Care Guidance for Persons with HIV for other laboratory tests generally recommended for primary health care maintenance of HIV patients.[1]

[b] If ART is initiated soon after HIV diagnosis and entry into care, repeat baseline laboratory testing is not necessary.

[c] ART is indicated for all people with HIV and should be started as soon as possible. However, if ART initiation is delayed, patients should be retained in care, with periodic monitoring as noted above.

[d] After 2 years of consistently suppressed HIV RNA, less frequent monitoring (e.g., every 6 months) may be considered.

[e] If HIV RNA is detectable at 4–8 weeks, repeat testing every 4–8 weeks until viral load is suppressed to <50 copies/mL. Thereafter, repeat testing every 3–6 months.

[f] For patients on ART, viral load typically is measured every 3–6 months. More frequent monitoring may be considered in individuals having difficulties with ART adherence or at risk for nonadherence. However, for adherent patients with consistently suppressed viral load and stable immunologic status for more than 1 year, monitoring can be extended to 6-month intervals.

[g] Standard genotypic drug-resistance testing in ARV-naive persons should focus on testing for mutations in the PR and RT genes. If transmitted INSTI resistance is a concern, or if a person has a history of INSTI use as PrEP or treatment, or a person presents with viremia while on an INSTI, providers also should test for resistance mutations in the IN gene. In ARV-naive patients who do not immediately begin ART, repeat testing before initiation of ART is optional if drug-resistance testing was performed at entry into care. In

Table 3. Laboratory Testing Schedule for Monitoring People With HIV Before and After Initiation of Antiretroviral Therapy[a]

patients with virologic suppression who are switching therapy because of toxicity or for convenience, viral amplification will not be possible; see the Drug-Resistance Testing section for a discussion of the potential limitations and benefits of proviral DNA assays in this situation. Results from prior drug-resistance testing should be considered because they can be helpful in constructing a new regimen.

[h] If a patient has HBV infection (as determined by a positive HBsAg or HBV DNA test result), TDF or TAF plus either FTC or 3TC should be used as part of the ARV regimen to treat both HBV and HIV infections (see the Hepatitis B Virus/HIV Coinfection section).

[i] If HBsAg, HBsAb, and HBcAb test results are negative, HBV vaccine series should be administered. Refer to the HIVMA/IDSA's Primary Care Guidance for Persons with HIV and the Adult and Adolescent Opportunistic Infection Guidelines for detailed recommendations.[1,2]

[j] Most patients with isolated HBcAb have resolved HBV infection with loss of HBsAb. Consider performing an HBV viral load test for confirmation. If the HBV viral load test is positive, the patient may be acutely infected (and will usually display other signs of acute hepatitis) or chronically infected. If the test is negative, the patient should be vaccinated. Refer to the HIVMA/IDSA's Primary Care Guidance for Persons with HIV and the Adult and Adolescent Opportunistic Infection Guidelines for more detailed recommendations.[2]

[k] The HCV antibody test may not be adequate for screening in the setting of recent HCV infection (acquisition within the past 6 months) or advanced immunodeficiency (CD4 count <100 cells/mm^3). HCV RNA screening is indicated in persons who have been successfully treated for HCV or who spontaneously cleared prior infection. HCV antibody-negative patients with elevated ALT may need HCV RNA testing.

[l] Injection drug users, people with a history of incarceration, men with HIV who have unprotected sex with men, and people with percutaneous/parenteral exposure to blood in unregulated settings are at risk of HCV infection.

[m] Serum Na, K, HCO_3, Cl, BUN, creatinine, glucose, and Cr-based eGFR. Serum P should be monitored in patients with CKD who are on TDF-containing regimens.[3]

[n] Consult the HIVMA/IDSA's Clinical Practice Guideline for the Management of Chronic Kidney Disease in Patients Infected with HIV for recommendations on managing patients with renal disease.[3] More frequent monitoring may be indicated for patients with evidence of kidney disease (e.g., proteinuria, decreased glomerular dysfunction) or increased risk of renal insufficiency (e.g., patients with diabetes, hypertension).

[o] CBC with differential should be done when a CD4 count is performed. When CD4 count is no longer being monitored, the recommended frequency of CBC with differential is once a year. More frequent monitoring may be indicated for people receiving medications that potentially cause cytopenia (e.g., TMP-SMX).

[p] If random lipids are abnormal, fasting lipids should be obtained. Consult the American College of Cardiology/American Heart Association's 2018 Guideline on the Management of Blood Cholesterol for diagnosis and management of patients with dyslipidemia.[4]

[q] If random glucose is abnormal, fasting glucose should be obtained. HbA1C is no longer recommended for diagnosis of diabetes in people with HIV on ART (see the American Diabetes Association Guidelines).[5]

[r] Urine glucose and protein should be assessed before initiating TAF- or TDF-containing regimens and monitored during treatment with these regimens.

[s] For persons of childbearing potential.

Key: 3TC = lamivudine; ABC = abacavir; ALT = alanine aminotransferase; ART = antiretroviral therapy; ARV = antiretroviral; AST = aspartate aminotransferase; BUN = blood urea nitrogen; CAB-LA = cabotegravir long-acting; CBC = complete blood count; CD4 = CD4 T lymphocyte; CKD = chronic kidney disease; Cl = chloride; Cr = creatinine; CV = cardiovascular; DAA = direct-acting antiviral; DM = diabetes mellitus; eGFR = estimated glomerular filtration rate; FTC = emtricitabine; HbA1C = hemoglobin A1c; HBcAb = hepatitis B core antibody; HBsAb = hepatitis B surface antibody; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCO_3 = bicarbonate; HCV = hepatitis C virus; IN = integrase; INSTI = integrase strand transfer inhibitor; K = potassium; Na = sodium; P = phosphorus; PR = protease; PrEP = pre-exposure prophylaxis; RT = reverse transcriptase; TAF = tenofovir alafenamide; TDF = tenofovir disoproxil fumarate; TMP-SMX = trimethoprim-sulfamethoxazole

Plasma HIV-1 RNA (Viral Load) and CD4 Count Monitoring

Updated: September 21, 2022
Reviewed: September 21, 2022

HIV RNA (viral load) and CD4 T lymphocyte cell (CD4) count are the two surrogate markers of antiretroviral therapy (ART) responses and HIV disease progression that have been used for decades to manage and monitor HIV infection.

Viral load is a marker of response to ART. A patient's pre-ART viral load level and the magnitude of viral load decline after initiation of ART provide prognostic information about the probability of disease progression.[1] The key goal of ART is to achieve and maintain durable viral suppression. Thus, the most important use of the viral load is to monitor the effectiveness of therapy after initiation of ART.

CD4 count provides information on the overall immune function of a person with HIV. Measurement of CD4 count is particularly useful **before** initiation of ART to establish the need for the initiation of opportunistic infection (OI) prophylaxis and to assess the urgency to initiate ART; and **after** initiation of ART to assess immunologic response and to establish the need for discontinuation of OI prophylaxis.

The management of patients with HIV has changed substantially with the availability of newer, more potent, and less toxic antiretroviral (ARV) agents. ART is now recommended for all patients with HIV regardless of their viral load or CD4 count **(AI)** (see the Initiation of Antiretroviral Therapy section). In the past, the clinical practice supported by treatment guidelines was generally to monitor both CD4 count and viral load concurrently. However, because most patients with HIV in care now receive ART, the rationale for frequent CD4 count monitoring is weaker. The roles and usefulness of these two tests in clinical practice are discussed in the following sections.

Plasma HIV-1 RNA (Viral Load) Monitoring

Viral load is the most important indicator of initial and sustained response to ART and should be measured in all patients with HIV at entry into care **(AI),** at initiation of therapy **(AI),** and on a regular basis thereafter. For those patients who choose to delay therapy or remain untreated for whatever reason, repeat viral load testing while not on ART is optional **(CIII).** Pre-treatment viral load level is also an important factor in the selection of an initial ARV regimen, because several currently approved ARV drugs or regimens have been associated with poorer responses in patients with high baseline viral load (see the What to Start section). Commercially available HIV-1 RNA assays do not detect HIV-2 viral load. For further discussion on HIV-2 RNA monitoring in patients with HIV-1/HIV-2 coinfection or HIV-2 mono-infection, see the HIV-2 Infection section.

Several systematic reviews of data from clinical trials involving thousands of participants have established that decreases in viral load following initiation of ART are associated with reduced risk of progression to AIDS or death.[1-3] Thus, viral load testing is an established surrogate marker for treatment response.[4] The minimal change in viral load considered to be statistically significant (2 standard deviations) is a three-fold change (equivalent to a 0.5 $\log_{10}$ copies/mL change). Optimal viral suppression is defined as a confirmed HIV RNA level below the lower limit of detection of available assays (generally <20 copies/mL, depending on the assay used). After virologic suppression, an isolated detectable HIV RNA level that is followed by a return to virologic suppression, known as a "blip," may occur in successfully treated patients and is not usually predictive of virologic failure.[5] Furthermore, the data on the association between persistently low level but quantifiable viremia (HIV RNA <200 copies/mL) and virologic failure is conflicting. One study showed an increased risk of subsequent failure at this level of viremia; however, the association was not observed in other studies.[6-9] These guidelines and the AIDS Clinical Trials Group (ACTG) now define

virologic failure as the inability to achieve or maintain suppression of viral replication to HIV RNA level <200 copies/mL—a threshold that eliminates most cases of apparent viremia caused by viral load blips or assay variability[10] (see the Virologic Failure section).

Individuals who are adherent to their ARV regimens and do not harbor resistance mutations to the component drugs can generally achieve viral suppression 8 to 12 weeks after ART initiation or after modification due to virologic failure; rarely, it may take longer in some patients. Recommendations on the frequency of viral load monitoring are summarized below:

- **After initiation of ART.** Plasma viral load should be measured before initiation of ART and within 4 to 8 weeks after treatment initiation **(AIII).** The purpose of the measurements is to confirm an adequate virologic response to ART, indicating appropriate regimen selection and patient adherence to therapy. Repeat viral load measurement should be performed at 4- to 8-week intervals until the level falls below the assay's limit of detection **(BIII).**
- **In patients with viral suppression, with ART modification because of drug toxicity or for regimen simplification.** Viral load measurement should be performed within 4 to 8 weeks after changing therapy **(AIII).** The purpose of viral load monitoring at this point is to confirm the effectiveness of the new regimen.
- **In patients on a stable, suppressive ARV regimen.** Viral load measurement should be repeated every 3 to 4 months **(AIII)** or as clinically indicated to confirm continuous viral suppression. Clinicians may extend the interval to 6 months for adherent patients whose viral load has been suppressed for more than a year, whose clinical and immunologic status is stable, and who are not at risk for inadequate adherence **(AIII).**
- **In patients with virologic failure who require a change in ARV regimen.** Plasma viral load should be measured before ART change and within 4 to 8 weeks after treatment modification **(AIII).** The purpose of the measurements is to confirm an adequate virologic response to the new regimen. Repeat viral load measurement should be performed at 4- to 8-week intervals until the level falls below the assay's limit of detection **(BIII).** If viral suppression is not possible, repeat viral load measurement every 3 months or more frequently if indicated **(AIII).**
- **In patients with suboptimal response.** The frequency of viral load monitoring will depend on clinical circumstances, such as adherence and availability of further treatment options. In addition to viral load monitoring, several other factors—such as patient adherence to prescribed medications, suboptimal drug exposure, or drug interactions—should be assessed. Patients who fail to achieve viral suppression should undergo drug-resistance testing to aid in the selection of an alternative ARV regimen (see the Drug-Resistance Testing and Virologic Failure sections).

CD4 Count Monitoring

The CD4 count is the most important laboratory indicator of immune function in patients with HIV. It is also the strongest predictor of disease progression and survival according to findings from clinical trials and cohort studies.[11,12] CD4 counts are highly variable; a significant change (2 standard deviations) between two tests is approximately a 30% change in the absolute count, or an increase or decrease in CD4 percentage by 3 percentage points. Monitoring of lymphocyte subsets other than CD4 (e.g., CD8, CD19) has not proven clinically useful and is more expensive than monitoring CD4 count alone; therefore, it **is not recommended (BIII).**

Use of CD4 Count for Initial Assessment

CD4 count should be measured in all patients at entry into care **(AI).** It is the key factor in determining the need to initiate OI prophylaxis (see the Adult and Adolescent Opportunistic Infections Guidelines)[13] and the urgency to initiate ART **(AI)** (see the Initiation of Antiretroviral Therapy section). Although most OIs occur in patients with CD4 counts <200 cells/mm^3, some OIs can occur in patients with higher CD4 counts.[14]

Use of CD4 Count for Monitoring Therapeutic Response

The CD4 count is used to assess a patient's immunologic response to ART. It is also used to determine whether prophylaxis for OIs can be discontinued (see the Adult and Adolescent Opportunistic Infections Guidelines).[13] For most patients on therapy, an adequate response is defined as an increase in CD4 count in the range of 50 cells/mm^3 to 150 cells/mm^3 in the first year of ART, generally with an accelerated response in the first 3 months of treatment. Subsequent increases average approximately 50 cells/mm^3 to 100 cells/mm^3 per year until a steady state level is reached.[15] Patients who initiate therapy with a low CD4 count[16,17] or at an older age[18] may have a blunted increase in their counts despite virologic suppression.

Frequency of CD4 Count Monitoring

ART is now recommended for all patients with HIV. In patients who remain untreated for whatever reason, CD4 counts should be monitored every 3 to 6 months to assess the urgency of ART initiation and the need for OI prophylaxis **(AIII).**

A repeat CD4 count 3 months after ART initiation will provide information regarding the magnitude of immune reconstitution **(AIII).** This repeat measurement is most important in patients who initiate ART with more advanced disease and require OI prophylaxis or treatment. In these patients, the magnitude and duration of CD4 count increase can be used to determine whether to discontinue OI prophylaxis and/or treatment as recommended in the Adult and Adolescent Opportunistic Infections Guidelines.[13] For patients beginning ART, CD4 count should be repeated every 3 months for the first 2 years of suppressive ART for those with CD4 counts <300 cells/mm^3 and every 6 months if CD4 count is ≥300 cells/mm^3. After 2 years of suppressive ART, CD4 count monitoring can be reduced to every 6 months for patients whose CD4 counts remain at <300 cells/mm^3 and every year for patients with CD4 counts between 300 cells/mm^3 and 500 cells/mm^3, and is optional for those with CD4 counts >500 cells/mm^3 **(BII).**

The CD4 count response to ART varies widely, but a poor CD4 response in a patient with viral suppression is rarely an indication for modifying an ARV regimen. In patients with consistently suppressed viral loads who have already experienced ART-related immune reconstitution (i.e., CD4 count >500 cells/mm^3), the CD4 count provides limited information. Frequent testing is unnecessary, because the results rarely lead to a change in clinical management. One retrospective study found that declines in CD4 count to <200 cells/mm^3 are rare in patients with viral suppression and CD4 counts >300 cells/mm^3.[19] Similarly, the ARTEMIS trial found that CD4 count monitoring had no clinical benefit in patients who had suppressed viral loads and CD4 counts >200 cells/mm^3 after 48 weeks of therapy.[20] Furthermore, the risk of *Pneumocystis jirovecii* pneumonia is extremely low in patients on suppressive ART who have CD4 counts between 100 cells/mm^3 and 200 cells/mm^3.[21] Although uncommon, CD4 count declines can occur in a small percentage of virologically suppressed patients and may be associated with adverse clinical outcomes, such as cardiovascular disease, malignancy, and death.[22] An analysis of costs associated with CD4 count monitoring in the United States estimated that reducing CD4 count monitoring in treated patients from every 6 months to every 12 months could result in annual savings of approximately $10 million.[23]

For the patient on a suppressive ARV regimen whose CD4 count has consistently ranged between 300 cells/mm^3 and 500 cells/mm^3 for at least 2 years, the Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) recommends CD4 count monitoring on an annual basis **(BII).** Continued CD4 count monitoring for virologically suppressed patients whose CD4 counts have been consistently >500 cells/mm^3 for at least 2 years may be considered optional **(CIII).** The CD4 count should be monitored more frequently, as clinically indicated, when there are changes in a patient's clinical status that may decrease CD4 count and thus prompt OI prophylaxis. Examples of such changes include the appearance of new HIV-associated clinical symptoms or initiation of treatment known to reduce CD4 count (e.g., chronic corticosteroids, antineoplastic agents) **(AIII).** In patients who fail to maintain viral suppression while on ART, the Panel recommends CD4 count monitoring every 3 to 6 months **(AIII).**

Factors that Affect Absolute CD4 Count

The absolute CD4 count is a calculated value based on the total white blood cell (WBC) count and the percentages of total and CD4 T lymphocytes. This absolute number may fluctuate in individuals or may be influenced by factors that may affect the total WBC count and lymphocyte percentages, such as use of bone marrow-suppressive medications, chronic corticosteroids, or the presence of acute infections. Splenectomy[24,25] or coinfection with human T-lymphotropic virus type I (HTLV-1)[26] may cause misleadingly elevated CD4 counts. In all these settings, CD4 percentage remains stable and may be a more appropriate parameter to assess a patient's immune function.[27]

Table 4. Recommendations on the Indications and Frequency of Viral Load and CD4 Count Monitoring[a]

Clinical Scenario	Viral Load Monitoring	CD4 Count Monitoring
Before initiating ART	At entry into care **(AIII)** If ART initiation is deferred, repeat before initiating ART **(AIII).** In patients not initiating ART, repeat testing is optional **(CIII).**	At entry into care **(AI)** If ART is deferred, every 3 to 6 months[a] **(AIII)**
After initiating ART	Preferably within 4 to 8 weeks after initiation of ART **(AIII);** thereafter, every 4 to 8 weeks until viral load is suppressed **(BIII).**	3 months after initiation of ART **(AIII)**
After modifying ART because of drug toxicities or for regimen simplification in a patient with viral suppression	4 to 8 weeks after modification of ART to confirm effectiveness of new regimen **(AIII).**	Monitor according to prior CD4 count and duration on ART, as outlined below.
After modifying ART because of virologic failure	Preferably within 4 to 8 weeks after modification **(AIII);** thereafter, every 4 to 8 weeks until viral load is suppressed **(BIII).** If viral suppression is not possible, repeat viral load testing every 3 months or more frequently if indicated **(AIII).**	Every 3 to 6 months **(AI)**
During the first 2 years of ART	Every 3 months **(AIII)**	Every 3 months if CD4 <300 cells/mm^3 **(BII)** Every 6 months if CD4 ≥300 cells/mm^3 **(BII)**
After 2 years of ART (VL consistently suppressed, CD4 remains <300 cells/mm^3)	Can extend to every 6 months for patients with consistent viral suppression for ≥2 years **(AIII).**	Every 6 months **(BII)**
After 2 years of ART (VL consistently suppressed, CD4 consistently 300–500 cells/mm^3)	Can extend to every 6 months for patients with consistent viral suppression for ≥2 years **(AIII).**	Every 12 months **(BII)**
After 2 years of ART (VL consistently suppressed, CD4 consistently >500 cells/mm^3)	Can extend to every 6 months for patients with consistent viral suppression for ≥2 years **(AIII).**	Optional **(CIII)**
While on ART with detectable viremia (VL repeatedly >200 copies/mL)	Every 3 months **(AIII)** or more frequently if clinically indicated (see Virologic Failure).	Every 3 to 6 months **(AIII)**
Change in clinical status (e.g., new HIV clinical symptom or initiation of chronic systemic corticosteroids, or antineoplastic therapy)	Every 3 months **(AIII)**	Perform CD4 count and repeat as clinically indicated[b] **(AIII)**

[a] Some experts may repeat CD4 count measurement every 3 months in patients with low baseline CD4 counts (<200–300 cells/mm^3) before ART but every 6 months in those who initiated ART at higher CD4 counts (e.g., >300 cells/mm^3).

[b] The following are examples of clinically indicated scenarios: changes in a patient's clinical status that may decrease CD4 count and thus prompt initiation of prophylaxis for opportunistic infection, such as new HIV-associated symptoms, or initiation of treatment with medications that are known to reduce CD4 count.

Key: ART = antiretroviral therapy; CD4 = CD4 T lymphocyte; VL = viral load

Drug-Resistance Testing

Updated: September 12, 2024
Reviewed: September 12, 2024

Panel's Recommendations

For Initial Treatment of HIV

- HIV drug-resistance testing is recommended at entry into care for people with HIV to guide the selection of the initial antiretroviral (ARV) regimen **(AII).** If antiretroviral therapy (ART) is deferred, repeat testing may be considered at the time of ART initiation **(CIII).**
- The Panel on Antiretroviral Guidelines for Adults and Adolescents recommends genotypic, rather than phenotypic, testing as the preferred resistance testing to guide therapy in ARV-naive people **(AIII).**
- In people with early (acute and recent) HIV infection, in pregnant people with HIV, or in people who will initiate ART on the day of or soon after HIV diagnosis, ART initiation should not be delayed while awaiting resistance testing results; the regimen can be modified once results are reported **(AIII).**
- Standard genotypic drug-resistance testing in ARV-naive people involves testing for mutations in the reverse transcriptase and protease genes. If transmitted integrase strand transfer inhibitor (INSTI) resistance is suspected, if the person has ever used long-acting cabotegravir (CAB-LA) as pre-exposure prophylaxis, or if the person has ever received an INSTI-based regimen for post-exposure prophylaxis, providers should ensure that genotypic resistance testing also includes the integrase gene **(AIII).**

For Antiretroviral Therapy–Experienced People

- HIV drug-resistance testing should be performed to assist the selection of active drugs when changing ARV regimens in—
  - People with virologic failure and HIV RNA levels >200 copies/mL (**AI** for >1,000 copies/mL**, AIII** for 501–1,000 copies/mL**, CIII** for confirmed HIV RNA 201–500 copies/mL). For people with confirmed HIV RNA levels >200 copies/mL but <500 copies/mL, drug-resistance testing may be unsuccessful but should still be considered.
  - People with suboptimal viral load reduction **(AII).**
- Reverse transcriptase and protease genotypic resistance testing should be performed on people with virologic failure. Integrase resistance testing should be performed on individuals who have virologic failure and have a history of prior use of an INSTI (for prevention or treatment) or are currently receiving an INSTI-based regimen **(AII).**
- For people taking a non–long-acting ARV regimen, drug-resistance testing in the setting of virologic failure should be performed while the person is still taking their ARV regimen or, if that is not possible, within 4 weeks after discontinuing their ARV regimen **(AII).** If more than 4 weeks have elapsed since the non–long-acting agents have been discontinued, resistance testing may still provide useful information to guide therapy; however, it is important to recognize that previously selected resistance mutations can be missed due to lack of drug-selective pressure **(CIII).**
- For people who previously received long-acting cabotegravir and rilpivirine (LA CAB/RPV) and present with virologic failure, resistance testing (including INSTI genotypic testing) should be performed regardless of the time since the last dose of LA CAB/RPV **(AIII).**
- Genotypic testing is preferred over phenotypic-resistance testing to guide therapy in people with suboptimal virologic response or virologic failure while on first- or second-line regimens and in people in whom resistance mutation patterns are known or not expected to be complex **(AII).**
- The addition of phenotypic to genotypic resistance testing is recommended for people with known or suspected complex drug-resistance mutation patterns **(BIII).**
- All prior and current drug-resistance test results, when available, should be reviewed and considered when constructing a new regimen **(AIII).**

• When the use of a CCR5 antagonist is being considered, a co-receptor tropism assay should be performed **(AI).**
Rating of Recommendations: *A = Strong; B = Moderate; C = Weak* ***Rating of Evidence:*** *I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion*

Genotypic and Phenotypic-Resistance Assays

Genotypic and phenotypic-resistance assays are used to assess viral strains and select treatment strategies. These assays provide information on resistance to nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and integrase strand transfer inhibitors (INSTIs). In some circumstances, INSTI-resistance tests may need to be ordered separately, and clinicians should check this with the testing laboratory. INSTI-resistance testing is particularly important in people who experience virologic failure while taking an INSTI-containing regimen or in those with prior use of injectable long-acting cabotegravir (CAB-LA) (either for treatment of HIV or as pre-exposure prophylaxis [PrEP]). Testing for fusion inhibitor resistance can be ordered separately when needed. There is currently no commercially available resistance test for the CD4 T lymphocyte post-attachment inhibitor ibalizumab, the gp120 attachment inhibitor fostemsavir, or the capsid inhibitor lenacapavir. For a description of co-receptor tropism testing, see Co-Receptor Tropism Assays.

Genotypic Assays

Genotypic assays detect drug-resistance mutations in relevant viral genes; in general, these assays require a plasma viral load of at least 500 to 1,000 copies/mL. Most genotypic assays involve conventional Sanger sequencing of the reverse transcriptase (RT), protease (PR), and integrase (IN) genes of circulating RNA in plasma to detect mutations that are known to confer drug resistance. A genotypic assay that assesses mutations in the gp41 (envelope) gene associated with resistance to the fusion inhibitor enfuvirtide is also commercially available. Genotypic assays can be performed rapidly, and results are available within 1 to 2 weeks of sample collection. Interpreting these test results requires knowledge of the mutations selected by different antiretroviral (ARV) drugs and of the potential for cross-resistance to other drugs conferred by certain mutations. The International AIDS Society–USA maintains an updated list of significant resistance-associated mutations in the RT, PR, IN, and envelope genes. The Stanford University HIV Drug Resistance Database also provides helpful guidance for interpreting genotypic resistance test results.[1] Various additional tools are available to assist providers in interpreting genotypic test results.[2-5] Clinical trials have demonstrated that consulting with specialists in HIV drug resistance improves virologic outcomes.[6] Clinicians are thus encouraged to consult a specialist to interpret genotypic test results and design new, optimal ARV regimens.

A next-generation sequencing genotypic resistance assay that analyzes HIV-1 proviral DNA in host cells is now commercially available. This test aims to detect archived resistance mutations in people with HIV RNA below the limit of detection or with low-level viremia.

Phenotypic Assays

Phenotypic assays measure the ability of a virus to grow in different concentrations of ARV drugs. RT, PR, and, more recently, IN and envelope gene sequences derived from a person's plasma HIV

RNA are inserted into the backbone of a laboratory clone of HIV or used to generate pseudotyped viruses that express that person's HIV genes of interest. Replication of these viruses at different drug concentrations is monitored by expression of a reporter gene and is compared with the replication of a reference HIV strain. The drug concentration that inhibits viral replication by 50% (i.e., the median inhibitory concentration [IC_{50}]) is calculated, and the ratio of the IC_{50} of test and reference viruses is reported as the fold increase in IC_{50} (i.e., fold resistance).

Automated phenotypic assays that can produce results in 2 to 3 weeks are commercially available, but they cost more to perform than genotypic assays. In addition, interpreting phenotypic assay results can be complicated by incomplete information regarding the specific resistance level (i.e., fold increase in IC_{50}) associated with drug failure, although clinically significant fold increase cutoffs have been described for some drugs.[7-11] Again, consulting with a specialist to interpret test results can be helpful.

Limitations of Genotypic and Phenotypic Assays

Limitations of both genotypic and phenotypic assays include lack of uniform quality assurance testing for all available assays, relatively high cost, and insensitivity to minor viral species. Drug-resistant viruses that constitute <10% to 20% of the circulating virus population will probably not be detected by commercially available assays. This limitation is important to note because a wild-type virus often re-emerges as the predominant population in the plasma after discontinuation of drugs that exert selective pressure on drug-resistant populations. As a consequence, the proportion of virus with resistance mutations can decrease to below the 10% to 20% threshold.[12-14] In the case of some oral ARV drugs, this reversion to predominantly wild-type virus can occur in the first 4 to 6 weeks after the drugs are discontinued. However, with injectable agents that have prolonged half-lives (e.g., long-acting cabotegravir and rilpivirine [LA CAB/RPV]), drug pressure may persist for prolonged periods. Prospective studies have demonstrated that despite plasma reversion, reinitiating the same ARV agents (or those with similar resistance pathways) often leads to early treatment failure; the virus responsible for this failure is derived from a previously archived resistant virus.[15] Therefore, for people taking a non–long-acting ARV regimen, drug-resistance testing in the setting of virologic failure should be performed while the person is still taking their ARV regimen or, if that is not possible, within 4 weeks after discontinuing their ARV regimen **(AII).** If more than 4 weeks have elapsed since the non–long-acting agents were discontinued, resistance testing may still provide useful information to guide therapy; however, it is important to recognize that previously selected resistance mutations can be missed due to lack of drug-selective pressure **(CIII).** Given the long half-lives of the long-acting injectable ARV drugs, resistance testing (including testing for resistance to INSTIs) should be performed in all people who have experienced virologic failure on a regimen of LA CAB/RPV or acquired HIV after receiving CAB-LA as PrEP, regardless of the amount of time since drug discontinuation **(AIII).** However, the absence of detectable resistance in people not currently on antiretroviral therapy (ART) must be interpreted with caution when designing subsequent ARV regimens. Importantly, in addition to considering prior ART history, prior genotypic- or phenotypic-resistance test results should be obtained from old records when possible. Because the most current drug-resistance test may not be able to detect resistance mutations that were previously detected, these prior test results are clinically important and should be reviewed and considered when designing a new ARV regimen **(AIII).**

A next-generation sequencing genotypic assay that analyzes HIV-1 proviral DNA may provide additional information on drug resistance in people with low levels of plasma HIV RNA or in people whose levels are below the limit of detection **(CIII).** However, these assays might miss some or all

previous drug-resistance mutations, and they should be interpreted with caution. The usefulness of these assays in the clinic is still under investigation and has yet to be fully determined.

Use of Resistance Assays in Clinical Practice

Note: See Table 5 below for recommendations for the use of drug resistance assays.

Use of Resistance Assays in Determining Initial Treatment

Transmission of drug-resistant HIV strains is well documented and associated with suboptimal virologic response to initial ART.[16-19] The risk of acquiring drug-resistant virus is related to the prevalence of drug resistance in people with HIV who engage in activities that may result in HIV transmission within a given community. The prevalence of resistance and mutations by ARV drug class depends upon the population being studied (e.g., people with previous ARV exposure versus ARV-naive people), geography, and ARV class available in the region.[20] Pre-existing HIV drug resistance before initiation of ART is recognized as an issue for both high- and low-income countries. The prevalence of transmitted drug resistance (TDR) in high-income countries ranges from 9% to 14% and varies by country.[21-23] Pre-treatment drug resistance—which includes people exposed to ARVs prior to initiating first-line therapy (e.g., for PrEP or for the prevention of perinatal transmission), as defined by the World Health Organization—exceeds 10% in many countries.[20] In most TDR surveys, NNRTI resistance and NRTI resistance are the most common mutation class types detected, followed by PI- and INSTI-resistance mutations, respectively.[21-23]

Resistance testing is recommended to guide therapy selection to optimize virologic response in all people starting ART **(AII).** A genotypic assay is preferred for this purpose **(AIII).** In early (acute and recent) HIV infection, in pregnant people with HIV, or in people willing and able to initiate ART on the day or soon after HIV diagnosis, treatment initiation should not be delayed pending resistance testing results. Once results are reported, the regimen can be modified if warranted (see Early [Acute and Recent] HIV Infection) **(AIII).** In the absence of ART, resistant viruses may decline over time to less than the detection limit of standard resistance tests. However, when ART is eventually initiated, even low levels of resistant viruses may still increase the risk of treatment failure.[24-26] Therefore, if ART is deferred, resistance testing should still be performed at the time of entry into care to optimize the chance of capturing transmitted resistance **(AIII).** In this situation, the genotypic resistance test result should be used for regimen selection in the future when the person begins ART. If a person received CAB-LA as part of ART or PrEP, genotypic resistance testing should include the IN gene.

The rate at which transmitted resistance-associated mutations revert to wild-type virus has not been completely delineated, but mutations present at the time of HIV transmission are more stable than those selected under drug pressure. It is often possible to detect resistance-associated mutations in viruses that were transmitted several years earlier.[27-29] Though no prospective trial has directly addressed whether drug-resistance testing before initiation of therapy confers benefit in this population, data from several studies, including one prospective clinical trial, suggest that virologic responses in people with baseline resistance mutations are suboptimal.[16-19,30-34] In addition, an analysis of early RT and PR genotypic resistance testing in ARV-naive people suggests that baseline testing in this population is cost-effective and should be performed.[35] Therefore, resistance testing in people with chronic HIV is recommended at the time of entry into HIV care **(AII).**

Although no definitive prospective data exist to support the choice of one type of resistance testing over another, genotypic testing is generally preferred over phenotypic testing because of lower cost,

faster turnaround time, greater sensitivity for detecting mixtures of wild-type and resistant virus, and easier interpretation of test results **(AIII).** If therapy is deferred, repeat testing shortly before initiating ART may be considered, because the person may have acquired drug-resistant virus (i.e., superinfection) **(CIII).**[36] Standard genotypic drug-resistance testing in ARV-naive people involves testing for mutations in the RT and PR genes. Although reports of transmission of INSTI-resistant virus are rare, as use of INSTIs increases, the potential for transmission of INSTI-resistant virus also may increase. The prior use of CAB-LA for PrEP also may increase the risk of INSTI resistance at the time of HIV diagnosis. When INSTI resistance is possible, providers should supplement standard, baseline, genotypic resistance testing with genotypic testing of the IN gene, which may need to be ordered separately **(AIII).**

The next-generation sequencing genotypic resistance assay that analyzes proviral DNA in host cells can be considered in people with baseline HIV RNA <1,000 copies/mL or when conventional HIV RNA drug-resistance testing is unsuccessful **(CIII).** As outlined above, the results should be interpreted with caution, as this assay might miss some or all previously existing drug-resistance mutations.

Use of Resistance Assays in the Event of Virologic Failure

Resistance assays are important tools to inform treatment decisions for people who experience virologic failure while on ART. Several prospective studies have assessed the utility of resistance testing to guide ARV drug selection in people who experience virologic failure. These studies have involved genotypic assays, phenotypic assays, or both.[6,37-43] In general, these studies have found that changes in therapy based on resistance test results produce better early virologic response to salvage regimens than regimen changes guided only by clinical judgment.

In addition, one observational cohort study found that the use of genotypic drug-resistance testing in ART-experienced people with detectable plasma HIV RNA was independently associated with improved survival.[44] Thus, resistance testing is recommended as a tool for selecting active drugs when changing ARV regimens because of virologic failure in people with HIV RNA >200 copies/mL (**AI** for >1,000 copies/mL, **AIII** for 501 to 1,000 copies/mL, **CIII** for confirmed HIV RNA 201 to 500 copies/mL) (see Virologic Failure). In people with HIV RNA >200 copies/mL but <500 copies/mL, testing may be difficult to obtain outside of a research setting but still should be considered. Conventional drug-resistance testing in people with plasma viral loads ≤200 copies/mL **is not recommended** because there are unclear benefits and drug-resistance assays cannot be consistently performed at very low HIV RNA levels **(AIII).**

Resistance testing can also help to guide treatment decisions for people with HIV who have suboptimal viral load reduction **(AII).** Virologic failure in the setting of ART is, for certain people with HIV, associated with resistance to only one component of the regimen.[45-47] In this situation, substituting individual drugs in a failing regimen may be an option, but this concept will require clinical validation (see Virologic Failure).

Genotyping is preferred for resistance testing in people with HIV who experience virologic failure or suboptimal viral load reduction while on a first or second ARV drug regimen and in people for whom resistance mutation patterns are known or not expected to be complex (i.e., mutations that are straightforward, usually limited in number, or those that have clear significance) **(AII).** Often in these situations, the mutation patterns detected can be interpreted by algorithms used to predict the impact of subsequent regimens on virologic response. For people with HIV who have extensive treatment

history, complex mutational patterns may occur. In such situations, the interpretation of complex genotypes and the impact of the mutation pattern on subsequent treatment regimens can be challenging. For these individuals, phenotypic-resistance testing may provide additional helpful information **(BIII).** Rather than only predicting the impact of the detected mutations, these assays can measure *in vitro* the actual fold change in drug susceptibility, as well as the actual impact of mutation combinations and interactions on each drug under consideration.

When compared with phenotypic testing, genotypic testing costs less to perform and has a faster turnaround time and greater sensitivity for detecting mixtures of wild-type and resistant virus. In addition, observations show that genotypic and phenotypic assays are comparable predictors of virologic response to subsequent ARV regimens.[48] In people with HIV who experience virologic failure while on INSTI-based regimens or in those with prior INSTI exposure, including to CAB-LA for HIV treatment or prevention, testing for INSTI resistance should be performed to determine whether to include drugs from this class in subsequent regimens **(AII).** In this circumstance, clinicians should confirm that, when they order a resistance test, their laboratory is testing for INSTI resistance in addition to NNRTI, NRTI, and PI resistance. If INSTI-resistance testing needs to be ordered separately (as is the case in some laboratories), clinicians should request this assay in addition to standard drug-resistance testing. The addition of phenotypic to genotypic testing is generally indicated for people with known or suspected complex drug-resistance mutation patterns **(BIII).**

The next-generation sequencing genotypic resistance assay that analyzes proviral DNA can be considered for people with HIV who are experiencing treatment failure and for whom conventional HIV RNA genotypic drug-resistance testing is unsuccessful or unavailable due to low HIV RNA levels **(CIII).** As outlined above, results should be interpreted with caution, as these assays might miss some or all previously existing drug-resistance mutations.

When the use of a CCR5 antagonist is being considered, a co-receptor tropism assay should be performed **(AI)** (see Co-Receptor Tropism Assays).

Use of HIV Proviral DNA Resistance Assays for Optimizing Antiretroviral Regimen in People With Viral Suppression

In the past decade, simpler, more potent, and better-tolerated ARV drugs have become available, and new ARV drugs will likely continue to emerge. Switching individual or multiple ARV drugs in a regimen is sometimes considered for people with HIV with suppressed viral load to simplify a regimen, avoid drug interactions or toxicity, or for other reasons. If a person's viral load is suppressed, standard drug-resistance testing will not be successful.

The next-generation sequencing genotypic resistance assay that analyzes proviral DNA can be considered for people with viral suppression, particularly if complex or semi-complex pre-existing resistance is suspected. In individuals who have experienced no prior virologic failures and who are on their first or second regimen, or who have genotypic testing results from when they had prior virologic failures, the use of the proviral DNA genotypic test is unlikely to provide additional useful information. However, in individuals who have experienced multiple prior failures, have a prolonged history of prior ARV regimens, or for whom prior genotypic resistance test results are not available, it may be appropriate to utilize proviral DNA genotypic testing **(CIII).** When such testing is obtained, results should be combined with all prior genotypic and phenotypic test results to construct a cumulative genotype, which incorporates all current and previously detected drug-resistance

mutations. Results from proviral DNA genotypes should be interpreted with caution, as these assays might miss some or all previously existing drug-resistance mutations.[49,50] The usefulness of these assays in the clinic is still under investigation and has yet to be fully determined.

Use of Resistance Assays in Pregnancy

In pregnancy, the goal of ART is to rapidly and maximally reduce plasma HIV RNA in order to provide optimal therapy for the pregnant person and to prevent perinatal transmission of HIV. Genotypic resistance testing is recommended for all pregnant people with HIV before initiation of therapy **(AIII)** and for those entering pregnancy with detectable HIV RNA levels while on therapy **(AI).** Phenotypic testing in those found to have complex drug-resistance mutation patterns may provide additional information **(BIII).** Optimal prevention of perinatal transmission requires prompt initiation of ART pending resistance testing results. Once the results are available, the ARV regimen can be changed as needed.

Table 5. Recommendations for the Use of Drug-Resistance Assays

Clinical Setting and Recommendation	Rationale
In Early (Acute and Recent) HIV Drug-resistance testing is recommended **(AII).** A genotypic assay is generally preferred **(AIII).** Treatment should not be delayed while awaiting resistance testing results **(AIII).** See Early (Acute and Recent) HIV Infection for discussion on ART selection.	Drug-resistance testing can determine whether drug-resistant virus was transmitted or acquired while using PrEP. The initial ARV regimen can be modified, if necessary, once resistance test results are available. Genotypic testing is preferred to phenotypic testing because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant virus.
If ART is deferred, repeat genotypic resistance testing may be considered when therapy is initiated **(CIII).** A genotypic assay is preferred **(AIII).**	Repeat testing when ART is initiated may be considered because the person may have acquired a drug-resistant virus (i.e., superinfection).
Before ART Initiation in People With Chronic HIV Drug-resistance testing is recommended at entry into HIV care to guide the selection of initial ART **(AII).** A genotypic assay is generally preferred **(AIII).** Treatment should not be delayed while awaiting resistance testing results **(AIII).**	Transmitted HIV with baseline resistance to at least one drug has been reported, and suboptimal virologic responses may be seen in people with baseline resistance mutations to ARVs in the prescribed regimen. Some drug-resistance mutations can remain detectable for years in untreated people with chronic HIV.
If transmitted or acquired INSTI resistance (including among people who had received INSTI for post-exposure prophylaxis) is a concern, providers should supplement standard resistance testing with a specific INSTI genotypic resistance assay, which may need to be ordered separately **(AIII).** Given the prolonged half-life of CAB-LA, INSTI-resistance testing should be considered in all people with HIV who previously received CAB-LA for PrEP, regardless of the time since drug discontinuation **(AIII).** See What to Start for discussion on ART selection.	Genotypic assays provide information on resistance to NRTIs, NNRTIs, PIs, and INSTIs. In some circumstances, INSTI-resistance tests need to be ordered separately (clinicians should check with the testing laboratory). Currently, transmitted INSTI resistance is infrequent, but the risk of people acquiring INSTI-resistant strains may be greater in certain known exposure settings. INSTI-resistance testing should be ordered for all people with prior exposure to CAB-LA for PrEP or an INSTI-based regimen for post-exposure prophylaxis.

Table 5. Recommendations for the Use of Drug-Resistance Assays

Clinical Setting and Recommendation	Rationale
For pregnant people or people who will initiate ART on the day of or soon after HIV diagnosis, treatment can be initiated prior to receiving resistance testing results.	If necessary, the ARV regimen can be modified once resistance test results are available.
If therapy is deferred, repeat genotypic resistance testing may be considered before initiation of ART **(CIII).** A genotypic assay is generally preferred **(AIII).**	Repeat testing before initiation of ART may be considered, because the person may have acquired a drug-resistant virus (i.e., a superinfection). Genotypic testing is preferred to phenotypic testing because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant virus.
In People With Virologic Failure Drug-resistance testing is recommended in people on ART with HIV RNA >200 copies/mL (**AI** for >1,000 copies/mL**, AIII** for 501–1,000 copies/mL) and a confirmed HIV RNA 201–500 copies/mL **(CIII).** In people with confirmed HIV RNA levels between 201–500 copies/mL, testing may not be successful but should still be considered.	Drug-resistance testing can help determine the role of resistance in virologic failure and maximize the ability to select active drugs for the new regimen. Resistance testing for HIV RNA levels 201–500 copies/mL may need to be conducted within a research setting.
Resistance testing should be done while the person is taking ART or, if that is not possible, within 4 weeks after discontinuation of non–long-acting ARV drugs **(AII).** If >4 weeks have elapsed, resistance testing may still be useful to guide therapy; however, previously selected mutations can be missed due to lack of drug-selective pressure **(CIII).**	The absence of detectable resistance in such people with HIV must be interpreted with caution when designing subsequent ARV regimens, as mutations may decay with time.
For people who previously received LA CAB/RPV and present with virologic failure, resistance testing (including INSTI genotypic testing) should be performed regardless of the time since the last dose of LA CAB/RPV **(AIII).**	Because of the long half-lives of LA CAB and RPV, resistance mutations to INSTI and NNRTI may emerge even months after the last doses of these drugs.
Reverse transcriptase and protease genotypic resistance testing should be performed on people with virologic failure. Integrase resistance testing should be performed on individuals who have virologic failure and have a history of prior use of an INSTI (for prevention or treatment) or are currently receiving an INSTI-based regimen **(AII).**	Genotypic testing is preferred to phenotypic testing because of lower cost, faster turnaround time, and greater sensitivity for detecting mixtures of wild-type and resistant HIV. INSTI-resistance tests may need to be ordered separately. (Clinicians should check with the testing laboratory.)
All prior and current drug-resistance testing results should be reviewed and considered when designing a new ARV regimen for a person experiencing virologic failure **(AIII).**	Drug-resistance mutations may decay with time, and mutations detected in prior resistance tests may not be detected in current tests, though they remain clinically relevant.
Adding phenotypic testing to genotypic testing is generally preferred in people with known or suspected complex drug-resistance patterns **(BIII).**	Phenotypic testing can provide additional useful information in people with complex drug-resistance mutation patterns.
If use of a CCR5 antagonist is being considered, a co-receptor tropism assay should be performed **(AI).**	See Co-Receptor Tropism Assays section.

Table 5. Recommendations for the Use of Drug-Resistance Assays

Clinical Setting and Recommendation	Rationale
In People With Suboptimal Suppression of Viral Load Drug-resistance testing is recommended in people with suboptimal viral load suppression after initiation of ART **(AII).**	Testing can determine the role of resistance in suboptimal viral suppression, and it can help the clinician identify the number of active drugs available in the current ARV regimen and assess the need for a new regimen.
In Pregnant People With HIV Genotypic resistance testing is recommended for all pregnant people before initial ART **(AIII)** and for those entering pregnancy with detectable HIV RNA levels while on therapy **(AI).**	The goals of ART in pregnant people with HIV are to achieve maximal viral suppression for treatment of HIV in the pregnant person and to prevent perinatal transmission of HIV. Genotypic resistance testing will assist the clinician in selecting the optimal ARV regimen. However, treatment should not be delayed while awaiting resistance testing results. The initial regimen can be modified once resistance test results are available, if needed.
In People With Undetectable Viral Load or Low-Level Viremia Who Are Planning to Change Their ARV Regimen HIV-1 proviral DNA resistance assays may be useful if HIV RNA is below the limit of detection or with low-level viremia, where a HIV RNA genotypic assay is unlikely to be successful **(CIII).**	HIV-1 proviral DNA resistance assays may provide information about previously circulating resistant viral variants that are archived within proviral DNA. These assays may miss some or all prior resistance mutations that have occurred within the viral quasi-species and, therefore, they should be interpreted with caution. The clinical utility of HIV-1 proviral DNA assays has not been fully determined.

Key: ART = antiretroviral therapy; ARV = antiretroviral; CAB-LA = long-acting cabotegravir; CCR5 = cysteine-cysteine chemokine receptor 5; INSTI = integrase strand transfer inhibitor; LA = long-acting; LA CAB/RPV = long-acting cabotegravir/rilpivirine; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; PrEP = pre-exposure prophylaxis; RPV = rilpivirine

Co-Receptor Tropism Assays

Updated: October 25, 2018
Reviewed: October 25, 2018

Panel's Recommendations
• A co-receptor tropism assay should be performed whenever the use of a CCR5 co-receptor antagonist is being considered **(AI).** • Co-receptor tropism testing is recommended for patients who exhibit virologic failure on a CCR5 antagonist **(BIII).** • A phenotypic tropism assay is preferred to determine HIV-1 co-receptor usage **(AI).** • A genotypic tropism assay should be considered as an alternative test to predict HIV-1 co-receptor usage **(BII).** • A proviral DNA tropism assay can be utilized for patients with undetectable HIV-1 RNA when a CCR5 antagonist is considered for use in a new regimen (e.g., as part of a regimen switch or simplification) **(BII).**
***Rating of Recommendations**: A = Strong; B = Moderate; C = Weak* ***Rating of Evidence**: I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion*

HIV enters cells by a complex process that involves sequential attachment to the CD4 T lymphocyte (CD4) receptor followed by binding to either the CCR5 or CXCR4 molecules and fusion of the viral and cellular membranes.[1] CCR5 co-receptor antagonists prevent HIV entry into target cells by binding to the CCR5 receptors.[2] Phenotypic and genotypic assays have been developed that can determine or predict the co-receptor tropism (i.e., use of CCR5, CXCR4, or both as either dual-tropic virus or a mixed population of viruses referred to for purposes of assay results as dual/mixed [D/M]) of the patient's dominant virus population. An older generation assay (Trofile,® Monogram Biosciences, Inc., South San Francisco, CA) was used to screen patients who were participating in clinical trials that led to the approval of maraviroc (MVC), the only CCR5 antagonist currently available. The assay has been improved and is now available with enhanced sensitivity. In addition, genotypic assays to predict co-receptor usage are commercially available.

During acute/recent infection, the vast majority of patients harbor a CCR5-utilizing virus (R5 virus), which suggests that the R5 variant is preferentially transmitted; however, up to 19% of individuals with acute/recent infection can harbor CXCR4-tropic virus.[3-5] Viruses in many untreated patients eventually exhibit a shift in co-receptor tropism from CCR5 usage to either CXCR4 usage or D/M tropism. This shift is temporally associated with a more rapid decline in CD4 counts,[6,7] but whether this tropism shift is a cause or a consequence of progressive immunodeficiency remains undetermined.[1] Antiretroviral-treated patients with extensive drug resistance or persistently high-level viremia are more likely to harbor CXCR4- or D/M-tropic variants than untreated patients with comparable CD4 counts.[8,9] The prevalence of CXCR4- or D/M-tropic variants increases to more than 50% in treated patients who have CD4 counts <100 cells/mm^3.[8,10] Since CXCR4-tropic viruses may be present at initial presentation or a patient may shift to CXCR4-tropism over the course of infection, co-receptor tropism should always be assessed prior to the use of CCR5 antagonists for treatment. Once a patient has ever been documented with detectable CXCR4- or D/M-tropic virus, it is assumed that such viruses will always be present. CCR5 co-receptor antagonists will no longer be active for that patient and should not be used.

Phenotypic Assays

Phenotypic assays characterize the co-receptor usage of plasma-derived virus. These assays involve the generation of laboratory viruses that express patient-derived envelope proteins (i.e., gp120 and gp41). These pseudoviruses, which are replication-defective, are used to infect target cell lines that express either CCR5 or CXCR4.[11,12] Using the Trofile® assay, the co-receptor tropism of the patient-derived virus is confirmed by testing the susceptibility of the virus to specific CCR5 or CXCR4 inhibitors *in vitro*. This assay takes about 2 weeks to perform and requires a plasma HIV RNA level ≥1,000 copies/mL.

The performance characteristics of these assays have evolved. Most, if not all, patients enrolled in premarketing clinical trials of MVC and other CCR5 antagonists were screened with an earlier, less sensitive version of the Trofile® assay.[12] This earlier assay failed to routinely detect low levels of CXCR4-utilizing variants. As a consequence, some patients enrolled in these clinical trials harbored low levels of such variants at baseline, which were below the assay limit of detection, and these patients exhibited rapid virologic failure after initiation of a CCR5 antagonist.[13] The assay has been improved and is now able to detect lower levels of CXCR4-utlizing viruses. *In vitro*, the assay can detect CXCR4-utilizing clones with 100% sensitivity when those clones represent 0.3% or more of the virus population.[14] Although this more sensitive assay has had limited use in prospective clinical trials, it is now the only assay that is commercially available. For unclear reasons, a minority of samples cannot be successfully phenotyped with either generation of the Trofile® assay.

In patients with an undetectable viral load or detectable plasma HIV RNA <1,000 copies/mL, phenotypic co-receptor usage can be determined using proviral DNA obtained from peripheral blood mononuclear cells (e.g., Trofile® DNA, Monogram Sciences); however, the clinical utility of this assay remains to be determined.[15]

Genotypic Assays

Genotypic determination of HIV-1 co-receptor usage is based on sequencing of the V3-coding region of HIV-1 *env*, the principal determinant of co-receptor usage. A variety of algorithms and bioinformatics programs can be used to predict co-receptor usage from the V3 sequence.[16] When compared to the phenotypic assay, genotypic methods show high specificity (~90%) but only modest sensitivity (~50% to 75%) for the presence of a CXCR4-utilizing virus. Studies in which V3 genotyping was performed on samples from patients screened for clinical trials of MVC suggest that genotyping performed as well as phenotyping in predicting the response to MVC.[17-19] An important caveat is that the majority of patients who received MVC were first shown to have R5 virus by a phenotypic assay (Trofile®). Consequently, the opportunity to assess treatment response to MVC in patients whose virus was considered R5 by genotype but D/M or X4 by phenotype was limited to a relatively small number of patients. Other studies have also demonstrated relatively high concordance between genotypic- and phenotypic-assessed tropism;[20,21] however, there is variability between different genotypic platforms.[22]

Given these performance characteristics, genotypic tropism assays may not be sufficiently robust to completely rule out the presence of an X4 or D/M variant;[23] therefore, the Panel preferentially recommends phenotypic testing. Based on accessibility, capacity, logistics, and cost, European guidelines currently include genotypic testing as an equivalent option to phenotypic testing when determining co-receptor usage among patients with HIV RNA >1,000 copies/mL and preferentially for those with HIV RNA ≤1,000 copies/mL.[24]

HIV-1 proviral DNA genotypic tropism testing is available for patients with HIV RNA <1,000 copies/mL. These assays evaluate the HIV-1 proviral DNA integrated within infected cells for CXCR4-utilizing viral strains.[25] As discussed above, caution is advised when using such assays, as their detection limit, concordance with plasma HIV RNA tropism, and clinical utility are not yet fully determined.

Use of Assays to Determine Co-receptor Usage in Clinical Practice

An assay for HIV-1 co-receptor usage should be performed whenever the use of a CCR5 antagonist is being considered (**AI**). This is true even in the setting of prior tropism testing showing CCR5 usage, as viral evolution may occur over the course of infection. In addition, because virologic failure may occur due to a shift from CCR5-using to CXCR4-using virus, testing for co-receptor usage is recommended in patients who exhibit virologic failure on a CCR5 antagonist **(BIII).** Virologic failure may also be caused by resistance of a CCR5-using virus to a CCR5 antagonist, but such resistance is uncommon. Compared to genotypic testing, phenotypic testing has more evidence supporting its utility. Therefore, a phenotypic test for co-receptor usage is generally preferred **(AI).** However, because phenotypic testing is more expensive, requires more time to perform, and may have logistic challenges, a genotypic test to predict HIV-1 co-receptor usage should be considered as an alternative test **(BII).**

As with HIV resistance testing, the results of all prior tropism tests should be obtained. If CXCR4-utlizing or D/M-tropic viruses have ever been detected previously, then repeat testing is not necessary and a CCR5 co-receptor antagonist **should not be used.**

If a CCR5 co-receptor antagonist is being considered in a patient with an undetectable HIV RNA (e.g., in cases of regimen simplification or a toxicity-related switch), a proviral DNA tropism assay can be utilized **(BII).**[26-28] If CXCR4-utlizing or D/M-tropic viruses are detected, then the CCR5 co-receptor antagonist **should not be used.**

HLA-B*5701 Screening

Updated: December 1, 2007
Reviewed: January 10, 2011

Panel's Recommendations
• The Panel recommends screening for HLA-B*5701 before starting patients on an abacavir (ABC)-containing regimen to reduce the risk of hypersensitivity reaction (HSR) **(AI).** • HLA-B*5701-positive patients should not be prescribed ABC **(AI).** • The positive status should be recorded as an ABC allergy in the patient's medical record **(AII).** • When HLA-B*5701 screening is not readily available, it remains reasonable to initiate ABC with appropriate clinical counseling and monitoring for any signs of HSR **(CIII).**
Rating of Recommendations: *A = Strong; B = Moderate; C = Weak* ***Rating of Evidence:*** *I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = expert opinion*

The abacavir (ABC) hypersensitivity reaction (HSR) is a multiorgan clinical syndrome typically seen within the initial 6 weeks of ABC treatment. This reaction has been reported in 5% to 8% of patients participating in clinical trials when using clinical criteria for the diagnosis, and it is the major reason for early discontinuation of ABC. Discontinuing ABC usually promptly reverses HSR, whereas subsequent rechallenge can cause a rapid, severe, and even life-threatening recurrence.[1]

Studies that evaluated demographic risk factors for ABC HSR have shown racial background as a risk factor, with white patients generally having a higher risk (5%–8%) than black patients (2%–3%). Several groups reported a highly significant association between ABC HSR and the presence of the major histocompatibility complex (MHC) class I allele HLA-B*5701.[2,3] Because the clinical criteria used for ABC HSR are overly sensitive and may lead to false-positive ABC HSR diagnoses, an ABC skin patch test (SPT) was developed as a research tool to immunologically confirm ABC HSR.[4] A positive ABC SPT is an ABC-specific delayed HSR that results in redness and swelling at the skin site of application. All ABC SPT–positive patients studied were also positive for the HLA-B*5701 allele.[5] The ABC SPT could be falsely negative for some patients with ABC HSR and, at this point, is not recommended for use as a clinical tool. The PREDICT-1 study randomized participants with HIV before starting ABC either to be prospectively screened for HLA-B*5701 (with HLA-B*5701–positive patients not offered ABC) or to standard of care at the time of the study (i.e., no HLA screening, with all patients receiving ABC).[6] The overall HLA-B*5701 prevalence in this predominately white population was 5.6%. In this cohort, screening for HLA-B*5701 eliminated immunologic ABC HSR (defined as ABC SPT positive) compared with standard of care (0% vs. 2.7%), yielding a 100% negative predictive value with respect to SPT and significantly decreasing the rate of clinically suspected ABC HSR (3.4% vs. 7.8%). The SHAPE study corroborated the low rate of immunologically validated ABC HSR in black patients and confirmed the utility of HLA-B*5701 screening for the risk of ABC HSR (100% sensitivity in black and white populations).[7]

On the basis of the results of these studies, the Panel recommends screening for HLA-B*5701 before starting an ABC-containing regimen in a person with HIV **(AI).** HLA-B*5701–positive patients should not be prescribed ABC **(AI),** and the positive status should be recorded as an ABC allergy in the patient's medical record **(AII).** HLA-B*5701 testing is needed only once in a patient's lifetime;

thus, efforts to carefully record and maintain the test result and to educate the patient about its implications are important. The specificity of the HLA-B*5701 test in predicting ABC HSR is lower than the sensitivity (i.e., 33%–50% of HLA-B*5701–positive patients would likely not develop confirmed ABC HSR if exposed to ABC). HLA-B*5701 should not be used as a substitute for clinical judgment or pharmacovigilance, because a negative HLA-B*5701 result does not absolutely rule out the possibility of some form of ABC HSR. When HLA-B*5701 screening is not readily available, it remains reasonable to initiate ABC with appropriate clinical counseling and monitoring for any signs of ABC HSR **(CIII).**

Treatment Goals

Updated: January 28, 2016
Reviewed: January 28, 2016

Antiretroviral therapy (ART) has reduced HIV-related morbidity and mortality at all stages of HIV infection[1-4] and has reduced HIV transmission.[5-8] Maximal and durable suppression of plasma viremia delays or prevents the selection of drug-resistance mutations, preserves or improves CD4 T lymphocyte (CD4) cell numbers, and confers substantial clinical benefits, all of which are important treatment goals.[9, 10] HIV suppression with ART may also decrease inflammation and immune activation thought to contribute to higher rates of cardiovascular and other end-organ damage reported in cohorts with HIV (see Initiating Antiretroviral Therapy). Despite these benefits, eradication of HIV infection cannot be achieved with available antiretrovirals (ARVs). Treatment interruption has been associated with rebound viremia, worsening of immune function, and increased morbidity and mortality.[11] Thus, once initiated, ART should be continued, with the following key treatment goals:

- Maximally and durably suppress plasma HIV RNA;
- Restore and preserve immunologic function;
- Reduce HIV-associated morbidity and prolong the duration and quality of survival; and
- Prevent HIV transmission.

Achieving viral suppression currently requires the use of combination ARV regimens that generally include three active drugs from two or more drug classes. Baseline patient characteristics and results from drug resistance testing should guide design of the specific regimen (see What to Start: Initial Combination Regimens for the Antiretroviral-Naive Patient). When initial HIV suppression is not achieved or not maintained, changing to a new regimen with at least two active drugs is often required (see Virologic Failure).The increasing number of ARV drugs and drug classes makes viral suppression below detection limits an achievable goal in most patients.

After initiation of effective ART, viral load reduction to below limits of assay detection usually occurs within the first 12 to 24 weeks of therapy. Predictors of virologic success include the following:

- Low baseline viremia;
- High potency of the ARV regimen;
- Tolerability of the regimen;
- Convenience of the regimen; and
- Excellent adherence to the regimen.

Strategies to Achieve Treatment Goals

Selection of Initial Combination Regimen

Several ARV regimens are recommended for use in ART-naive patients (see What to Start). Most of the recommended regimens have comparable efficacy but vary in pill burden, potential for drug interactions and/or side effects, and propensity to select for resistance mutations if ART adherence is suboptimal. Regimens should be tailored for the individual patient to enhance adherence and support long-term treatment success. Considerations when selecting an ARV regimen for an individual patient include potential side effects, patient comorbidities, possible interactions with conconcomitant medications, results of pretreatment genotypic drug-resistance testing, and regimen convenience (see Table 7).

Improving Adherence

Suboptimal adherence may result in reduced treatment response. Incomplete adherence can result from complex medication regimens; patient-related factors, such as active substance abuse, depression, or the experience of adverse effects; and health system issues, including interruptions in patient access to medication and inadequate treatment education and support. Conditions that promote adherence should be maximized before and after initiation of ART (see Adherence to Antiretroviral Therapy).

Initiation of Antiretroviral Therapy

Updated: December 18, 2019
Reviewed: December 18, 2019

Panel's Recommendations
• Antiretroviral therapy (ART) is recommended for all persons with HIV to reduce morbidity and mortality **(AI)** and to prevent the transmission of HIV to others **(AI).** • The Panel on Antiretroviral Guidelines for Adults and Adolescents recommends initiating ART immediately (or as soon as possible) after HIV diagnosis in order to increase the uptake of ART and linkage to care, decrease the time to viral suppression for individual patients, and improve the rate of virologic suppression among persons with HIV **(AII).** • When initiating ART, it is important to educate patients regarding the benefits of ART and to deploy strategies to optimize care engagement and treatment adherence **(AIII).**
Rating of Recommendations: *A = Strong; B = Moderate; C = Weak* ***Rating of Evidence:*** *I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion*

Introduction

The primary goal of antiretroviral therapy (ART) is to prevent HIV-associated morbidity and mortality. This goal is accomplished by using effective ART to achieve and maintain a plasma HIV-1 RNA (viral load) below the quantification limits of commercially available assays. Durable viral suppression improves immune function and overall quality of life, lowers the risk of both AIDS-defining and non-AIDS–defining complications, and allows persons with HIV to live a lifespan approaching that of persons without HIV.[1]

Another goal of ART is to reduce the risk of HIV transmission to sexual partners and to infants born to persons with HIV. High plasma HIV RNA levels are a major risk factor for HIV transmission; effective ART can reduce both viremia and the risk of transmission of HIV to sexual partners[2-6] and prevent perinatal transmission.[7, 8] Modelling studies and ecological studies of populations with high ART uptake and high viral suppression rates suggest that expanded use of ART may lower the incidence of HIV and, eventually, the prevalence of HIV on a community or population level.[9-11]

Two large, randomized controlled trials addressed the optimal time to initiate ART—START[12] and TEMPRANO.[13] Both studies demonstrated reductions in morbidity and mortality among individuals with HIV who had CD4 T lymphocyte (CD4) cell counts >500 cells/mm^3 and who were randomized to receive ART immediately when compared to individuals who delayed initiation of ART.

Deferring ART until CD4 counts decline puts individuals with HIV at risk of both AIDS-defining conditions and certain serious non-AIDS–defining conditions. Furthermore, the magnitude of CD4 recovery is directly correlated with CD4 count at ART initiation. Consequently, many individuals who start treatment with CD4 counts <350 cells/mm^3 do not achieve CD4 counts >500 cells/mm^3 after up to 10 years on ART,[14, 15] and they have a shorter life expectancy than those who initiated therapy at higher CD4 count thresholds.[14-16]

Fundamental to the recommendation for earlier initiation of ART in these guidelines is the assumption that HIV will be diagnosed early in the course of the disease. Unfortunately, in some individuals, the diagnosis of HIV is not made until the later stages of the disease. In a survey conducted between 2016 and 2017, it was noted that fewer than 40% of American adults had ever had an HIV test.[17] Evidence shows that many people with HIV access health care years before their HIV diagnosis but are not offered HIV testing despite recommendations from the Centers for Disease Control and Prevention (CDC) for routine testing for everyone aged 13 to 64 years.[18, 19] There are also economic benefits to early diagnosis, including prolonging life, improving the quality of life, and decreasing the costs related to the management of AIDS and its co-morbidities.[20, 21] Additionally, HIV screening is a key step in the Ending the HIV Epidemic initiative to prevent the transmission of HIV to others.[22]

Diagnosis of HIV is delayed more often in nonwhite individuals, those who inject drugs, those who live in rural communities, and older adults, and many individuals in these groups develop AIDS-defining illnesses within 1 year of diagnosis.[23-25] Therefore, to ensure that the current treatment guidelines have maximum impact, routine HIV screening per current CDC recommendations is essential. The U.S. Preventative Services Task Force recommends HIV testing for persons aged 15 to 65 years and for all pregnant individuals. HIV testing should also be performed for younger and older persons when indicated. This recommendation has been designated a Grade A recommendation by the U.S. Preventative Services Task Force, meaning that third-party payers should cover this service without cost to patients.[26] It is critical that everyone who receives an HIV diagnosis be educated about HIV disease and linked to care for full evaluation, follow-up, and management as soon as possible. In order for both individuals with HIV and their sexual partners to fully benefit from early diagnosis, clinicians should initiate ART as soon as possible and provide support to enhance retention in care and ART adherence (see Adherence to the Continuum of Care).

Initiating Antiretroviral Therapy

ART is recommended for all individuals with HIV to reduce the morbidity and mortality associated with HIV infection **(AI)** and to prevent HIV transmission to sexual partners and infants **(AI).** ART should be initiated as soon as possible after HIV diagnosis **(AII).** When initiating ART, it is important to educate patients about the goals and benefits of ART and to identify and address barriers to care engagement and treatment adherence **(AIII).** Patients should also understand that currently available ART does not cure HIV. To improve and maintain immunologic function and maintain viral suppression, ART should be continued indefinitely without interruption. Initiating ART early is particularly important for patients with AIDS-defining conditions, those with acute or recent HIV infection, and individuals who are pregnant; delaying therapy in these subpopulations has been associated with high risks of morbidity, mortality, and HIV transmission.

Immediate Antiretroviral Therapy Initiation on the Day of HIV Diagnosis

Since individuals may fail to engage in care between the initial HIV diagnosis (or first clinic visit) and the time ART is prescribed, some groups have proposed rapid ART initiation on the same day of HIV diagnosis as a strategy to increase ART uptake and engagement in care and to accelerate the time to ART-mediated viral suppression. Rapid ART initiation also has the potential to reduce the time during which people with newly diagnosed HIV can transmit HIV. The rapid ART initiation strategy is supported by randomized controlled trials that were performed in resource-limited settings outside of the United States[27-29] and observational trials in the United States that included both

immediate initiation of ART (on the day of diagnosis)[30-32] and rapid ART initiation (within days or weeks of diagnosis).[32, 33] The results from some of these studies are discussed below.

A randomized controlled trial conducted in South Africa enrolled 377 individuals who had recently received HIV diagnoses (median CD4 count was 210 cells/mm^3). Participants were randomized to receive ART on the day of diagnosis or to receive the usual care (three to five additional visits over 2–4 weeks before ART initiation). Those who received immediate ART were significantly more likely to be virally suppressed at 10 months (64% vs. 51% of patients achieved viral suppression, respectively).[27] In another randomized controlled trial conducted in Haiti, a higher proportion of participants who were randomized to receive same-day ART initiation were retained in care and had viral suppression at the end of 1 year than those who initiated ART at the standard time (3 weeks after HIV testing); survival was also higher in the same-day ART initiation group.[28] A novel randomized controlled trial in Lesotho compared same-day, home-based ART to usual care and standard clinic referral (which involved a minimum of two counseling sessions prior to ART initiation). Participants randomized to receive same-day ART initiation were significantly more likely to achieve linkage to care within 90 days after enrollment (68.6% vs. 43.1%) and virologic suppression at approximately 12 months (50.4% vs. 34.3%).[29]

There are many differences between health care in southern Africa and Haiti and in the United States—including differences in the health care systems, structural barriers to engagement in care, underlying HIV and tuberculosis (TB) epidemics, and ART regimens used—that limit the generalizability of the findings of the results from the studies described above. These studies, however, suggest that same-day initiation of ART is feasible and could potentially improve clinical outcomes.

While no randomized controlled trials have been conducted in the United States, several prospective observational studies have demonstrated the feasibility of same-day ART initiation. City-wide implementation of the San Francisco RAPID program among 225 patients who were newly diagnosed with HIV showed a median time from HIV diagnosis to ART start of 0 days (with a range of 0–56 days) and a median time from ART initiation to viral suppression (defined as <200 copies/mL) of 41 days. Over a median follow-up of 1.09 years (range 0–3.92 years), 92.1% of patients achieved virologic suppression. The RAPID study included a diverse and traditionally marginalized population, with a substantial proportion of participants having a major substance use disorder (51.4%), a major mental health disorder (48.1%), or unstable housing (30.6%).[31]

Whether rapid ART initiation improves long-term care engagement and virologic suppression is not yet known. One cohort study from France, however, found that earlier initiation of ART was negatively associated with care engagement at 1 year.[34] It should be emphasized that ART initiation on the same day of HIV diagnosis is resource intensive, and this strategy may require additional staff, multidisciplinary coordination, provision of ART starter packs, and consolidation of "usual care" patient services (e.g., clinical evaluation, education, counseling, initiation or optimization of insurance coverage, intake laboratory testing) into a 2- or 3-hour visit.[31] While the infrastructure and resources necessary to implement an immediate ART program may not be available in all health care settings, removing structural barriers in order to facilitate rapid ART initiation may improve outcomes in the United States. The Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) recommends initiating ART at the time of diagnosis (when possible) or soon afterwards to increase the uptake of ART, decrease the time required to achieve linkage to care and virologic suppression, and improve the rate of virologic suppression among individuals who have recently received HIV diagnoses **(AII).** This rating for this recommendation reflects the fact that only

observational trials have been conducted in the United States or other highly resourced countries, where health systems and socioeconomic contexts differ substantially from those in the countries where randomized trials were conducted.

Antiretroviral Therapy for Persons with Acute Opportunistic Infections and Malignancies

Initiation of ART in the setting of an acute, AIDS-associated opportunistic infection (OI) or malignancy can improve immune function and potentially enhance treatment success for the OI. Clinicians should refer to the Adult and Adolescent Opportunistic Infection Guidelines for a more in-depth discussion on specific OIs. Below is a list of important factors to consider when initiating ART in these situations.

- When no effective therapy exists for the OI (e.g., cryptosporidiosis, microsporidiosis, progressive multifocal leukoencephalopathy): In these situations, ART may be the only treatment that can improve immune function and clinical outcomes. ART should be initiated without delay in these patients (see the Adult and Adolescent Opportunistic Infection Guidelines for more information).
- Concerns regarding immune reconstitution inflammatory syndrome (IRIS): For some OIs, such as cryptococcal and TB meningitis, immediate ART initiation may increase the risk of serious IRIS. A short delay before initiating ART may be warranted.[35-38] After ART initation, the patient should be closely monitored for signs and symptoms associated with IRIS.
- Non-meningeal TB: In these patients, initiating ART during treatment for TB confers a significant survival advantage;[39-43] therefore, ART should be initiated as recommended in Tuberculosis/HIV Coinfection.
- For patients with mild to moderate cutaneous Kaposi sarcoma: Prompt initiation of ART alone without chemotherapy has been associated with improvement of cutaneous Kaposi sarcoma lesions, even though initial transient progression of Kaposi sarcoma lesions as a manifestation of IRIS can also occur.[44]
- For patients with malignancies that require chemotherapy:
    - A diagnosis of malignancy should not delay initiation of ART, nor should initiation of ART delay treatment for the malignancy.
    - Although an IRIS-like presentation of non-Hodgkin's lymphoma after initiation of ART has been described,[45] ART-mediated viral suppression is associated with longer survival among individuals undergoing treatment for AIDS-related lymphoma.[46]
    - Drug interactions should be considered when selecting ART, as there is the potential for significant interactions between chemotherapeutic agents and some antiretroviral drugs (particularly some ritonavir-boosted or cobicistat-boosted regimens).

Evidence Supporting the Benefits of Antiretroviral Therapy in Preventing Morbidity and Mortality

Randomized Controlled Trials of Early vs. Deferred Antiretroviral Therapy

Two large randomized controlled trials, START and TEMPRANO, provide the evidence for the Panel's recommendation to initiate ART in all patients regardless of CD4 count **(AI).** The results of these two studies are summarized below.

START was a large, multi-national, randomized controlled clinical trial designed to evaluate the role of early ART initiation in asymptomatic patients with HIV in reducing a composite clinical endpoint of AIDS-defining illnesses, serious non-AIDS events, or death. The study began at a time when initiating ART was not recommended until an individual's CD4 count fell below 350 cells/mm^3. In this study, ART-naive adults (aged >18 years) with CD4 counts >500 cells/mm^3 were randomized to initiate ART at randomization (early initiation arm) or to wait to initiate ART until their CD4 counts declined to <350 cells/mm^3 or until they developed a clinical indication for therapy (deferred initiation arm).

The study enrolled 4,685 participants, with a mean follow-up of 3 years. The primary endpoint of serious AIDS or non-AIDS events was reported in 42 participants (1.8%, or 0.60 events per 100 person-years) who were randomized to initiate ART early, and 96 participants (4.1%, or 1.38 events per 100 person-years) in the deferred ART arm (hazard ratio [HR] 0.43, favoring early ART; 95% confidence interval [CI], 0.30–0.62, $P < 0.001$). The most common clinical events reported were TB and malignancies (including both AIDS and non-AIDS malignancies). The majority of clinical events (59%) in the deferred ART arm occurred in participants whose CD4 counts were still above 500 cells/mm^3, evidence for a benefit of initiating ART even before CD4 count declines below this threshold. Furthermore, the benefit of early ART was consistent across all participant subgroups, including gender, age, plasma HIV RNA levels, and income level of country. Although START was not sufficiently powered to compare the benefits of early ART initiation and deferred ART initiation for each category of clinical events, the benefit appeared to be particularly strong for AIDS events (HR 0.28), TB (HR 0.29), malignancies (HR 0.36), and severe bacterial infections (HR 0.39). The benefit at lower CD4 counts was primarily a reduction in the number of AIDS events, while the benefit at higher CD4 counts was primarily a reduction in the number of serious non-AIDS events. Importantly, early ART initiation also significantly reduced the rate of pooled serious non-AIDS events (HR 0.61).[12, 47]

The TEMPRANO ANRS 12136 study was a randomized controlled trial conducted in Cote d'Ivoire. Using a two-by-two factorial design, participants with HIV who had CD4 counts <800 cells/mm3 and who did not meet the criteria for starting ART according to World Health Organization guidelines at that time were randomized to start ART early (upon enrollment) or defer ART based on the national guidelines criteria for starting treatment. Half of the participants in each group received isoniazid for prevention of TB for 6 months and half did not. The primary study endpoint was a combination of all-cause deaths, AIDS diseases, non-AIDS malignancies, and non-AIDS invasive bacterial diseases.

More than 2,000 participants enrolled in the trial, with a median follow-up of 30 months. Among the 849 participants who had baseline CD4 counts >500 cells/mm^3, 68 primary outcome events were reported in 61 patients. The risk of primary events was lower among those who were randomized to start ART early than among those in the deferred arm, with an HR of 0.56 in favor of early ART

(95% CI, 0.33–0.94). On the basis of these results, the study team concluded that early ART initiation is beneficial in reducing the rate of these clinical events.[13]

The TEMPRANO and START trials had very similar estimates for the protective effect of ART among individuals with HIV who had CD4 counts >500 cells/mm^3, further supporting the Panel's recommendation that ART be initiated in all patients regardless of CD4 count.

Use of Antiretroviral Therapy to Prevent HIV Transmission

Prevention of Sexual Transmission

A randomized clinical trial[3] and several large observational cohort studies[4-6] have provided strong evidence that achieving sustained viral suppression prevents sexual transmission of HIV. Thus, a key goal of ART is to prevent transmission of HIV to seronegative sexual partners **(AI).** All persons with HIV should be informed that maintaining a plasma HIV RNA (viral load) of <200 copies/mL, including any measurable value below this threshold value, with ART prevents sexual transmission of HIV to their partners **(AII).** Patients may recognize this concept as Undetectable = Untransmittable, or U=U. The results of these studies are summarized in Antiretroviral Therapy to Prevent Sexual Transmission of HIV.

Prevention of Perinatal Transmission

The first well-established example of ART reducing the risk of HIV transmission is the use of ART during pregnancy to prevent perinatal transmission of HIV. Effective suppression of HIV replication is a key determinant in reducing the risk of perinatal transmission. In the setting of maternal viral load suppressed to <50 copies/mL near delivery, the use of combination ART during pregnancy has reduced the rate of perinatal HIV transmission from approximately 20% to 30% to 0.1% to 0.5%.[7, 8] ART is thus recommended for all pregnant individuals with HIV, for both maternal health and for the prevention of HIV transmission to the newborn. In ART-naive pregnant individuals, ART should be initiated as soon as possible, with the goal of suppressing plasma viremia throughout pregnancy. All pregnant individuals should be tested for HIV upon confirmation of pregnancy, with testing repeated throughout pregnancy as needed for those at risk of HIV acquisition (see Maternal HIV Testing and Identification of Perinatal HIV Exposure in the Perinatal Guidelines).

Considerations When Initiating Antiretroviral Therapy

The ART regimens that are currently recommended as initial therapy in these guidelines (see What to Start) can suppress and maintain viral loads below the level of quantification in most patients who adhere to their regimens. Most of the recommended regimens have a low pill burden and are well tolerated. Once started on treatment, patients must continue ART indefinitely.

Optimizing Adherence, Antiretroviral Therapy Access, and Care Engagement

The key to successfully maintaining viral suppression is continuous access to ART and adherence to the prescribed regimen. Lack of adherence or intermittent access to ART can result in treatment failure and the emergence of drug resistance mutations that may compromise future treatment options. While optimizing adherence and linkage to care and ensuring continuous access are critical regardless of the timing of ART initiation, the evidence thus far indicates that drug resistance occurs more frequently in individuals who initiate therapy later in the course of infection than in those who

initiate ART earlier.[48] It is important to discuss strategies to optimize adherence, care engagement, and ART access with all patients.

Several clinical, behavioral, and social factors have been associated with poor adherence. These factors include untreated major psychiatric disorders, neurocognitive impairment, substance use disorder, unstable housing, unfavorable social circumstances, patient concerns about side effects, and poor adherence to clinic visits. Clinicians should identify areas where additional intervention is needed to improve adherence both before and after initiation of therapy. Some strategies to improve adherence are discussed in Adherence to the Continuum of Care. However, mental illness, substance use disorder, and psychosocial challenges are not reasons to withhold ART from a patient. Rather, these issues indicate the need for additional interventions to support adherence, and they may influence the ART regimen that is recommended (see What to Start).

Considerations for Special Populations

Elite HIV Controllers

A small subset of individuals with HIV maintains plasma HIV-1 RNA levels below level of quantification for years without ART. These individuals are often referred to as elite HIV controllers.[49, 50] There are limited data on the benefits of initiating ART in these individuals. The START and TEMPRANO studies demonstrated that initiating ART is clearly beneficial for the patient regardless of CD4 count; therefore, delaying ART to see if a patient becomes an elite controller is **strongly discouraged**. Nevertheless, significant uncertainty remains about the optimal management of elite controllers who have maintained undetectable viremia in the absence of ART for years.

Given that ongoing HIV replication occurs even in elite controllers, ART is strongly recommended for controllers with evidence of HIV disease progression, which is defined by declining CD4 counts or the development of HIV-related complications **(AIII).** Nonetheless, even elite controllers with normal CD4 counts show evidence of abnormally high immune activation and surrogate markers of atherosclerosis, which may contribute to an increased risk of non-AIDS–related diseases.[49, 51-53] One observational study suggested that elite controllers are hospitalized more often for cardiovascular and respiratory disease than patients from the general population and ART-treated patients.[54] Moreover, elite controllers with preserved CD4 counts appear to experience a decline in immune activation after ART initiation, suggesting that treatment may be beneficial.[55] Whether this potential immunologic benefit of ART in elite controllers outweighs the potential risks of ART toxicity and results in clinical benefit is unclear. Unfortunately, it is unlikely that randomized controlled trials will be able to address this question, given the very low prevalence of elite controllers. Although the START study included a number of participants with very low viral loads and demonstrated the benefit of immediate ART initiation regardless of the extent of viremia, the study did not include a sufficient number of controllers to definitively determine the clinical impact of ART in this specific population.[56] Nevertheless, there is a clear rationale for prescribing ART to elite controllers even in the absence of detectable plasma HIV RNA levels. If ART is withheld, elite controllers should be followed closely, as some may experience CD4 cell decline, loss of viral control, or complications related to HIV infection.

Adolescents with HIV

Neither the START trial nor the TEMPRANO trial included adolescents. The Panel's recommendation to initiate ART in all patients is extrapolated to adolescents based on the expectation that they will derive benefits from early ART initiation that are similar to those observed in adults. Compared to adults, youth have demonstrated significantly lower levels of ART adherence and viral suppression, and higher rates of viral rebound following initial viral suppression.[57] In recent years, more adolescents have been prescribed once-daily regimens, which has increased the rate of viral suppression in this population, even though there has been no significant difference in treatment adherence.[58] Because youth often face psychosocial and other barriers to adherence, their ability to adhere to therapy should be carefully considered when making decisions about ART initiation. Although some adolescents may not be ready to initiate therapy, clinicians should offer ART while providing effective interventions to assess and address barriers to receiving care and to adherence. To optimize the benefits of ART for youth, a multidisciplinary care team should provide psychosocial and adherence support to adolescent patients (see Adolescents and Young Adults with HIV).[59]

Antiretroviral Therapy to Prevent Sexual Transmission of HIV (Treatment as Prevention)

Updated: December 18, 2019
Reviewed: December 18, 2019

Panel's Recommendations
• All persons with HIV should be informed that maintaining a plasma HIV RNA (viral load) of <200 copies/mL, including any measurable value below this threshold value, with antiretroviral therapy (ART) prevents sexual transmission of HIV to their partners. Patients may recognize this concept as Undetectable = Untransmittable or U=U **(AII).**
• Persons with HIV who are starting ART should use another form of prevention with sexual partners (e.g., condoms, pre-exposure prophylaxis [PrEP] for the HIV-negative sexual partner, sexual abstinence) for at least the first 6 months of treatment and until a viral load of <200 copies/mL has been documented **(AII).** Many experts would recommend confirming sustained suppression before assuming that there is no further risk of sexual HIV transmission **(AIII).**
• When the viral load is ≥200 copies/mL, additional methods are needed to prevent transmission of HIV to sexual partners until resuppression to <200 copies/mL has been confirmed **(AIII).**
• Persons with HIV who intend to rely upon ART for prevention need to maintain high levels of ART adherence **(AIII).** They should be informed that transmission is possible during periods of poor adherence or treatment interruption **(AIII).**
• At each visit for HIV care, clinicians should assess adherence to ART and counsel patients regarding the importance of ART to their own health as well as its role in preventing sexual HIV transmission **(AIII).**
• Providers should inform patients that maintaining a viral load of <200 copies/mL does not prevent acquisition or transmission of other sexually transmitted infections (STIs) **(AII).**
• Providers should also routinely screen all sexually active persons with HIV for STIs, both for their own health and to prevent transmission of STIs to others **(AIII).**
***Rating of Recommendations**: A = Strong; B = Moderate; C = Weak*
***Rating of Evidence**: I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion*

Antiretroviral therapy (ART) not only reduces morbidity and mortality for persons with HIV but has now been definitively shown to prevent sexual transmission of the virus when the plasma HIV RNA (viral load) is consistently suppressed to <200 copies/mL, which includes any measurable viral load that is lower than this threshold value. Providers who manage patients with HIV need to be aware of the data supporting treatment as prevention (TasP, which persons with HIV may recognize as Undetectable = Untransmittable or U=U), its implications, and how to operationalize this prevention strategy in clinical practice. For persons with HIV who intend to rely on TasP for HIV prevention, providers should make an individualized assessment of the person's risk tolerance, personal health, history of maintaining viral suppression on treatment, and access to health care services and ART, as well as other factors that may affect their ability to maintain a high level of adherence to ART.

Evidence That Viral Load Suppression Prevents Sexual HIV Transmission

Suppressing the HIV viral load to <200 copies/mL with ART prevents sexual transmission of HIV. Observational data collected in the early 1990s from heterosexual couples demonstrated that sexual transmission from untreated persons with HIV was rare at viral loads of <1,000 copies/mL to 1,500 copies/mL and that the risk of transmission increased in dose-response fashion with increasing viral

load.[1, 2] Additional reports[3-7] and a meta-analysis[8] supported the observation that sexual HIV transmission risk in heterosexual persons was correlated with plasma viral load, and transmission was infrequent below the lowest limits of quantification for the viral load assays used at the time.

The first prospective clinical trial designed specifically to address this question was HPTN 052, which randomized people with HIV who were in mixed HIV status couples (previously referred to as serodiscordant couples) to initiate ART early or to delay initiation. Initial results from this study were reported in 2011,[9] with final results reported in 2016.[10] The 2016 analysis reported that no phylogenetically linked sexual transmissions of HIV occurred among 1,763 couples who were followed a median of 5.5 years while the person with HIV was on ART and had a viral load <400 copies/mL for at least 6 months. Notably, four phylogenetically linked infections occurred within the 90 days after the partner with HIV had started ART and was presumably not yet virally suppressed, and four others occurred after the partner with HIV had experienced virologic failure. There were also a number of transmission events that were not phylogenetically linked, indicating acquisition from someone other than the enrolled study index partner.[11] HPTN 052 was conducted almost exclusively among heterosexual couples that lived in Africa and Asia and did not track the number or type of sexual exposures. In addition, ART was used as an adjunct to a comprehensive prevention package that provided condoms and encouraged condom use, as well as frequent testing for HIV and other sexually transmitted infections (STIs).

Three prospective observational studies—PARTNER 1,[12] PARTNER 2,[13] and Opposites Attract[14]—provided data from more diverse populations of mixed HIV status couples in which condomless sex was common. Clinical follow-up in these studies closely mimicked that of routine clinical care. Conducted in 14 European countries (PARTNER 1 and PARTNER 2) as well as Australia, Thailand, and Brazil (Opposites Attract), the investigators followed 548 heterosexual and 1,481 male-male mixed HIV status couples that engaged in 144,631 episodes of condomless vaginal or anal sex while the partner with HIV had a suppressed viral load on ART, defined as <200 copies/mL. In these studies, no phylogenetically linked transmissions were observed; however, as in HPTN 052, there were numerous non-phylogenetically linked transmissions attributed to partners outside the enrolled study couple relationship.

Integrating the Principles of Treatment as Prevention into Clinical Care

The Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) recommends that providers inform all persons with HIV that maintaining an HIV viral load <200 copies/mL with ART prevents sexual transmission of HIV **(AII).** This information may help motivate patients and help relieve stigma that can be a barrier to getting tested and entering into care, starting and remaining adherent to ART, and ultimately achieving and maintaining a viral load <200 copies/mL.[15] Although PARTNER 1, PARTNER 2, and Opposites Attract were designed to follow patients in the study as they would be typically be followed in clinical care for HIV, the participants reported high levels of ART adherence at study entry and many reported at least 1 year of condomless sex with an established sexual partner without transmission. As the principles of TasP are integrated into the clinical management of people with HIV who are on ART, implementation research will be critical to maximize the effectiveness of TasP in practice.

Frequency of Viral Load Assessment

The Panel has issued recommendations for viral load monitoring to manage the health of persons with HIV (see Plasma HIV-1 RNA (Viral Load) and CD4 Count Monitoring). However, current data

are insufficient to determine whether these recommendations represent the optimal monitoring schedule for the purpose of preventing sexual transmission of HIV. In the PARTNER studies and Opposites Attract, viral loads were generally assessed every 3 to 6 months during study follow-up, usually during the course of regular HIV care. Pending further data, the Panel recommends no change to the existing recommendations for monitoring viral load (see Plasma HIV-1 RNA (Viral Load) and CD4 Count Monitoring) **(BII).**

Time to Adequate Suppression after Starting Antiretroviral Therapy

A subgroup analysis from the Partners PrEP Study provided data regarding the risk of HIV transmission during and after the first 6 months on ART for the partner with HIV.[16] This analysis included 1,573 heterosexual East African couples in which the partners without HIV were randomized to the placebo arm of the Partners PrEP Study and were tested monthly for HIV while the viral load of the partner with HIV was assessed every 6 months. Three phylogenetically linked infections were diagnosed in the 6 months prior to the first follow-up visit for the partners with HIV. The observed incidence rate of 1.79 per 100 person-years during this initial 6-month period after the partner with HIV started ART was slightly less than the 2.08 per person-years incidence rate observed in couples in which the person with HIV was not receiving ART. Viral suppression in this study was defined as <40 copies/mL, and the three infections were diagnosed at 0 days, 56 days, and 149 days after the partner with HIV started ART. After the partners with HIV had been taking ART for ≥6 months, no further transmissions were observed.

At this time, the Panel recommends that persons with HIV who are starting ART use another form of prevention with sexual partners for at least the first 6 months of treatment and until a viral load of <200 copies/mL has been documented **(AII).** Many experts would recommend confirming sustained suppression before assuming that there is no further risk of sexual transmission of HIV **(AIII).**

Adherence to Antiretroviral Therapy

Adherence to ART is paramount for persons who intend to prevent HIV transmission by achieving and maintaining a suppressed viral load. Viral rebound typically occurs within days to weeks after ART cessation and has been observed as early as 3 to 6 days after stopping treatment.[17-29] The minimum level of adherence that is required to prevent sexual transmission has not been determined and may vary depending on the ART regimen. In the key studies that defined the efficacy of TasP, adherence levels prior to study entry and during follow-up were very high. In clinical practice, most people who start ART will achieve a viral load <200 copies/mL within 6 months, but once this viral load is achieved, maintaining viral suppression can be a challenge, especially for those who have difficulty accessing ART and other HIV care. The Centers for Disease Control and Prevention (CDC) estimates that during 2015, 60% of persons with HIV and 78% of persons engaged in clinical care had viral loads <200 copies/mL at their most recent assessment.[30] Observational cohort data have demonstrated that within the first year of starting ART, up to 10% of persons with HIV can experience loss of viral suppression; however, the likelihood of maintaining a suppressed viral load generally improves over time. After a few years, 5% or fewer of persons on ART may experience loss of viral suppression.[31, 32]

The Panel recommends that persons with HIV who intend to rely upon TasP be made aware of the need for high levels of ART adherence **(AIII).** The Panel further recommends that adherence be assessed and counseling be provided at each visit for HIV care to reinforce the importance of adherence for the individual's health as well as its role in preventing HIV transmission **(AIII).**

Patients should be informed that transmission is possible during periods of poor adherence or treatment interruption **(AIII).**

Adherence can be especially challenging for certain groups of patients, such as adolescents and young adults, homeless persons, persons with active substance use disorder, and persons who are involved with the criminal justice system. Recommendations to help manage and maximize ART adherence can be found in Adherence to the Continuum of Care. Persons for whom there is concern about adherence also merit counseling on how to properly use other prevention methods, especially barrier methods that prevent STIs.

Managing Transient Viremia, or "Blips"

Highly adherent patients may experience intermittent or transient viremia, commonly termed "viral blips." Blips are defined in the context of effective treatment as a single, measurable HIV RNA level, typically <200 copies/mL, that is followed by a return to a viral load below the limit of detection or quantification. With contemporary ART regimens, about 10% of persons per year who are adherent to ART may experience a blip.[33-35] Most blips likely represent normal biological fluctuation (i.e., variation around a mean undetectable viral load) or laboratory artifact and not inadequate adherence.[36-38] Persistent viremia ≥200 copies/mL has been associated with increasing risk of virologic failure[33, 39] that, in the context of TasP, can lead to increased risk of sexual transmission.[10] The PARTNER studies and Opposites Attract excluded observation time when the viral load of the participant with HIV was ≥200 copies/mL. The frequency of blips <200 copies/mL was not reported in Opposites Attract; however, in PARTNER 1 and PARTNER 2, transient elevations in viral loads above the limit of detection (50 copies/mL in these studies) but <200 copies/ml were observed for 6% and 4% of the total follow-up time, respectively, during which time no phylogenetically linked infections were observed.

One of the clinical challenges with blips is that they can only be defined retrospectively once the viral load has returned to a suppressed value. The Panel recommends that when the viral load is ≥200 copies/mL, persons with HIV and their sexual partners should use another form of prevention (e.g., condoms, pre-exposure prophylaxis for sexual partners without HIV, sexual abstinence) to protect against HIV transmission until a viral load <200 copies/mL is achieved (AII). This recommendation applies both to persons who are starting ART (as noted earlier) and to those who have been taking ART and have achieved viral suppression but develop viral loads ≥200 copies/mL.

In cases where a patient achieves resuppression to <200 copies/mL after a detectable viral load ≥200 copies/mL, or when a patient with a viral load <200 copies/mL switches regimens (e.g., for regimen simplification or to avoid certain side effects), providers should check the viral load per recommendations in Plasma HIV-1 RNA (Viral Load) and CD4 Count Monitoring and Optimizing Antiretroviral Therapy in the Setting of Virologic Suppression, respectively **(AIII).** There are presently no data to guide how long, if at all, a person might need to continue to use another form of prevention in these two circumstances. Individualized assessment is recommended based on the length and quality of adherence and time with viral load <200 copies/mL preceding the viral load ≥200 copies/mL.

Effect of Sexually Transmitted Infections on Treatment as Prevention

The presence of STIs in a person with HIV does not appear to meaningfully alter the risk of sexual transmission when the person's viral load is <200 copies/mL. The PARTNER studies and the

Opposites Attract study regularly assessed participants for STIs, which were diagnosed in 6% of heterosexual participants and 13% to 27% of men who have sex with men. Although the authors of the studies noted that their findings could not rule out the possibility that STIs in participants with viral loads <200 copies/mL might affect the risk of HIV transmission, when viewed collectively, these data suggest that any effect is very small, since STIs were common and no linked infections were observed. The Panel recommends that patients using TasP be informed that maintaining a viral load of <200 copies/mL does not prevent acquisition or transmission of other STIs, and that it is not substitute for condoms or behavioral modifications **(AII).** Providers should also routinely screen all sexually active persons with HIV for STIs, both for their own health and to prevent transmission of STIs to others **(AIII).** Refer to CDC's Sexually Transmitted Diseases Treatment Guidelines for details.

Treatment as Prevention Applies Only to Sexual Transmission of HIV

Available clinical data only support the use of TasP to prevent sexual HIV transmission in patients with viral loads <200 copies/mL. The effectiveness of this strategy to prevent transmission from blood exposure (e.g., through nonsterile drug injection) has not been determined. In addition, while suppression of maternal viral load substantially reduces the risk of perinatal transmission and transmission through breastfeeding, it does not eliminate these risks, and transmission has occurred via breastfeeding despite continuous viral suppression (refer to the Perinatal Guidelines for details).

What to Start: Initial Combination Antiretroviral Regimens for People With HIV

Updated: September 12, 2024
Reviewed: September 12, 2024

Introduction

More than 30 antiretroviral (ARV) drugs in nine mechanistic classes are U.S. Food and Drug Administration (FDA)–approved for treatment of HIV infection. These nine classes include nucleos(t)ide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase strand transfer inhibitors (INSTIs), a fusion inhibitor, a CCR5 antagonist, a CD4 T lymphocyte (CD4) cell post-attachment inhibitor, a gp120 attachment inhibitor, and a capsid inhibitor. In addition, two drugs—ritonavir (RTV) and cobicistat (COBI)—are used as pharmacokinetic (PK) enhancers (or boosters) to improve the PK profiles of PIs and the INSTI elvitegravir (EVG).

Over time, incremental improvements in potency, tolerability, safety, convenience, drug interactions and genetic barriers to the emergence of drug resistance have led to streamlined recommendations for initial ARV regimens for most people with HIV. The Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) now recommends initial ARV regimens based on an oral second-generation INSTI plus two NRTIs—bictegravir (BIC)/tenofovir alafenamide (TAF)/emtricitabine (FTC) **(AI)** or dolutegravir (DTG) plus TAF/FTC or tenofovir disoproxil fumarate (TDF)/ FTC or TDF/lamivudine (3TC) **(AI)**—for most people with HIV. In some people with HIV, the two-drug regimen DTG/3TC can be used **(AI).** When INSTI resistance is possible, such as after exposure to long-acting injectable cabotegravir (CAB-LA) as pre-exposure prophylaxis (PrEP) and/or if INSTI genotype results are not yet available, a boosted PI (boosted darunavir [DRV]) in combination with two NRTIs (TAF or TDF with FTC or 3TC) is recommended **(AIII).** The Panel's recommendations are summarized in Tables 6a and 6b.

Table 6a. Recommended Initial Regimens for Most People With HIV

Selection of antiretroviral therapy (ART) should be based on the regimen's virologic efficacy, potential adverse effects, pill burden, dosing frequency, drug–drug interaction potential, cost, access, resistance test results, and the comorbid condition of the person with HIV. A pregnancy test should be performed in people of childbearing potential, and choice of ART for pregnant individuals should be guided by recommendations from the Perinatal Guidelines. Drug classes and regimens within each class are arranged first by evidence rating and, when ratings are equal, in alphabetical order. Additional initial ARV regimen options for certain clinical scenarios are listed in Table 6b below.

Table 6a. Recommended Initial Regimens for Most People With HIV Recommended regimens are those with demonstrated durable virologic efficacy, favorable tolerability and toxicity profiles, and ease of use. Choice of ART during pregnancy should be guided by recommendations from the Perinatal Guidelines.
For people who do not have a history of using CAB-LA as PrEP, one of the following regimens is recommended[a]: • BIC/TAF/FTC **(AI)**

Table 6a. Recommended Initial Regimens for Most People With HIV

- DTG plus (TAF or TDF)[b] plus (FTC or 3TC) **(AI)**
- DTG/3TC **(AI),** except for individuals with HIV RNA >500,000 copies/mL, HBV coinfection, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available.

For people who have a history of CAB-LA use as PrEP, INSTI genotype resistance testing should be performed before starting ART. If ART is to be started before results of genotypic testing results, the following regimen is recommended:

- DRV/c[c] or DRV/r with (TAF or TDF)[b] plus (FTC or 3TC)—pending the results of the genotype test **(AIII)**

Rating of Recommendations: *A = Strong; B = Moderate; C = Weak*

Rating of Evidence: *I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials, observational cohort studies with long-term clinical outcomes, relative bioavailability/bioequivalence studies, or regimen comparisons from randomized switch studies; III = Expert opinion*

[a] Because of the current low rates of transmitted INSTI resistance in the United States, even when there is suspicion that HIV was acquired from a partner with virologic failure while on an INSTI, an INSTI-based regimen can be started pending the results of the INSTI genotype.

[b] TAF and TDF are two forms of TFV approved by the U.S. Food and Drug Administration. TAF has fewer bone and kidney toxicities than TDF, while TDF is associated with lower lipid levels. Safety, cost, and access are among the factors to consider when choosing between these drugs.

[c] COBI should be avoided in pregnancy because lower concentrations of COBI and DRV have been reported during the second and third trimesters. For further information, refer to the Perinatal Guidelines.

Note: The following are available as coformulated drugs: BIC/TAF/FTC, DRV/c/TAF/FTC, DTG/3TC, TAF/FTC, TDF/3TC, and TDF/FTC.

Key: 3TC = lamivudine; ART = antiretroviral therapy; BIC = bictegravir; CAB-LA = long-acting cabotegravir; COBI = cobicistat; DRV = darunavir; DRV/c = darunavir/cobicistat; DRV/r = darunavir/ritonavir; DTG = dolutegravir; FTC = emtricitabine; HBV = hepatitis B virus; INSTI = integrase strand transfer inhibitor; PrEP = pre-exposure prophylaxis; TAF = tenofovir alafenamide; TDF = tenofovir disoproxil fumarate; TFV = tenofovir

Table 6b. Other Initial Antiretroviral Regimens for Certain Clinical Scenarios

Several antiretroviral regimens are found to be effective and tolerable as initial regimens but have some disadvantages or have fewer supporting data from randomized clinical trials compared with the recommended regimens listed in Table 6a. However, one of these regimens may be preferred for an individual with HIV in certain clinical situations (also see Table 7). These regimens are listed below.

Type of Regimen	ARV Regimen	For Certain Clinical Scenarios	Other Considerations
INSTI Plus Two NRTIs	DTG/ABC/3TC **(BI)** (if HLA-B*5701-negative)	When concern about renal- or bone-associated AEs precludes the use of TDF or TAF	Test for HLA-B*5701 before prescribing ABC; do not prescribe if HLA-B*5701-positive. Consider avoiding ABC for people with multiple CV risk factors or known CV disease.

Table 6b. Other Initial Antiretroviral Regimens for Certain Clinical Scenarios

Type of Regimen	ARV Regimen	For Certain Clinical Scenarios	Other Considerations
			Do not use in people with HBV coinfection unless an HBV-active drug, such as entecavir, TAF, or TDF is also used. Do not use following exposure to CAB-LA unless INSTI genotype shows sensitivity.
Boosted PI Plus Two NRTIs	(DRV/c[a] or DRV/r) plus (TAFor TDF[b]) plus (FTC or 3TC) **(BI)**	To avoid an INSTI-based regimen (e.g., documented INSTI resistance).	Assess for potential RTV- or COBI-related DDIs.
	(DRV/c[a] or DRV/r) plus ABC/3TC **(BII)** (if HLA-B*5701-negative)	To avoid an INSTI-based regimen (e.g., with suspected or documented INSTI resistance), *and* When concern about renal or bone-associated AEs precludes the use of TDF or TAF	Test for HLA-B*5701 before prescribing ABC; do not prescribe if HLA-B*5701-positive. Consider avoiding ABC for people with multiple CV risk factors or known CV disease. Do not use in people with HBV coinfection unless used with an HBV-active drug other than 3TC. Assess for potential RTV- or COBI-related DDIs.
NNRTI Plus Two NRTIs	DOR/TDF/3TC[b] **(BI)** or DOR plus TAF/FTC[b] **(BIII)**	To avoid an INSTI-based regimen (e.g., with suspected or documented INSTI resistance), *and* To avoid a PI-based regimen (e.g., with significant DDIs with concomitant medications)	
	RPV/TAF/FTC **(BII)** Only if HIV RNA <100,000 copies/mL **and** CD4 count >200 cells/mm^3	To avoid an INSTI-based regimen (e.g., with suspected or documented INSTI resistance), *and* To avoid a PI-based regimen (e.g., with significant DDIs with concomitant medications), *and* When a single-tablet regimen containing an NNRTI and TAF is desired	Cannot take with PPI; space apart from H2 antagonist. Needs to be taken with a meal.

Table 6b. Other Initial Antiretroviral Regimens for Certain Clinical Scenarios

Type of Regimen	ARV Regimen	For Certain Clinical Scenarios	Other Considerations
Rating of Recommendations: *A = Strong; B = Moderate; C = Weak*			
Rating of Evidence: *I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials, observational cohort studies with long-term clinical outcomes, relative bioavailability/bioequivalence studies, or regimen comparisons from randomized switch studies; III = Expert opinion*			

[a] COBI should be avoided in pregnancy because lower concentrations of COBI and DRV have been observed during the second and third trimesters. For further information, refer to the Perinatal Guidelines.

[b] TAF and TDF are two forms of TFV approved by the U.S. Food and Drug Administration. TAF has fewer bone and kidney toxicities than TDF, while TDF is associated with lower lipid levels. Safety, cost, and access are among the factors to consider when choosing between these drugs.

Note: The following are available as coformulated drugs: ABC/3TC, DOR/TDF/3TC, DRV/c, DRV/c/TAF/FTC, DTG/ABC/3TC, RPV/TAF/FTC, TAF/FTC, TDF/3TC, and TDF/FTC.

Key: 3TC = lamivudine; ABC = abacavir; AE = adverse event; ARV = antiretroviral; CD4 = CD4 T lymphocyte; COBI = cobicistat; CV = cardiovascular; DDI = drug–drug interaction; DOR = doravirine; DRV/c = darunavir/cobicistat; DRV/r = darunavir/ritonavir; DTG = dolutegravir; FTC = emtricitabine; H2 = histamine type 2; HBV = hepatitis B virus; HLA = human leukocyte antigen; INSTI = integrase strand transfer inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; PPI = proton pump inhibitor; RPV = rilpivirine; RTV = ritonavir; TAF = tenofovir alafenamide; TDF = tenofovir disoproxil fumarate; TFV = tenofovir

Supporting Evidence and Rationale Used for the Panel's Recommendations

The Panel's recommendations are primarily based on clinical trial data published in peer-reviewed journals and on data prepared by drug manufacturers for FDA review. In select cases, the Panel considers data from abstracts presented at major scientific meetings. The Panel considers published information from randomized prospective clinical trials with adequate sample size that demonstrate that an ARV regimen produces high rates of viral suppression, increases CD4 count, and has a favorable safety profile to be the strongest evidence on which to base recommendations. Comparative clinical trials of initial treatments generally are not designed to show significant differences in HIV-related clinical endpoints (such as progression to AIDS-defining conditions) or survival. Thus, the assessment of regimen efficacy and safety is primarily based on surrogate marker endpoints (i.e., rates of HIV RNA suppression) and the incidence and severity of adverse events.

In some instances, the Panel recommends regimens that include ARV drugs approved by the FDA based on bioequivalence or relative bioavailability studies that demonstrate that the exposure of the drug(s) in the new formulation or combination is comparable to the exposure of a reference drug(s) that has demonstrated safety and efficacy in randomized clinical trials. When developing recommendations, the Panel may also consider data from randomized switch studies in which a drug in an ARV initial regimen that suppressed patients' viral loads is replaced by a new drug from the same class. Switch trials do not evaluate the ability of a drug or regimen to induce viral suppression; they only examine the drug or regimen's ability to maintain suppression. Therefore, results from switch trials may not be directly applicable to the selection of an initial regimen and should be considered in conjunction with other data, including data from bioavailability/bioequivalence studies and from trials conducted in people taking their first ARV treatment regimen. In this section of the guidelines, the definition of an evidence rating of **II** is expanded to include supporting data from bioavailability/bioequivalence studies or randomized switch studies.

When developing recommendations, the Panel also considers tolerability and toxicity profiles, pill burden and dosing frequency, drug interaction potential, cost and access, postmarketing safety data, observational cohort data published in peer-reviewed publications, the experience of clinicians who are actively engaged in patient care, and the views of community members.

The Panel reviewed the available data to arrive at two classifications for initial ARV treatment regimens: (1) *Recommended Initial Regimens for Most People With HIV* (Table 6a) and (2) *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (Table 6b). *Recommended Initial Regimens for Most People With HIV* are those regimens with demonstrated durable virologic efficacy, favorable tolerability and toxicity profiles, and ease of use. The Panel also recognizes that in certain clinical situations, other regimens may be preferred; these options are included in Table 6b. See Table 7 for examples of clinical scenarios in which certain drugs in these regimens may be particularly advantageous.

Many other ARV regimens are effective for initial therapy but have disadvantages when compared with the regimens listed in Tables 6a and 6b. These disadvantages include greater toxicity, higher pill burden, less supporting data from large comparative clinical trials, and limitations for use in certain populations. These regimens are no longer included in Tables 6a and 6b. For people with HIV who have a suppressed viral load and are not experiencing any adverse effects while on a regimen that is not listed, changing to a regimen listed in Table 6a or 6b is not necessary. Clinicians should refer to Optimizing Antiretroviral Therapy in the Setting of Viral Suppression for further guidance if switching to a new regimen is desired.

Several tables in these guidelines provide clinicians with guidance on selecting and prescribing an optimal regimen for a person with HIV. Table 7 provides information on considerations based on specific clinical scenarios and ARV drug characteristics. Table 9 lists the potential advantages and disadvantages of the different ARV drug components. Appendix B, Tables 3–11, lists characteristics of individual ARV agents for initial therapy (e.g., formulations, dosing recommendations, PK, common adverse effects). Appendix B, Table 12 provides ARV dosing recommendations for people who have renal or hepatic insufficiency.

Changes Since the Last Revision of the Guidelines

Since the last revision of these guidelines, the Panel has made several important changes to the recommendations for initial therapy in people with HIV. Among these changes, the following deserve emphasis:

Changes in the Panel's Recommendations for Initial Regimens in Most People With HIV:

- The single-tablet regimen (STR) DTG/abacavir (ABC)/3TC has moved from *Recommended Initial Regimens for Most People With HIV* (Table 6a) to *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (Table 6b) due to the necessity of obtaining an HLA-B*5701 assay to avoid ABC-associated hypersensitivity, data suggesting increased risk for cardiovascular events associated with ABC, and the availability of several other options for initial therapy (see the Nucleoside Reverse Transcriptase Inhibitor Options as Part of Initial Therapy section for more information).
- Because of the current low rates of transmitted INSTI resistance in the United States, even when there is suspicion that HIV was acquired from a partner with virologic failure while on an INSTI, an INSTI-based regimen can be started pending the results of the INSTI genotype test.

No Longer Recommended as Initial Antiretroviral Regimens:

- Raltegravir (RAL)-, elvitegravir/cobicistat (EVG/c)-, boosted atazanavir (ATV)-, and efavirenz (EFV)-based regimens and rilpivirine (RPV)/TDF/FTC are no longer recommended as initial therapy due to the following disadvantages compared with other regimens:
  - RAL: Low genetic barrier to resistance and higher pill burden
  - EVG/c: Drug–drug interactions with COBI and low genetic barrier to resistance of EVG
  - Boosted ATV: Toxicities, including hyperbilirubinemia, and drug–drug interactions
  - EFV: Toxicities, including neuropsychiatric effects and suicidality; low barrier to resistance; and drug–drug interactions
  - RPV/TDF/FTC: Availability of doravirine (DOR)/TDF/3TC as an STR, more drug–drug interactions than DOR, food restrictions, and HIV RNA and CD4 restrictions. RPV/TAF/3TC remains an option for those who wish to use an STR containing RPV and TAF
- The two-drug regimens darunavir/ritonavir (DRV/r) plus RAL and DRV/r plus 3TC are no longer recommended for initial therapy.
  - DRV/r plus RAL is not recommended due to the higher rate of virologic failure in people with HIV RNA >100,000 copies/mL, the low genetic barrier to resistance, and the high pill burden of RAL.[1-3]
  - DRV/r plus 3TC is not recommended because it requires a PK booster with accompanying drug interactions, and published clinical trial data are lacking.[4] For further information, see Other Antiretroviral Regimens for Initial Therapy.

Selecting an Initial Antiretroviral Regimen

The goal of ART is to improve health and prolong life for people with HIV and to prevent the transmission of HIV to others by maximizing virologic suppression. This is achieved by initiating therapy with a potent, safe, tolerable, and easy-to-adhere-to ARV regimen as soon as possible after diagnosis. Table 6a provides a list of Panel-recommended ARV regimens for most people with HIV. Some factors listed below may influence the selection of a regimen. See Table 6b and Table 7 for additional regimen recommendations to use in specific clinical scenarios.

Initial Characteristics to Consider in All People With HIV

- Pre-treatment HIV RNA level (viral load)
- Pre-treatment CD4 count
- History of prior exposure to CAB-LA or oral TDF/FTC or TAF/FTC as PrEP, or use of INSTI-based post-exposure prophylaxis (PEP)
- Suspected drug resistance (prior to availability of genotypic testing results)
- HIV genotypic drug resistance test results
  - Genotypic drug resistance testing in people without prior ARV exposure should focus on testing for mutations in the reverse transcriptase and protease genes.

  - If transmitted INSTI resistance is a concern, providers should also test for resistance mutations to this class of drugs.
- Individual preferences
- Anticipated adherence to the regimen

Presence of Specific Conditions

- Comorbid conditions: Cardiovascular disease; hyperlipidemia; renal disease; liver disease; osteopenia, osteoporosis, or other conditions associated with bone mineral density loss; psychiatric illness; neurologic disease; substance use disorder requiring narcotic replacement therapy
- Coinfections: Hepatitis B virus (HBV), hepatitis C virus, tuberculosis
- Pregnancy and potential for pregnancy: See below in General Considerations for Persons of Childbearing Potential Initiating Antiretroviral Therapy

Regimen-Specific Considerations

- Regimen's barrier to resistance
- HLA-B*5701 status (only for those considering initiation of ABC). Those who are HLA-B*5701 positive should not receive ABC. See Table 7 for regimens to initiate.
- Potential adverse effects and drug toxicities, including risk for the development of comorbid diseases
- Known or potential drug interactions with other medications (see Drug–Drug Interactions)
- Convenience (e.g., pill burden, dosing frequency, availability of a fixed-dose combination or of STR formulations, food requirements)
- Cost and access (see Cost Considerations and Antiretroviral Therapy)

Considerations for People With Prior Use of Pre- or Post-Exposure Prophylaxis

- For people who acquired HIV after taking oral PrEP with TAF/FTC or TDF/FTC, there is concern for transmitted resistance, especially related to FTC or 3TC with the M184V/I mutation. In a cohort of people in New York City with newly diagnosed HIV, 2% had the M184V/I mutation. People who had used prior oral PrEP were four to seven times more likely to harbor resistance than people who had never used oral PrEP.[5] This reinforces the Panel's recommendation not to initiate DTG/3TC without the results of genotypic resistance testing.
- For people who acquired HIV after exposure to CAB-LA as PrEP, there is concern for INSTI resistance. CAB-LA may remain detectable after treatment discontinuation for up to 3 years in men and 4 years in women.[6] This long PK tail may contribute to the selection of drug-resistant variants in the setting of incident infection. In the HPTN 083 trial of CAB-LA as PrEP in cisgender men and transgender women, 10 of 32 people who acquired HIV after exposure to CAB-LA were found to harbor major INSTI resistance mutations.[7] This is the basis for the Panel's recommendation to obtain INSTI genotypic drug resistance testing in people with prior CAB-LA exposure and not to initiate INSTIs before these results are available and show INSTI

sensitivity. If therapy is initiated before INSTI sensitivity is confirmed, the Panel recommends initiating a boosted DRV regimen with TAF/FTC or TDF/FTC while awaiting INSTI genotype results; once INSTI sensitivity is confirmed by genotypic resistance testing, a switch to an INSTI-based regimen can occur **(AIII).**

- For people with no history of using CAB-LA for PrEP and who acquire HIV despite INSTI-based PEP use, an INSTI genotype should be obtained prior to beginning an INSTI-based regimen. However, because selection of INSTI-resistant virus is likely to be uncommon in this setting, an INSTI-based regimen could be started prior to the return of genotype results **(CIII).** This recommendation is based largely on theoretical concerns that INSTI resistance could occur in the setting of INSTI-based PEP failure, but it is likely to be uncommon. In addition, transmitted INSTI resistance remains low in the United States. For these reasons, the Panel supports using INSTI-based regimens in this setting.

General Considerations for Persons of Childbearing Potential Initiating Antiretroviral Therapy

- A pregnancy test should be performed before initiating ART.
- Clinicians should discuss intentions regarding pregnancy with all persons of childbearing potential.
- People with HIV should attain maximum viral suppression before attempting conception in order to protect their own health, prevent sexual HIV transmission to partners without HIV, and minimize the risk of perinatal HIV transmission to the infant.
- For individuals who are trying to conceive, the Panel recommends initiating a regimen designated as a *Preferred* regimen during pregnancy, as detailed in the Perinatal Guidelines.

General Considerations for INSTI-, PI-, or NNRTI-Based Regimens

Except when HIV is acquired after exposure to CAB-LA as PrEP and results from INSTI genotypic resistance testing are not available, INSTIs (specifically BIC and DTG) are recommended for initial therapy in most people because of their demonstrated efficacy, high barrier to resistance, tolerability, low potential for drug–drug interactions, convenience, and better adverse effects profile compared with NNRTIs and boosted PIs (see Tables 7 and 9).

INSTI-Based Regimens

The Panel's *Recommended Initial Regimens for Most People With HIV*, as listed in Table 6a, include one of two INSTIs: BIC coformulated with TAF/FTC **(AI);** or DTG plus TAF or TDF plus FTC or 3TC **(AI);** or coformulated DTG/3TC **(AI)** for people who have not had exposure to CAB-LA as PrEP. In those with prior exposure to CAB-LA as PrEP, these regimens should not be initiated unless a recent genotype test result showing no INSTI resistance mutations is available. If an INSTI-based regimen is initiated and viral suppression is not achieved in 8 to 12 weeks, genotypic resistance testing should be repeated, including for INSTIs.

For most people, these INSTI-containing regimens will be highly effective and have relatively infrequent treatment-limiting adverse effects and few drug interactions. In several head-to-head comparisons between boosted PI- and INSTI-containing regimens, the INSTI-based regimens were better tolerated and caused fewer treatment discontinuations.[8-10]

The Panel recommends a two-drug regimen of DTG/3TC for initial therapy if certain criteria are met. Data from two randomized trials showed that, in terms of virologic efficacy, DTG plus 3TC was non-inferior to a three-drug regimen of DTG plus TDF/FTC. No treatment-emergent resistance was seen in either the two-drug or the three-drug group.[11] Based on these data, DTG/3TC is not currently recommended for rapid ARV initiation as initial therapy before the availability of HBV serology, HIV RNA level, and an HIV genotypic test demonstrating sensitivity to 3TC.

Among the INSTI-based regimens, BIC- and DTG-containing regimens have a higher barrier to resistance than the first-generation INSTI-based regimens containing EVG or RAL and do not require a PK booster. Transmitted resistance to BIC or DTG is rare. Treatment-emergent resistance has been reported in individuals who failed three-drug DTG-based therapy[12-15] and BIC-based regimens.[16-19] Because of this high barrier to resistance and tolerability, BIC- and DTG-containing regimens may be used in people who have not previously used CAB-LA for PrEP and plan to start ART before resistance testing results are available (e.g., with rapid initiation of ART after diagnosis). BIC-based regimens have been shown to be non-inferior to DTG-based regimens in clinical trials.[20-22]

There are data suggesting greater weight gain after initiating therapy with certain INSTI-based regimens and TAF than with other ARV drugs. The reasons for differences in weight gain are unclear and should not be a reason to withhold an INSTI- or TAF-based regimen.[23-30]

EVG- and RAL-based regimens have the disadvantage of having lower barriers to resistance than DTG- or BIC-containing regimens and therefore are no longer recommended as initial therapy. Additionally, the pill burden with RAL is higher than for other INSTI-based regimens whereas EVG-based regimens have a greater potential for drug interactions because EVG is combined with COBI, a strong cytochrome P3A4 inhibitor (see Table 7).

PI-Based Regimens

In the setting of HIV acquisition following CAB-LA exposure, an RTV- or COBI-boosted DRV regimen containing TAF or TDF plus FTC or 3TC is recommended as initial therapy if a genotypic drug resistance test indicating INSTI sensitivity is not available at the time of ART initiation **(AIII),** if resistance to INSTI is confirmed **(BI),** or in certain clinical situations, such as when INSTIs must be avoided **(BI).** DRV/c/TAF/FTC is available as an STR. Large observational cohorts found an association between some PIs, including DRV/r, and an increased risk of cardiovascular events; however, further study is needed.[31-36] COBI-boosted regimens should not be initiated during pregnancy because of inadequate drug levels. Boosted ATV is no longer recommended as initial therapy due to frequent adverse events (e.g., hyperbilirubinemia) and high rates of drug–drug interactions, including with tenofovir and acid-suppressive therapy.

Boosted ATV is no longer recommended as initial therapy due to frequent adverse events, such as hyperbilirubinemia and higher rates of drug–drug interactions (including with tenofovir and acid-suppressive therapy) compared to boosted DRV.

NNRTI-Based Regimens

NNRTI-based regimens are not recommended for initial therapy in most people with HIV, but selected regimens may be useful in some circumstances. The NNRTI-based regimens that are currently recommended by the Panel to be used in certain clinical scenarios include DOR/TDF/3TC **(BI),** DOR plus TAF/FTC **(BIII),** and RPV/TAF/FTC **(BII).** The emergence of drug resistance at the time of virologic failure has been reported with all NNRTIs, which generally have a lower barrier to resistance than INSTIs or boosted PIs.

DOR is available both as a single-drug tablet to be used with two NRTIs and as part of an STR with TDF/3TC. In randomized trials, DOR was non-inferior to both EFV and DRV/r when either of these drugs was taken in combination with two NRTIs,[37,38] but DOR has not yet been compared against INSTIs. DOR has fewer central nervous system (CNS) side effects than EFV and more favorable lipid effects than both DRV/r and EFV. DOR also has fewer potential drug interactions than EFV or RPV, and unlike RPV, the virologic efficacy of DOR is not compromised in people with high HIV RNA levels and low CD4 counts.

RPV has fewer adverse effects than EFV, and RPV/TAF/FTC is available as one of the smallest tablet sizes among STRs. However, RPV has lower virologic efficacy in people with baseline HIV RNA levels >100,000 copies/mL and CD4 counts <200 cells/mm^3 and is subject to numerous drug–drug interactions.[39] EFV is no longer recommended for initial therapy due to a relatively high rate of CNS-related side effects, reported suicidality, high rates of drug discontinuation, and numerous drug–drug interactions.

Regimens When Abacavir, Tenofovir Alafenamide, and Tenofovir Disoproxil Fumarate Cannot Be Used or Are Not Optimal

In people in whom ABC, TDF, or TAF cannot be used or are not optimal, only DTG/3TC is recommended by the Panel **(AI).** Several other NRTI-sparing/limiting two-drug regimens have been evaluated in clinical trials but are not currently recommended for initial therapy due to insufficient data. For more information on these regimens, see Other Antiretroviral Regimens for Initial Therapy. Two-drug ARV options **should not be used** in pregnancy due to insufficient data, or in those with known pre-existing resistance to any of the ARVs in the combination. Tenofovir-sparing regimens **should not be used** in individuals with HBV coinfection unless a drug with HBV activity (i.e., entecavir) is also used.

Table 7. Antiretroviral Regimen Considerations for Initial Therapy Based on Specific Clinical Scenarios

Updated: September 12, 2024
Reviewed: September 12, 2024

This table guides clinicians in choosing an initial antiretroviral (ARV) regimen according to various patient and regimen characteristics and specific clinical scenarios. ARV drugs/regimens that are listed in Table 6a as *Recommended Initial Regimens for Most People With HIV* and in Table 6b as *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* are included in this table (see Initial Combination Antiretroviral Regimens for People With HIV). When more than one scenario applies to a person with HIV, clinicians should review considerations for each relevant scenario and use their clinical judgment to select the most appropriate regimen. Please see Table 9 for additional information regarding the advantages and disadvantages of particular ARV medications recommended to be used as initiation therapy.

Patient or Regimen Characteristics	Clinical Scenario	Consideration(s)	Rationale/Comments
Pre-ART Characteristics	CD4 count <200 cells/mm^3	**Do not use** RPV-based regimens.	Higher rates of virologic failure have been observed in those with low pre-treatment CD4 counts.
	HIV RNA >100,000 copies/mL (also see next row if HIV RNA >500,000 copies/mL)	**Do not use** RPV-based regimens.	Higher rates of virologic failure have been observed in those with high pre-treatment HIV RNA levels.
	HIV RNA >500,000 copies/mL	**Do Not Use** the Following Regimens: • RPV/TAF/FTC • DTG/3TC	For DTG/3TC, limited data are available in patients with viral loads above this threshold.
	HLA-B*5701 positive or result unknown	**Do not use** ABC-containing regimens.	ABC hypersensitivity is a potentially fatal reaction that is highly associated with the HLA-B*5701 allele.
	Prior exposure to oral TDF/(3TC or FTC) or TAF/3TC PrEP	Use DTG or BIC plus two NRTIs. DTG/3TC could be considered if testing confirms no 3TC resistance mutations.	DTG/3TC should be avoided if resistance testing results are not available, as presence of 3TC resistance mutations may lead to use of DTG monotherapy.

Table 7. Antiretroviral Regimen Considerations for Initial Therapy Based on Specific Clinical Scenarios

Patient or Regimen Characteristics	Clinical Scenario	Consideration(s)	Rationale/Comments
	Prior exposure to CAB-LA for PrEP	INSTI genotype resistance testing should be performed. **If INSTI Resistance Is Present or If ART Needs to Be Started Before Genotype Test Results** • (DRV/r or DRV/c) plus (TAF or TDF)[a] plus (3TC or FTC) **If No INSTI Resistance Is Identified** • BIC/TAF/FTC, *or* • DTG plus (TAF or TDF)[a] plus (3TC or FTC)	Mutations conferring resistance to INSTIs have been seen in association with CAB-LA PrEP. CAB-LA has a very long half-life, and drug exposure may persist at levels suboptimal to prevent infection and may select for INSTI-resistant virus.

	People with **no prior exposure** to CAB-LA for PrEP and ARV regimen should be started rapidly and before HIV drug resistance results are available.	**Avoid** ABC, DTG/3TC, and NNRTI-based regimens.
		
		Use
		• BIC/TAF/FTC, *or*
		• DTG plus (TAF or TDF)[a] plus (3TC or FTC)
		
		In People Who Used INSTI-Based ART for PEP Post-exposure Prophylaxis or Who Are Suspected to Have Acquired HIV From Someone Failing an INSTI-Based Regimen
		• Obtain INSTI genotypic resistance test and start one of the following regimens:
		  ○ BIC/TAF/FTC, *or*
		  ○ DTG plus (TAF or TDF)[a] plus (3TC or FTC)
			Transmitted mutations conferring NNRTI and NRTI resistance are more likely than mutations associated with PI or INSTI resistance.
			
			HLA-B*5701 results may not be available rapidly; thus, ABC is not recommended.
			
			Because of the current low rates of transmitted INSTI resistance in the United States, even when there is suspicion that HIV was acquired from a partner with virologic failure while on an INSTI, an INSTI-based regimen can be started, pending the results of the INSTI genotype.

Table 7. Antiretroviral Regimen Considerations for Initial Therapy Based on Specific Clinical Scenarios

Patient or Regimen Characteristics	Clinical Scenario	Consideration(s)	Rationale/Comments
ART-Specific Characteristics	A one-pill, once-daily regimen is desired.	**STR Options as Initial ART Include the Following:** • BIC/TAF/FTC • DOR/TDF/3TC • DRV/c/TAF/FTC • DTG/ABC/3TC • DTG/3TC • RPV/TAF/FTC	**Do not use** DTG/ABC/3TC if the patient is HLA-B*5701 positive. DTG/3TC **is not recommended** if HIV RNA is >500,000 copies/mL. **Do not use** DTG/ABC/3TC or DTG/3TC in the setting of HBV coinfection without another HBV agent. **Do not use** RPV/TAF/FTC if HIV RNA is >100,000 copies/mL and CD4 count is <200 cells/mm^3.
	Food effects	**Regimens That Can Be Taken Without Regard to Food** • BIC-, DOR-, or DTG-based regimens	Oral bioavailability of these regimens is not significantly affected by food.
		Regimens That Should Be Taken With Food • DRV/r- or DRV/c-based regimens • RPV/TAF/FTC	Food improves absorption of these regimens. RPV-containing regimens should be taken with ≥390 calories of food.
Presence of Other Conditions	Chronic kidney disease (defined as CrCl <60 mL/min)	In general, **avoid TDF.** For patients with progressively declining renal function, consider avoiding all TFV-containing (TAF or TDF) regimens. Refer to Appendix B, Table 12 for specific ARV drug dosing recommendations in patients with renal impairment.	TDF has been associated with proximal renal tubulopathy. Higher rates of renal dysfunction have been reported in patients using TDF in conjunction with RTV-containing regimens. TAF has less impact on renal dysfunction than TDF. Avoid the use of TDF- or TAF-sparing regimens in the setting of HBV coinfection or unknown HBV status unless also receiving a fully active HBV regimen (see Hepatitis B Virus/HIV Coinfection).
	Liver disease with cirrhosis	Some ARVs are contraindicated or may require dosage modification in patients with Child-Pugh class B or C disease.	Refer to Appendix B, Table 12 for specific dosing recommendations. Patients with cirrhosis should be carefully evaluated by an expert in advanced liver disease.

Table 7. Antiretroviral Regimen Considerations for Initial Therapy Based on Specific Clinical Scenarios

Patient or Regimen Characteristics	Clinical Scenario	Consideration(s)	Rationale/Comments
	Concern for weight gain	For many people with HIV, gaining weight after starting ART is part of a "return to health." However, some ARV regimens are associated with greater weight increase than others.	Reasons for differences in weight gain among ART regimens are unknown. **Note:** Weight gain should not be a reason to avoid taking an INSTI-based regimen.
	Osteoporosis	**Avoid TDF.**[a]	TDF is associated with decreases in BMD, along with renal tubulopathy, urine phosphate wasting, and resultant osteomalacia. TAF[a] and ABC are associated with smaller declines in BMD than TDF.
	Psychiatric illnesses	**Consider avoiding** RPV-based regimens. Patients on INSTI-based regimens who have preexisting psychiatric conditions should be closely monitored. Some ARVs are contraindicated, and some psychiatric medications need dose adjustments when coadministered with certain ARVs.	RPV can exacerbate psychiatric symptoms and may be associated with suicidality. Some INSTIs have been associated with adverse neuropsychiatric effects in some retrospective cohort studies and case series. See the drug–drug interaction tables (Tables 24a, 24b, 24d, and 24g) for dosing recommendations when drugs used for psychiatric illnesses are used with certain ARVs.
	Cardiac QTc interval prolongation	Consider avoiding RPV-based regimens if the patient is taking other medications with known risk of Torsades de Pointes or in patients at higher risk of Torsades de Pointes.	High RPV concentrations may cause QTc prolongation.
	High risk for CV events	Consider avoiding ABC-based regimens. Refer to Hyperlipidemia, below, for regimens associated with more favorable lipid profiles.	An increased risk of CV events with ABC has been observed in some, but not all, studies. Certain ARV regimens are associated with more favorable lipid profiles than other regimens.

Table 7. Antiretroviral Regimen Considerations for Initial Therapy Based on Specific Clinical Scenarios

Patient or Regimen Characteristics	Clinical Scenario	Consideration(s)	Rationale/Comments
	Hyperlipidemia	PI/c and PI/r have been associated with hyperlipidemia. BIC, DOR, DTG, and RPV have fewer lipid effects.	TDF has been associated with lower lipid levels than ABC or TAF.
	Patients with history of poor adherence to non-ARV medications or inconsistent engagement in care	Consider using regimens with a boosted PI or BIC or DTG.	These regimens have a high genetic barrier to resistance.
	Pregnancy	Refer to the Perinatal Guidelines for further guidance on ARV use during pregnancy.	
Presence of Coinfections	HBV infection	**Avoid regimens** that do not contain NRTIs. Use (TDF or TAF) with (FTC or 3TC) as part of the ARV regimen. **If TDF and TAF Are Contraindicated** • For treatment of HBV, use FTC or 3TC with entecavir and a suppressive ARV regimen (see Hepatitis B Virus/HIV Coinfection).	TDF, TAF, FTC, and 3TC are active against both HIV and HBV. 3TC- or FTC-associated HBV resistance mutations can emerge when these drugs are used without another drug that is active against HBV.
	HCV treatment required	Refer to recommendations in Hepatitis C Virus/HIV Coinfection, with special attention to potential interactions between ARV drugs and HCV drugs.	
	Concomitant use with rifamycin antibiotics (e.g., rifabutin, rifampin, and rifapentine)	Recommended regimens may require dose adjustment. See the drug–drug interaction tables (Tables 24a, 24b, 24c, 24d, 24e, 24f, 24g, 25a, and 25b) and Tuberculosis/HIV Coinfection for information on ARV use with rifamycin antibiotics.	Rifamycin antibiotics are inducers of CYP3A4 and UGT1A1 enzymes, causing significant decreases in concentrations of PIs, INSTIs, and RPV.

[a] TAF and TDF are two U.S. Food and Drug Administration–approved forms of TFV. TAF has fewer bone and kidney toxicities than TDF, whereas TDF is associated with lower lipid levels. Safety, cost, and access are among the factors to consider when choosing between these drugs.

Key: 3TC = lamivudine; ABC = abacavir; ART = antiretroviral therapy; ARV = antiretroviral; BIC = bictegravir; BMD = bone mineral density; CAB-LA = long-acting cabotegravir; CD4 = CD4 T lymphocyte; CrCl = creatinine clearance; CV = cardiovascular; CYP = cytochrome P; DOR = doravirine; DRV/c = darunavir/cobicistat; DRV/r = darunavir/ritonavir; DTG = dolutegravir; FTC = emtricitabine; HBV = hepatitis B virus; HCV = hepatitis C virus; HLA = human leukocyte antigen;

Table 7. Antiretroviral Regimen Considerations for Initial Therapy Based on Specific Clinical Scenarios

INSTI = integrase strand transfer inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; PI/c = cobicistat-boosted protease inhibitor; PI/r = ritonavir-boosted protease inhibitor; PEP = post-exposure prophylaxis; PrEP = pre-exposure prophylaxis; QTc = QT corrected for heart rate; RPV = rilpivirine; RTV = ritonavir; STR = single-tablet regimen; TAF = tenofovir alafenamide; TDF = tenofovir disoproxil fumarate; TFV = tenofovir; UGT = uridine diphosphate glucuronosyltransferase

Nucleoside Reverse Transcriptase Inhibitor Options as Part of Initial Therapy

Updated: September 12, 2024
Reviewed: September 12, 2024

The following sections provide detailed information on antiretroviral (ARV) drugs that the Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) recommends for initial therapy for most people with HIV and for initial therapy in certain clinical scenarios (see Tables 6a and 6b in the Initial Combination Antiretroviral Regimens for People With HIV section), including ARV drug characteristics, adverse effects, clinical trial results, and Panel recommendations on their use.

Table 8a. Characteristics of Nucleoside Reverse Transcriptase Inhibitor Options for People Without Prior Antiretroviral Treatment

Note: Listed in order of the Panel's recommendations in Tables 6a and 6b.

Characteristics	TAF/FTC	TDF/FTC	TDF/3TC	3TC	ABC/3TC
Dosing Frequency	Once daily	Once daily	Once daily	Once daily	Once daily
Available Coformulations for People Without Prior ARV Treatment	• TAF 25 mg/FTC • BIC/TAF 25 mg/FTC • DRV/c/TAF 10 mg/FTC • RPV/TAF 25 mg/FTC	• TDF/FTC	• TDF/3TC • DOR/TDF/3TC	• DTG/3TC	• ABC/3TC • DTG/ABC/3TC
Adverse Effects	**TAF** • Renal insufficiency, proximal renal tubulopathy (less frequent than with TDF) • Decrease in BMD (less than with TDF)	**TDF** • Renal insufficiency, proximal renal tubulopathy • Decrease in BMD • Renal and bone toxicity are exacerbated by pharmacologic boosters.	**TDF** • Renal insufficiency, proximal renal tubulopathy • Decrease in BMD • Renal and bone toxicity are exacerbated by pharmacologic boosters.	**3TC** • No notable adverse effects	**ABC** • HSR to ABC is associated with the presence of HLA-B*5701 allele.[b] • Increase in CV events is associated with ABC use in some but not all cohort studies.
Other Considerations	• Also used for HBV treatment. Discontinuation may precipitate HBV flare. • See Appendix B, Table 11 for dosing recommendations in people with renal insufficiency.			• 3TC or ABC/3TC **should not be used** as treatment for HBV without adding another HBV-active drug.	

Table 8a. Characteristics of Nucleoside Reverse Transcriptase Inhibitor Options for People Without Prior Antiretroviral Treatment

Characteristics	TAF/FTC	TDF/FTC	TDF/3TC	3TC	ABC/3TC
	• Some studies reported less weight gain and lower LDL, HDL, TC, and triglycerides with TDF than with TAF.				

[a] 3TC is recommended for use with DTG in some people as initial ART. See Table 6a and the discussion below for more information. Otherwise, dual-NRTI backbones are recommended.

[b] Perform HLA-B*5701 testing before initiating ABC; if result is positive, do not start ABC and add ABC to patient's allergy list. See the HLA-B*5701 Screening section for more information.

Key: 3TC = lamivudine; ABC = abacavir; ART = antiretroviral therapy; ARV = antiretroviral; BIC = bictegravir; BMD = bone mineral density; CV = cardiovascular; DOR = doravirine; DRV = darunavir; DRV/c = darunavir/cobicistat; DTG = dolutegravir; FTC = emtricitabine; HBV = hepatitis B virus; HDL = high-density lipoprotein; HLA = human leukocyte antigen; HSR = hypersensitivity reaction; LDL = low-density lipoprotein; NRTI = nucleoside reverse transcriptase inhibitor; RPV = rilpivirine; TAF = tenofovir alafenamide; TC = total cholesterol; TDF = tenofovir disoproxil fumarate

Summary

The U.S. Food and Drug Administration (FDA)–approved nucleos(t)ide reverse transcriptase inhibitors (NRTIs) include zidovudine (ZDV), stavudine (d4T), didanosine (ddI), abacavir (ABC), tenofovir disoproxil fumarate (TDF), tenofovir alafenamide (TAF), lamivudine (3TC), and emtricitabine (FTC). Older NRTIs (ZDV, d4T, ddI) are no longer recommended for use in clinical practice in the United States because of high rates of serious toxicities. All of these drugs can cause mitochondrial toxicity that may lead to myopathy, hepatic steatosis, lactic acidosis, or lipoatrophy; ZDV may cause bone marrow suppression, whereas peripheral neuropathy is commonly seen with ddI or d4T use. The incidence of these complications is substantially lower with 3TC, FTC, ABC, TDF, and TAF than with older NRTIs.[1,2]

TAF/FTC, TDF/3TC, and TDF/FTC are NRTI combinations that are part of *Recommended Initial Regimens for Most People With HIV* (see Table 6a in Initial Combination Antiretroviral Regimens for People With HIV). In addition, 3TC may be used as a single NRTI with dolutegravir (DTG), except in individuals with HIV RNA >500,000 copies/mL or in whom antiretroviral therapy (ART) is to be started before the results of HIV RNA and HIV genotypic resistance tests are available. If used in those with hepatitis B virus (HBV) coinfection, another HBV-active drug should be added. Tables 6a and 6b in the Initial Combination Antiretroviral Regimens for People With HIV section provide recommendations and ratings for the individual regimens. These recommendations are based on the virologic potency and durability, short- and long-term toxicity, and dosing convenience of these drugs. TDF has been associated with bone and kidney toxicities, especially when used with a pharmacologic booster.[3] TAF is less likely to cause kidney and bone toxicities than TDF, whereas TDF is associated with lower lipid levels than TAF. Like TDF, TAF is a recommended option in pregnancy because of reassuring data from a multinational trial in pregnant women with HIV[4] and data from the Antiretroviral Pregnancy Registry that show no evidence of teratogenicity. Please refer to the Perinatal Guidelines for more information on the use of ARVs during pregnancy.

ABC/3TC, including DTG/ABC/3TC, is no longer recommended for initial therapy in most people with HIV but may be considered in circumstances in which tenofovir (TFV)-containing regimens or DTG/3TC cannot be used. Before starting any regimen with ABC, screening for the HLA-B*5701 allele is necessary because there is a strong link with a potentially life-threatening hypersensitivity reaction in people who test positive for this allele. In addition, some data continue to support an association between ABC and an increased risk for serious cardiovascular events.[5,6]

Along with safety and efficacy, cost and access are among the factors to consider when choosing among available options. ABC/3TC, TDF/3TC, TDF/FTC, and 3TC are available as generic formulations.

Clinical Trials Comparing Nucleoside Reverse Transcriptase Inhibitors

Tenofovir Alafenamide Compared to Tenofovir Disoproxil Fumarate

Safety and HIV Efficacy

Two randomized double-blind Phase 3 clinical trials compared the safety and efficacy of elvitegravir/cobicistat (EVG/c)/TDF/FTC and EVG/c/TAF/FTC in 1,733 ART-naive adults with estimated glomerular filtration rate (eGFR) ≥50 mL/min.

- TAF/FTC was virologically non-inferior to TDF/FTC at Week 48 (92% vs. 90% of participants had plasma HIV RNA <50 copies/mL, respectively),[7] but TAF/FTC was superior to TDF/FTC at Week 144 (84.2% vs. 80% of participants with plasma HIV RNA <50 copies/mL), largely driven by a higher rate of treatment discontinuation in the TDF arm.[8]
- Participants in the TAF arm had significantly smaller reductions in bone mineral density (BMD) at the spine and hip than those in the TDF arm through 144 weeks.[8] Those receiving TAF also had less pronounced changes in eGFR and renal biomarkers and fewer clinically significant renal events through Week 96.[9] Conversely, levels of fasting low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglycerides increased more in the TAF group than in the TDF group at Week 96, with no change in total cholesterol to HDL ratio.[10]

Two randomized studies have compared the safety and efficacy of TAF/FTC to TDF/FTC, with each combination administered with boosted darunavir (DRV) in ART-naive participants:

- A Phase 2 study of coformulated darunavir/cobicistat (DRV/c) plus TAF/FTC versus DRV/c plus TDF/FTC in treatment-naive participants demonstrated similar virologic suppression rates in both arms (75% vs. 74%).[11] In the TAF arm, fewer participants developed proteinuria. Changes in BMD were also less pronounced among participants in the TAF group.
- The AMBER study randomized ART-naive participants to receive either coformulated DRV/c/TAF/FTC or DRV/c plus TDF/FTC. At Week 48, HIV RNA <50 copies/mL was achieved in 91% of the DRV/c/TAF/FTC participants versus 88% of the DRV/c plus TDF/FTC participants. Participants in the TAF/FTC arm showed less decline in hip and spine BMD and eGFR than participants in the TDF/FTC arm.[12]

One analysis evaluated data from 14 randomized trials that compared the virologic efficacy, frequency of renal events, and bone density changes associated with the use of TDF and TAF when either drug was taken with or without pharmacokinetic (PK) boosters (ritonavir [RTV] or cobicistat [COBI]). No significant differences appeared between unboosted regimens with TDF and TAF in terms of virologic efficacy. When used with PK boosters, TAF resulted in a clinically small but statistically significant greater virologic efficacy than TDF (94% vs. 92%; $P = 0.0004$). No difference was seen in bone-related toxicities and clinical or laboratory adverse events between TAF and TDF, regardless of whether used with a boosting agent. The rate of discontinuation due to renal adverse events was higher for those on boosted regimens containing TDF compared with those containing TAF, with a small but statistically significant difference ($P = 0.03$).[13]

Although conducted in people without HIV for pre-exposure prophylaxis (PrEP), the DISCOVER trial, with 5,387 treated participants, was the largest trial to directly compare the adverse effects of TAF/FTC with those of TDF/FTC.[14] The following findings were observed after 48 weeks of follow-up:

- Adverse events did not significantly vary between the two groups, including Grade 3 and 4 events, serious adverse events, discontinuations due to adverse events, and overall.
- Changes in renal biomarkers and bone density significantly favored the TAF arm over TDF. One case of proximal tubular disease occurred in the TDF arm.
- LDL, HDL, and total cholesterol were significantly lower in the TDF arm than in the TAF arm, with no significant difference in the total cholesterol to HDL ratio.
- Participants in the TAF arm gained an average of 1.1 kg whereas those in the TDF arm had a mean loss of 0.1 kg.

Efficacy in People With HIV and HBV

To assess the ability of TAF to maintain HIV and HBV suppression, 72 people with HIV/HBV coinfection who had HIV RNA <50 copies/mL and HBV DNA <9 $\log_{10}$ IU/mL on a stable regimen were switched to EVG/c/TAF/FTC.[15] In this study, 96% of participants were on a TDF/FTC-containing regimen before the switch. Key results of the study showed the following:

- Among those who switched to EVG/c/TAF/FTC, HIV suppression was maintained in 91.7% of participants at Week 48, and 91.7% of participants had HBV DNA <29 IU/mL.
- Markers of proximal tubular proteinuria and biomarkers of bone turnover decreased in those who switched to EVG/c/TAF/FTC.[15]

Lamivudine Compared to Tenofovir Disoproxil Fumarate/Emtricitabine

A single-tablet regimen (STR) of DTG/3TC has now been approved as an initial ARV regimen. Please refer to the Integrase Strand Transfer Inhibitor-Based Regimens section for a full discussion.

GEMINI 1 and GEMINI 2 were identically designed randomized, double-blind clinical trials that found DTG plus 3TC non-inferior to DTG plus TDF/FTC in ART-naive adults with HIV RNA <500,000 copies/mL and eGFR ≥50 mL/min.[16,17]

Abacavir/Lamivudine Compared to Tenofovir Disoproxil Fumarate/Emtricitabine

Several randomized controlled trials in ART-naive participants compared ABC/3TC to TDF/FTC, each administered in combination with a third ARV drug[18-20] (see the Integrase Strand Transfer Inhibitor-Based Regimen section).[21]

- The ACTG 5202 study, a randomized controlled trial in >1,800 participants, evaluated the efficacy and safety of ABC/3TC and TDF/FTC when each combination was used with either efavirenz (EFV) or atazanavir/ritonavir (ATV/r). In people with baseline HIV RNA ≥100,000 copies/mL, the time to virologic failure was significantly shorter with ABC/3TC than with TDF/FTC, regardless of whether the third active drug was EFV or ATV/r. In addition, time to first adverse event was also shorter in the ABC/3TC groups.[18]

- In the HEAT study, 688 participants received ABC/3TC or TDF/FTC with once-daily lopinavir/ritonavir. Virologic efficacy was similar in the two study arms, including in a subgroup of participants with HIV RNA ≥100,000 copies/mL.[20]
- The ASSERT study compared open-label ABC/3TC with TDF/FTC in 385 HLA-B*5701-negative people with HIV who were ART-naive; all participants also received EFV. The primary study endpoint was renal safety of the regimens. Although eGFR did not differ significantly between the regimens, biomarkers associated with tubular dysfunction (retinol-binding protein and beta-2 microglobulin) increased significantly, to a greater extent in the TDF/FTC arm than the ABC/3TC arm (+50% vs. +24% and no change vs. −47%, respectively). At Week 48, the proportion of participants with HIV RNA <50 copies/mL was lower among ABC/3TC-treated participants (59%) than among TDF/FTC-treated participants (71%).[19]

Nucleoside Reverse Transcriptase Inhibitor Options for Initial Therapy

Tenofovir Alafenamide/Emtricitabine

TAF, an oral prodrug of TFV, is hydrolyzed to TFV in plasma and then converted to TFV-diphosphate (TFV-DP) intracellularly, where it exerts its activity as an NRTI. Unlike TDF, which readily converts to TFV in plasma after oral absorption, TAF remains relatively stable in plasma, resulting in lower plasma and higher intracellular TFV concentrations. After oral administration, TAF 25 mg resulted in plasma TFV concentrations that were 90% lower than those seen with TDF 300 mg. Intracellular TFV-DP concentrations, however, were substantially higher with TAF.

Adverse Effects

Renal and Bone Effects

- In randomized controlled trials that compared TAF and TDF in people without prior ARV treatment experience or those with virologic suppression, TAF had more favorable effects on renal biomarkers and bone density than TDF.

Lipid Effects

- In randomized controlled trials in ART-naive participants, in switch studies, and in a large study of PrEP, levels of LDL and HDL cholesterol and triglycerides were lower in participants who received TDF than those who received TAF. However, total cholesterol to HDL ratios did not differ between participants receiving TAF and those receiving TDF. The clinical significance of this finding is not clear.[7,22,23]

Weight Gain

- Initiation of TAF in previously untreated individuals and in people without HIV has been associated with greater weight gain than initiation of TDF[24-26] and ABC.[25] In ADVANCE, an open-label trial conducted in South Africa that compared EFV/TDF/FTC versus DTG plus TDF/FTC versus DTG plus TAF/FTC in ART-naive participants, a greater increase in body weight was reported with initiation of TAF than with TDF.[24] This area is under intense investigation, and the reason for the difference in weight gain between regimens is still uncertain. It is also unclear whether change of ART results in reversal of weight gain.

Other Factors and Considerations

- TAF/FTC is available in fixed-dose combinations (FDCs) with bictegravir (BIC), DRV/c, EVG/c, and rilpivirine (RPV), allowing the regimens to be administered as a single pill taken once daily.
- TAF-containing regimens are approved for people with eGFR ≥30 mL/min. Renal function, urine glucose, and urine protein should be assessed before initiating treatment with TAF, and these assessments should be repeated periodically during treatment. EVG/c/FTC/TAF was safe and effective in a single-arm switch study that was conducted in people on hemodialysis.[27] Based on the results from this study, TAF/FTC can be used without dosage adjustment in people with HIV who require hemodialysis.
- Both TAF and FTC are active against HBV. In people with HIV/HBV coinfection, TAF/FTC may be used as the NRTI pair in an ARV regimen because these drugs have activity against both viruses (see Hepatitis B Virus/HIV Coinfection).[15]
- TAF is recommended as a preferred drug in pregnancy because of reassuring data from a multinational trial of pregnant women and data from the Antiretroviral Pregnancy Registry that show no evidence of teratogenicity.[4]

The Panel's Recommendation

- On the basis of clinical trial safety and efficacy data, and its availability as a component of various FDCs, the Panel considers TAF/FTC a recommended NRTI combination for initial ART in most people with HIV when prescribed with BIC or DTG **(AI),** and as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (see Table 6b in the Initial Combination Antiretroviral Regimens in People With HIV section) when given with RPV, DOR, RTV-boosted DRV (DRV/r), or DRV/c.

Tenofovir Disoproxil Fumarate/Emtricitabine and Tenofovir Disoproxil Fumarate/Lamivudine

TDF, with either 3TC or FTC, has been studied in combination with DOR, EFV, RPV, several boosted protease inhibitors (PIs), EVG/c, RAL, and DTG in randomized clinical trials.[28-37]

Adverse Effects

Renal Effects

- New onset or worsening renal impairment has been associated with TDF use.[38,39] Risk factors may include advanced HIV disease, longer treatment history, low body weight (especially in women),[40] and preexisting renal impairment.[41] Adverse effects on renal biomarkers, such as proteinuria, especially tubular proteinuria, were more frequent with TDF than with TAF.[42]
- Adverse renal outcomes are more likely when TDF/FTC is coadministered with PK boosters (RTV or COBI). A meta-analysis of randomized trials found that discontinuation due to renal adverse events is more frequent in people who take TDF/FTC than TAF/FTC with PK boosters.[13]

Bone Effects

- Although initiation of all NRTI-containing regimens has been associated with a decrease in BMD, the loss of BMD is greater with TDF-containing regimens. For example, in two randomized studies that compared TDF/FTC with ABC/3TC, participants who received TDF/FTC experienced a significantly greater decline in BMD than ABC/3TC-treated participants.[43,44] BMD generally stabilizes following an early decline after ART initiation. Loss of BMD is also greater with TDF than with TAF.
- Cases of osteomalacia associated with proximal renal tubulopathy have been reported with the use of TDF.[45] Adverse bone outcomes have been found to be more likely when TDF/FTC is coadministered with PK boosters. However, a meta-analysis found no difference in bone-related toxicities between TAF and TDF, regardless of boosting.[13]

Other Factors and Considerations

- TDF/3TC is available as a coformulated generic drug.
- TDF/3TC is available in an FDC with DOR 100 mg.
- Renal function, urine glucose, and urine protein should be assessed before initiating treatment with TDF and periodically during treatment (see Laboratory Testing for Initial Assessment and Monitoring of People With HIV Receiving Antiretroviral Therapy). In people who have preexisting renal insufficiency (CrCl <60 mL/min),[46] use of TDF generally should be avoided. If TDF is used, a dose adjustment is required if the person's CrCl falls below 50 mL/min (see Appendix B, Table 12 for dose recommendations).
- TDF, FTC, and 3TC are active against HBV. In people with HBV/HIV coinfection, TDF/FTC or TDF/3TC may be used as the NRTI pair of the ARV regimen because these drugs have activity against both viruses (see Hepatitis B Virus/HIV Coinfection).

The Panel's Recommendations

- On the basis of clinical trial safety and efficacy data, long-term experience in clinical practice, and the combination's availability as a component of FDC drugs, the Panel considers TDF/FTC and TDF/3TC as recommended NRTI combinations for initial ART in most people with HIV when combined with DTG, and as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (Table 6b in the Initial Combination Antiretroviral Regimens for People With HIV section).
- TDF should be used with caution or avoided in people with renal disease and/or osteopenia/osteoporosis.
- When TDF is used, especially in conjunction with a PK booster, clinicians should monitor for renal and bone safety during therapy. Boosters should be avoided when possible in people taking TDF.

Emtricitabine Versus Lamivudine

FTC and 3TC generally are used interchangeably in combination with other ARVs, based on the results of randomized clinical trials and a meta-analysis of 12 trials that compared virologic efficacy and safety.[47,48] In the ATHENA cohort, virologic efficacy of TDF/FTC was compared to TDF/3TC

when either was combined with a non-nucleoside reverse transcriptase inhibitor (NNRTI)—EFV or nevirapine[49]—or with a boosted PI.[50] No difference was reported in the rates of virologic failure in people who were taking TDF/FTC and people who were taking TDF/3TC when these drug combinations were used with a boosted PI. TDF/3TC was associated with higher rates of virologic failure than TDF/FTC in the NNRTI analysis; however, participants in the NNRTI cohort who were taking 3TC generally had higher viral loads and lower CD4 T lymphocyte cell counts and were more likely to be using injection drugs at the start of the study than those taking FTC.

Adverse Effects

- Both FTC and 3TC have been well tolerated with no significant treatment-limiting adverse effects.
- In early clinical trials, FTC was infrequently associated with mild hyperpigmentation of palms and soles.

Other Factors and Considerations

- 3TC is now generic in the United States and is coformulated with other drugs, such as DOR/TDF/3TC and DTG/ABC/3TC.
- Both 3TC and FTC have activity against hepatitis B but are insufficient for HBV treatment when used alone due to the emergence of resistance. Discontinuation of FTC or 3TC can precipitate a flare in HBV if no other HBV-active drugs are in the regimen.
- See Appendix B, Table 12 for dosing recommendations in people with renal impairment.
- No significant drug interactions have been identified with FTC. Sorbitol-containing drugs can decrease 3TC concentration, and coadministration should be avoided.
- Both FTC and 3TC select for the M184V mutation when viral suppression is suboptimal.

The Panel's Recommendation

- FTC and 3TC are considered interchangeable in combination with other ARV drugs.

Lamivudine as a Single Nucleoside Reverse Transcriptase Inhibitor

Based on the GEMINI-1 and GEMINI-2 studies[17] that found DTG plus 3TC non-inferior to DTG plus TDF/FTC in ART-naive people with HIV RNA <500,000 copies/mL, 3TC may be used as a single NRTI with DTG (see Drug Interactions Between Integrase Strand Transfer Inhibitors and Other Drugs for more information).

Other Factors and Considerations

- 3TC with DTG is available as a STR.
- 3TC is active against HBV but is insufficient for HBV treatment when used alone due to the emergence of resistance. Discontinuation of 3TC can precipitate a flare in HBV if no other HBV-active drugs are in the regimen.
- 3TC is available in two brand-name formulations (one for HIV and the other for HBV), but the doses are different. The dose for HIV treatment is 3TC 300 mg daily.

- See Appendix B, Table 12 for dosing recommendations in people with renal impairment.
- Sorbitol-containing drugs can decrease 3TC concentration, and coadministration should be avoided.

The Panel's Recommendations

The Panel recommends the use of DTG/3TC **(AI)** as a *Recommended Initial Regimen for Most People With HIV,* with four exceptions. DTG/3TC **is not recommended** for:

- Individuals with HIV RNA >500,000 copies/mL.
- Individuals with HBV coinfection unless receiving another HBV-active drug.
- Individuals who have received long-acting injectable cabotegravir as PrEP and do not have integrase strand transfer inhibitor (INSTI) genotype resistance testing results available demonstrating INSTI sensitivity.
- Individuals starting ART before the results of genotypic resistance testing for reverse transcriptase are available.

Abacavir/Lamivudine

ABC plus 3TC has been studied in combination with EFV, several PIs, and DTG in people who are ART-naive.[21,51-53]

Adverse Effects

Hypersensitivity Reactions

- Clinically suspected hypersensitivity reactions (HSRs) were observed in 5% to 8% of individuals who started ABC in clinical trials conducted before the use of HLA-B*5701 testing. The risk of HSRs is highly associated with the presence of the HLA-B*5701 allele; approximately 50% of people who are HLA-B*5701-positive and are given ABC will have a related HSR.[54,55] HLA-B*5701 testing should be done if the use of ABC is being considered. A person who tests positive for HLA-B*5701 should not be given ABC, and ABC hypersensitivity should be noted on the person's allergy list. People who are HLA-B*5701 negative are far less likely to experience an HSR, but they should be counseled about the symptoms of the reaction. People who discontinue ABC because of a suspected HSR **should never be rechallenged,** regardless of their HLA-B*5701 status.

Cardiovascular Risk

- An association between ABC use and myocardial infarction (MI) was first reported in the Data Collection on Adverse Events of Anti-HIV Drugs (D:A:D) study. This large, multinational, observational study group found that recent (i.e., within 6 months) or current use of ABC was associated with an increased risk of an MI, particularly in participants with preexisting cardiac risk factors.[5,6]
- Since the D:A:D report, several studies have evaluated the relationship between ABC therapy and cardiovascular events. Some studies have found an association.[56-63] Others, including an FDA meta-analysis of 26 randomized clinical trials that evaluated ABC, have not.[64-68]

- No consensus has been reached on the association between ABC use and MI risk or the mechanism for such an association.

Other Factors and Considerations

- ABC/3TC is available as a coformulated tablet and as a coformulated STR with DTG.
- ABC and 3TC are available separately and as a coformulated tablet in generic tablet formulations.
- ABC does not cause renal dysfunction and can be used instead of TDF in people with underlying renal dysfunction or in those who are at high risk for renal effects. No dose adjustment is required in people with renal dysfunction.

The Panel's Recommendations

- ABC should be prescribed only for people who are HLA-B*5701 negative.
- Due to the need for HLA-B*5701 testing before use, ongoing concerns about increased risk of cardiovascular events seen in association with ABC (observed in some but not all studies), and the availability of other effective and well-tolerated options, the Panel no longer recommends DTG/ABC/3TC for most individuals initiating ART and now classifies DTG/ABC/3TC as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (see Table 6b in the Initial Combination Antiretroviral Regimens in People With HIV section) **(BI)** (see Characteristics of Integrase Strand Transfer Inhibitors for discussion regarding the clinical efficacy data for ABC/3TC plus DTG).
- ABC/3TC use with DRV/r or DRV/c is also recommended as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (Table 6b in the Initial Combination Antiretroviral Regimens in People With HIV section) **(BII).**
- ABC should be used with caution or avoided in people with cardiovascular disease or known high cardiovascular risk.

Integrase Strand Transfer Inhibitor–Based Regimens as Initial Antiretroviral Therapy

Updated: September 12, 2024
Reviewed: September 12, 2024

Table 8b. Characteristics of Integrase Strand Transfer Inhibitors That Are Recommended as Part of Initial Antiretroviral Therapy

	BIC	DTG
Dosing Frequency	Once daily	**Once Daily** • As initial ART or in people with no INSTI-resistance mutations **Twice Daily** • If used with certain CYP3A4 and UGT1A1 inducers; *or* • In people with certain INSTI drug resistance mutations
STR Available as Initial ART	BIC/TAF/FTC	• DTG/ABC/3TC • DTG/3TC
Available as a Single Drug Tablet	No	Yes
Virologic Efficacy Against EVG- or RAL-Resistant HIV	*In vitro* data indicate activity, but clinical trial data are not available.	Yes, for some isolates; effective with DTG 50 mg twice-daily dose
Adverse Reactions	• ↑ CPK 4% • CNS side effects were rarely reported in clinical trials. • Diarrhea, nausea, and headache may occur in some cases.	• ↑ CPK, myositis • CNS side effects such as insomnia and headache have been reported; depression and suicidality are rare, occurring primarily in people with preexisting conditions. • Hypersensitivity, hepatotoxicity
CYP3A4 Drug–Drug Interactions	CYP3A4 substrate	CYP3A4 substrate (minor)
Chelation With Polyvalent Cation Supplements and Antacids	Oral absorption may be reduced by polyvalent cations. See Table 24d for recommendations regarding dosing separations and these drugs.	
Other Key Potential Drug Interaction Mechanisms	P-gp substrate, UGT1A1 substrate, OCT2 and MATE1 inhibitor	P-gp substrate, UGT1A1 substrate
Other Factors	Both BIC and DTG decrease tubular secretion of creatinine without affecting glomerular function. This may result in an increase in serum creatinine of approximately 0.1–0.2 mg/dL.	

Key: 3TC = lamivudine; ABC = abacavir; ART = antiretroviral therapy; BIC = bictegravir; CNS = central nervous system; CPK = creatine phosphokinase; CYP = cytochrome P450; DTG = dolutegravir; EVG = elvitegravir; FTC = emtricitabine; INSTI = integrase strand transfer inhibitor; MATE1 = multidrug and toxic compound extrusion 1; OCT2 = organic cation transporter 2; P-gp = p-glycoprotein; RAL = raltegravir; STR = single-tablet regimen; TAF = tenofovir alafenamide; UGT = uridine diphosphate glucuronosyltransferase

Four oral integrase strand transfer inhibitors (INSTIs)—bictegravir (BIC), dolutegravir (DTG), elvitegravir (EVG), and raltegravir (RAL)—are approved for use in people with HIV as their initial ARV treatment. Intramuscular cabotegravir (CAB) is approved for use with rilpivirine (RPV) (with or without an oral CAB + RPV lead-in) as part of a long-acting injectable complete antiretroviral (ARV) regimen to replace a stable oral regimen in people with HIV and viral suppression. The role of this combination is discussed in the Optimizing Antiretroviral Therapy in the Setting of Viral Suppression section. Long-acting injectable cabotegravir (CAB-LA) is also approved for pre-exposure prophylaxis (PrEP). The first-generation INSTIs EVG and RAL have some disadvantages, which include a low barrier to resistance. In addition, because EVG has to be given with cobicistat (COBI), a pharmacokinetic (PK) booster, it has a high potential for drug–drug interactions, whereas RAL-based regimens have a higher pill burden than other INSTI regimens. Because of these disadvantages, elvitegravir/cobicistat (EVG/c) and RAL are no longer recommended by the Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) as initial ART. Because the second-generation INSTIs BIC and DTG have high barriers to resistance, BIC/tenofovir alafenamide (TAF)/emtricitabine (FTC) and DTG plus TAF/FTC or tenofovir disoproxil fumarate (TDF)/FTC are recommended for most people with HIV (see Appendix B, Table 6 for more information on the INSTIs BIC and DTG).

This section of the guidelines will focus on BIC and DTG, the two INSTIs recommended by the Panel as part of the *Recommended Initial Regimens for Most People With HIV* (Table 6a) and *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (Table 6b) (see Tables 6a and 6b and Table 7).

Panel's Recommendations for Integrase Strand Transfer Inhibitor–Based Regimens as Initial Therapy

The Panel recommends one of the following INSTI-based regimens as initial ART for people with HIV who do not have a history of using CAB-LA as PrEP (see Table 6a in Initial Combination Antiretroviral Regimens for People With HIV):

- BIC/TAF/FTC **(AI)**
- DTG plus (TAF or TDF) with (FTC or lamivudine [3TC]) **(AI)**
- DTG/3TC **(AI),** except for those with HIV RNA >500,000 copies/mL, with hepatitis B virus (HBV) coinfection, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available.

INSTI resistance has been reported in people who acquired HIV following exposure to CAB-LA as PrEP.[1] For a person who has had exposure to CAB-LA as PrEP, an INSTI-containing regimen should not be initiated unless an INSTI genotypic resistance test result is available and shows no INSTI-resistance mutations **(AIII).** If treatment is initiated before genotypic test results are available, boosted darunavir (DRV) plus (TAF or TDF) plus (FTC or 3TC) should be used, pending INSTI resistance results **(AIII).** See Table 6a in Initial Combination Antiretroviral Regimens for People With HIV for more details.

Because of the low rates of transmitted INSTI resistance in the United States at present, when there is suspicion that HIV was acquired from a partner with virologic failure while on an INSTI, an INSTI-based regimen can be started pending the results of the INSTI genotype test.

For people who have never used CAB-LA for PrEP and who acquired HIV despite using INSTI-based post-exposure prophylaxis, an INSTI genotype should be obtained prior to beginning an INSTI-based regimen. However, because selection of INSTI-resistant virus is likely to be uncommon in this setting, an INSTI-based regimen could be started prior to the return of genotype results **(CIII).**

The Panel also recommends using DTG/abacavir (ABC)/3TC **(BI)** when concerns about renal or bone-associated adverse events preclude the use of TAF or TDF. However, ABC should only be given to people who are documented to be HLA-B*5701-negative.

Rating of Recommendations: *A = Strong; B = Moderate; C = Weak*

Rating of Evidence: *I = One or more randomized trials with clinical outcomes and/or validated laboratory endpoints; II = One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion*

Adverse Effects

BIC and DTG are generally well tolerated, although there are reports of insomnia in some people. Depression and suicidal ideation, primarily in people with a history of psychiatric illnesses, have been reported rarely in those receiving INSTI-based regimens.[2-5]

Among people with HIV who have not yet received ART, initiation of INSTI-containing regimens has been associated with greater weight increases compared to non-nucleoside reverse transcriptase inhibitor (NNRTI) or boosted protease inhibitor (PI) regimens.[6-11] In randomized trials of ARV-naive individuals, the mean increase in weight from baseline associated with BIC and DTG was similar and greater than with EVG/c or with efavirenz (EFV).[8,12-14] Weight gain was also greater in those initiating TAF than other nucleoside reverse transcriptase inhibitors (NRTIs).[7,8,15] These weight increases appear to disproportionately affect women and Black and Hispanic people,[6-8,16] yet predictors and mechanisms for the weight gain are still unclear. In general, concerns for weight gain should not be a reason to avoid an INSTI- or TAF-based regimen.

Integrase Strand Transfer Inhibitor Use in People of Childbearing Potential

Clinicians should refer to the Perinatal Guidelines for detailed recommendations on ARV regimens in treatment-naive people, including recommendations on the use of INSTI-based regimens during conception and throughout pregnancy.

- Earlier data from a birth outcomes surveillance study in Botswana raised concern about an increased risk of neural tube defects (NTDs) (0.9%) in infants born to women who were receiving DTG at the time of conception.[17,18] Updated data from the same study showed that the prevalence of NTDs in infants born to women on DTG at the time of conception is not significantly different from those on non-DTG regimens at the time of conception.[19] Based on these data, DTG is now the preferred INSTI for pregnant individuals with HIV. See the Perinatal Guidelines for further discussion.
- BIC is recommended as an alternative INSTI during pregnancy because data about safety, PK, and efficacy in pregnancy are available but are more limited than data about drugs classified as *Preferred* by the Perinatal Guidelines. See the Perinatal Guidelines for more details.

Bictegravir

BIC is approved by the U.S. Food and Drug Administration for initial therapy in adults with HIV as a component of a once-daily single-tablet regimen with TAF and FTC.

Efficacy in Clinical Trials

- The efficacy of BIC in ART-naive adults has been evaluated in two large Phase 3 randomized double-blind clinical trials that compared BIC to DTG administered in combination with two NRTIs. The primary efficacy endpoint was the proportion of participants with plasma HIV RNA <50 copies/mL at Week 48.
  - The GS-US-380-1490 trial randomized participants 1:1 to receive either BIC/TAF/FTC or DTG with coformulated TAF/FTC. Both regimens were given once daily. At Week 96, 84% of participants in the BIC arm and 86% of those in the DTG arm achieved HIV RNA <50 copies/mL.[15]
  - The GS-US-380-1489 trial randomized participants 1:1 to receive BIC/TAF/FTC or coformulated DTG/ABC/3TC once daily. At Week 96, 88% of participants in the BIC/TAF/FTC arm and 90% of those in the DTG/ABC/3TC arm achieved HIV RNA <50 copies/mL.[20]
  - Week 144 follow-up from both trials demonstrated noninferiority of the BIC/TAF/FTC regimen to both DTG-containing regimens, with high levels of virologic suppression and no treatment-emergent resistance.

Adverse Effects

- BIC is generally well tolerated.
- Neuropsychiatric adverse events have been reported with INSTIs. BIC-associated serious neuropsychiatric effects were uncommon (<1%) in clinical trials and mainly occurred in the setting of preexisting depression, other psychiatric illness, or prior suicide attempt.[21]

Drug–Drug Interactions

Note: See Table 24d for a comprehensive list of potential INSTI-related drug–drug interactions.

- BIC is a cytochrome P450 (CYP) 3A4 substrate and a uridine diphosphate glucuronosyltransferase (UGT) 1A1 substrate; therefore, its metabolism may be affected by concomitant use of CYP3A4 and UGT1A1 inducers or inhibitors. Rifampin or other rifamycins may decrease BIC or TAF concentrations, which may result in loss of therapeutic effect of the ART. For people who require rifamycins, BIC/FTC/TAF should not be used. Use of certain anti-seizure medications and St. John's wort should also be avoided.[21]
- BIC is an inhibitor of the drug transporters OCT2 (organic cation transporter 2) and MATE1 (multidrug and toxic compound extrusion 1); therefore, BIC may increase concentrations of drugs that are substrates of these transporters. For this reason, dofetilide is **contraindicated** with BIC/TAF/FTC.

- Like other INSTIs, oral absorption of BIC may be reduced when BIC is coadministered with polyvalent cations (e.g., aluminum-, magnesium-, or calcium-containing antacids; calcium or iron supplements).

Other Factors and Considerations

- BIC decreases tubular secretion of creatinine without affecting glomerular function. Increases in serum creatinine are observed typically within the first 4 weeks of BIC therapy (with a median increase of 0.10 mg/dL after 48 weeks). This increase is comparable to that seen with other ARV drugs that have a similar effect on creatinine secretion, including DTG, RPV, and COBI.
- Treatment-emergent mutations that confer BIC resistance have rarely been reported in people receiving BIC for initial therapy.[22] BIC has not been studied in prospective trials for people with prior INSTI failure or INSTI-related resistance mutations. One analysis of 20 individuals with preexisting INSTI-related resistance mutations showed maintenance of virologic suppression in 19 people after switch to BIC, and viral suppression after beginning BIC in one person without prior ARV treatment. There are, however, insufficient data at present to recommend BIC use in such cases.

The Panel's Recommendation

The Panel recommends the use of BIC/TAF/FTC as a *Recommended Initial Regimen for Most People With HIV* **(AI)** (see Table 6a and Table 7 for more detailed recommendations).

Dolutegravir

As initial ARV regimens, both DTG plus two NRTIs and DTG/3TC demonstrated high efficacy in achieving HIV suppression in clinical trials. DTG is given once daily, with or without food.

Efficacy in Clinical Trials

The efficacy of DTG in ART-naive individuals has been evaluated in several fully powered randomized controlled clinical trials. In these trials, DTG-based regimens were noninferior or superior to a comparator INSTI-, NNRTI-, or PI-based regimen. The primary efficacy endpoint in these clinical trials was the proportion of participants with plasma HIV RNA <50 copies/mL.[13,23,24]

DTG Plus Two NRTIs Versus Other INSTIs Plus Two NRTIs

- DTG-based regimens (with TAF/FTC or ABC/3TC) have been compared to BIC/TAF/FTC in two randomized controlled trials. These regimens have virologic efficacy that is similar to BIC/TAF/FTC (see discussion in the BIC section above).[15,20,23,25]

DTG Plus Two NRTIs Versus EFV Plus Two NRTIs

- The SINGLE trial compared DTG 50 mg once daily plus ABC/3TC to EFV/TDF/FTC in 833 participants. At Week 48, DTG plus ABC/3TC was superior to EFV/TDF/FTC, primarily because the study treatment discontinuation rate was higher in the EFV arm than in the DTG arm.[26] At Week 144, DTG plus ABC/3TC remained superior to EFV/TDF/FTC.[27]
- The ADVANCE trial, an open-label, noninferiority trial conducted in South Africa, compared DTG with either TDF/FTC or TAF/FTC to EFV/TDF/FTC. At Week 96, the DTG-based

regimens were noninferior to the EFV regimen based on the proportion of participants with HIV RNA levels <50 copies/mL (79% in DTG/TAF/FTC vs. 78% in DTG/TDF/FTC vs. 74% in EFV/TDF/FTC arms). More participants discontinued the trial regimen in the EFV group than in the DTG group. Mean weight gain was 7.1 kg in the DTG/TAF/FTC group, 4.3 kg in the DTG/TDF/FTC group, and 2.3 kg in the EFV/TDF/FTC group and was greater among women than men.[14]

DTG Plus Two NRTIs Versus Ritonavir-Boosted Darunavir Plus Two NRTIs

- The FLAMINGO study, a randomized open-label clinical trial, compared DTG 50 mg once daily to the boosted PI—darunavir/ritonavir (DRV/r) 800 mg/100 mg once daily—each administered in combination with investigator-selected ABC/3TC or TDF/FTC. At Week 48, DTG was superior to DRV/r, with 90% and 83% of participants achieving HIV RNA <50 copies/mL, respectively. More participants discontinued their assigned regimen in the DRV/r arm.[28] The difference in efficacy between the DTG and DRV/r regimens was more pronounced in people with pre-treatment HIV RNA levels >100,000 copies/mL. At Week 96, DTG remained superior to DRV/r.[29]

DTG/3TC

- In the GEMINI-1 and GEMINI-2 trials, 1,433 ART-naive participants with baseline HIV RNA <500,000 copies/mL and no evidence of HBV infection were randomized to receive DTG plus 3TC or DTG plus TDF/FTC. At Week 96, DTG plus 3TC was noninferior to DTG plus TDF/FTC with 86% of participants in the DTG plus 3TC group and 89.5% in the DTG plus TDF/FTC group with viral load <50 copies/mL.[30] Virologic nonresponse was uncommon, occurring in 3.1% of participants who received DTG plus 3TC and 2% of participants who received DTG plus TDF/FTC. No treatment-emergent NRTI or INSTI resistance occurred in either treatment group. Among participants who started the study with CD4 counts <200 cells/mm^3, the rate of HIV RNA <50 copies/mL at Week 96 was lower in the DTG plus 3TC group than in the DTG plus TDF/FTC group; however, the difference was not related to a higher rate of virologic failure in the two-drug group. Overall mean change in weight from baseline was 3.1 kg in the DTG plus 3TC group and 2.1 kg in the DTG plus TDF/FTC group. At Week 144, DTG plus 3TC maintained noninferiority to DTG plus TDF/FTC with 82% versus 84% of participants maintaining viral load <50 copies/mL, respectively. The proportion of participants with viral load ≥50 copies/mL was 3% in both treatment groups. A lower risk of drug-related adverse events was found with DTG plus 3TC versus DTG plus TDF/FTC (20% vs. 27%; relative risk, 0.76 [95% confidence interval, 0.63–0.92]).[30]
- Two other small, nonrandomized single-arm studies showed similar rates of viral suppression with DTG plus 3TC.[31,32]

Adverse Effects

- DTG is generally well tolerated. The most reported adverse reactions of moderate-to-severe intensity were insomnia and headache.
- Some studies have shown greater weight increase among people initiating INSTI-based regimens, including regimens with DTG.[7,8,33,34] In a pooled analysis of eight randomized controlled trials in ART-naive individuals, the weight gain at 96 weeks with BIC- and

DTG-based regimens was similar (approximately 3.5 kg). The clinical significance of weight gain in this setting is unclear.[8]

- Neuropsychiatric adverse events (e.g., sleep disturbances, depression, anxiety, suicidal ideation) associated with the initiation of DTG and other INSTIs have been reported.[2,3,35,36] However, analyses of data from large randomized controlled trials and a health care database demonstrated similar rates of neuropsychiatric adverse events between DTG-based regimens and regimens that included RAL, EFV, DRV, and ATV.[37] Neuropsychiatric events rarely led to DTG discontinuation.

Drug–Drug Interactions

Note: See Table 24d for a comprehensive list of potential INSTI-related drug–drug interactions.

- DTG has fewer drug interactions than BIC.
- DTG oral absorption may be reduced when the ARV is coadministered with polyvalent cations. DTG should be taken at least 2 hours before or 6 hours after cation-containing antacids or laxatives are taken. Alternatively, DTG and supplements containing calcium or iron can be taken simultaneously with food.

Other Factors and Considerations

- DTG decreases tubular secretion of creatinine without affecting glomerular function, with increases in serum creatinine observed within the first 4 weeks of treatment.
- Treatment-emergent mutations that confer DTG resistance have been rarely reported in people receiving DTG as part of a three-drug regimen for initial therapy.[38-40] The incidence of resistance with DTG is much lower than with EVG or RAL, which suggests that DTG, like BIC, has a higher barrier to resistance than EVG or RAL.

The Panel's Recommendations

- The Panel classifies the following as *Recommended Initial Regimens for Most People With HIV* (see Table 6a and Table 7 for more detailed recommendations):
  - DTG plus (TAF or TDF) plus (FTC or 3TC) **(AI)**
  - DTG/3TC **(AI)—not recommended** for those with HIV RNA >500,000 copies/mL, with HBV coinfection, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available.
- The Panel recommends DTG/ABC/3TC **(BI)** in certain clinical scenarios for people with HIV who are documented to be HLA-B*5701-negative and who have concerns about renal or bone toxicities associated with TAF or TDF. This regimen should not be used in people with HBV coinfection unless an HBV-active drug (i.e., entecavir) other than 3TC is used.

Non-Nucleoside Reverse Transcriptase Inhibitor–Based Regimens as Initial Antiretroviral Therapy

Updated: September 12, 2024
Reviewed: September 12, 2024

Table 8c. Characteristics of Non-Nucleoside Reverse Transcriptase Inhibitors That Are Recommended as Initial Antiretroviral Therapy in Certain Clinical Scenarios

Characteristics	DOR	RPV[a]
Dosing Frequency	Once daily	Once daily
Food Requirement	With or without food	With a meal
STR Available as Initial ART Recommended in Table 6b	DOR/TDF/3TC	RPV/TAF/FTC
Available as a Single-Drug Tablet	Yes	Yes
Adverse Effects	Generally well tolerated	• Depression • Headache • Skin rash • QTc prolongation
CYP3A4 Drug–Drug Interactions	CYP3A4 substrate	CYP3A4 substrate
Other Significant Drug Interactions	None	RPV oral absorption is reduced with increased gastric pH. Use of RPV with PPIs is not recommended; see Drug–Drug Interactions for dosing recommendations when RPV is coadministered with an H2 blocker or antacids.

[a] See Optimizing Antiretroviral Therapy section and Appendix B, Table 4 for information regarding injectable RPV.

Key: 3TC = lamivudine; ART = antiretroviral therapy; CYP = cytochrome P; DOR = doravirine; FTC = emtricitabine; H2 = histamine 2; PPI = proton pump inhibitor; QTc = QT corrected for heart rate; RPV = rilpivirine; STR = single-tablet regimen; TAF = tenofovir alafenamide; TDF = tenofovir disoproxil fumarate

Summary

Four non-nucleoside reverse transcriptase inhibitors (NNRTIs)—doravirine (DOR), efavirenz (EFV), nevirapine (NVP), and rilpivirine (RPV)—are currently approved by the U.S. Food and Drug Administration (FDA) for the initial treatment of HIV when used in combination with other antiretroviral (ARV) drugs. A fifth NNRTI, etravirine (ETR), is approved only for people who are ART-experienced.

NNRTI-based regimens have demonstrated virologic potency and durability. The major disadvantages of currently available NNRTIs (especially EFV and RPV) include the prevalence of NNRTI-resistant viral strains in people without prior antiretroviral therapy (ART),[1] a low barrier for

the development of resistance, and potential for drug–drug interactions, although drug–drug interactions are less common with DOR. Resistance testing should be performed before initiation of an NNRTI-based regimen in people without prior ART. High-level resistance to all NNRTIs (except ETR or DOR) may occur with a single mutation. In people treated with RPV, the presence of RPV resistance mutations at virologic failure may confer cross-resistance to other NNRTIs, including ETR.[2,3] DOR-based regimens and one of the RPV-based regimens are now categorized as recommended *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios*. More details about these NNRTIs are provided below.

This section of the guidelines focuses on DOR and RPV, the two NNRTIs recommended by the Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) as part of an initial ART regimen for people with HIV in certain clinical scenarios (see Table 6b in the Initial Combination Antiretroviral Regimens for People With HIV section and Table 7). There is no clinical trial comparing the efficacy of these two NNRTIs as initial ARV regimens. The Panel no longer recommends EFV as initial therapy because of the high incidence of serious toxicities, including neuropsychiatric effects and suicidality. NVP is no longer commonly used in clinical practice in the United States due to a relatively high potential for adverse effects compared to other NNRTIs.

Doravirine

Efficacy in Clinical Trials

The efficacy of DOR-based therapy as initial ART was demonstrated in two randomized, double-blind, placebo-controlled trials.

Doravirine-Based Regimen Versus Efavirenz-Based Regimen

- In the DRIVE-AHEAD trial, 734 participants received either DOR/tenofovir disoproxil fumarate (TDF)/lamivudine (3TC) or EFV/TDF/emtricitabine (FTC), both as a daily fixed-dose combination (FDC) tablet.[4]
  - At 96 weeks, DOR/TDF/3TC was noninferior to EFV/TDF/FTC, with 77.5% of participants who received DOR/TDF/3TC and 73.6% of those who received EFV/TDF/FTC achieving HIV RNA <50 copies/mL. Although virologic responses to ART overall were lower in participants with pre-treatment HIV RNA >100,000 copies/mL or pre-treatment CD4 T lymphocyte (CD4) cell counts of ≤200 cells/mm^3, there was no difference between the DOR-treated and EFV-treated participants.
  - Virologic rebound and virologic nonresponse were similar in the DOR/TDF/3TC (9.3%) and EFV/TDF/FTC (7.7%) treatment groups. At 96 weeks, genotype resistance results were reported for 21 participants with protocol-defined virologic failure in the DOR arm and 15 participants in the EFV arm. For the DOR arm, 7 of 21 (33.3%) participants had NNRTI resistance and 6 of 21 (28.6%) had NRTI resistance. For EFV, 10 of 15 (66.7%) participants had NNRTI resistance and 5 of 15 (33.3%) had NRTI resistance.
  - More participants in the EFV arm discontinued their assigned ART due to adverse events than in the DOR arm (6.6% vs. 3.0%). Neuropsychiatric side effects and rash were more common in the EFV arm.

Doravirine-Based Regimen Versus Darunavir/Ritonavir-Based Regimen

- In the DRIVE-FORWARD trial, 769 participants received DOR or darunavir/ritonavir (DRV/r) once daily along with two investigator-selected nucleoside reverse transcriptase inhibitors (NRTIs), either abacavir (ABC)/3TC or TDF/FTC.[5]
  - At 48 weeks, DOR was noninferior to DRV/r with 84% of study participants who received DOR versus 80% of those who received DRV/r achieving HIV RNA <50 copies/mL. Participants who received DOR plus ABC/3TC (n = 48) and those who received DOR plus TDF/FTC (n = 316) had similar virologic responses.
  - At 96 weeks, DOR was superior to DRV/r in terms of virologic suppression (73% vs. 66%).[5]
  - Protocol-defined virologic failure was similar in the DOR and DRV/r groups (9% vs. 11%) by Week 96. Genotype resistance results were reported for 11 and 14 participants with virologic failure in the DOR and DRV/r arms, respectively. Treatment-emergent resistance to any study drug occurred in 2 of 11 participants in the DOR group and 1 of 14 participants in the DRV/r group.
  - Treatment-related diarrhea was more frequently reported in the DRV/r arm. Greater increases in fasting low-density lipoprotein cholesterol, triglycerides, non–high-density lipoprotein cholesterol, and total cholesterol were seen in the participants who received DRV/r than in those who received DOR.
- In a pooled analysis of DRIVE-AHEAD and DRIVE-FORWARD participants who entered an open-label extension phase following the initial 96 weeks of randomized treatment, 550 participants continued their DOR-based regimen and 502 participants switched to a DOR-based regimen from the control arms. At 192 weeks, 83% percent of participants who continued on DOR and 81% of participants in the switch arm maintained viral suppression. Discontinuation due to drug-related adverse events was <1% overall and similar between the two arms, with no discontinuations due to renal adverse events.[6]

Other Factors and Considerations

- DOR is available as a single-drug 100-mg tablet[7] and as part of a single-tablet regimen (STR) that contains DOR/TDF/3TC 100 mg/300 mg/300 mg[8] and is dosed once daily, with or without food.
- DOR-based regimens have not been directly compared to integrase strand transfer inhibitor (INSTI)–based regimens in clinical trials and have not been studied with tenofovir alafenamide (TAF) in clinical trials.
- A post hoc analysis of three randomized controlled trials examined weight gain among ART-naive participants receiving DOR versus DRV/r or EFV. At week 96, mean weight gain was similar in the DOR group (2.4 kg), DRV/r group (1.8 kg), and EFV group (1.6 kg). No significant differences between treatment groups were found in the proportion of participants whose body mass index classification increased to overweight or obese at Week 48 or Week 96.[9]
- DOR is primarily metabolized by the CYP3A4 enzyme and should not be coadministered with strong CYP3A4 inducers. DOR concentration may increase in the presence of a CYP3A4 inhibitor (see Table 24b). DOR is not a CYP3A4 inducer or inhibitor; thus, it is not expected to affect the concentrations of concomitant CYP3A4 substrates.

- Treatment-emergent resistance mutations to DOR may confer cross-resistance to certain other NNRTIs. Most isolates with DOR mutations remain susceptible to ETR.[10]
- There are currently no data on the safety of DOR use during pregnancy.
- There are limited clinical trial data with the combination of DOR + ABC/3TC, so the Panel is less certain about the efficacy of this regimen.

The Panel's Recommendations

- Based on the clinical trial data discussed above, the Panel classifies DOR/TDF/3TC **(BI)** and DOR plus two NRTIs (**BI** for TDF/FTC and **BIII** for TAF/FTC) as *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios*.

Rilpivirine

Oral RPV is approved for use in combination with two NRTIs as initial ART for people with HIV who have pre-treatment viral loads <100,000 copies/mL. RPV is also approved as an extended-release injectable suspension as part of a long-acting (LA) injectable complete ARV regimen when used with cabotegravir (CAB), an INSTI. This regimen is approved to replace oral ART in people with virologic suppression and no history of resistance to RPV or INSTIs (see Optimizing Antiretroviral Therapy in the Setting of Viral Suppression for discussion of LA CAB/RPV).

Efficacy in Clinical Trials

- Two Phase 3 randomized, double-blind clinical trials—ECHO and THRIVE—compared RPV and EFV, each combined with two NRTIs.[11] At 96 weeks, the following findings were reported:
  - RPV was noninferior to EFV overall.
  - Among participants with pre-ART viral loads >100,000 copies/mL, more RPV-treated participants experienced virologic failure than EFV-treated participants. NNRTI and NRTI resistance were more frequently found in RPV-treated participants with virologic failure.
  - Among the RPV-treated participants, the rate of virologic failure was greater in those with pre-treatment CD4 counts <200 cells/mm^3 than in those with CD4 counts ≥200 cells/mm^3.
- STaR, a Phase 3b, open-label study, compared two STRs—RPV/TDF/FTC and EFV/TDF/FTC—as initial ART in 786 people with HIV. The results at 96 weeks[12] were similar to those reported at 48 weeks.[13]
  - RPV was noninferior to EFV overall.
  - RPV was superior to EFV in participants with pre-ART viral loads ≤100,000 copies/mL and noninferior in those with pre-ART viral loads >100,000 copies/mL. Among participants with pre-ART viral loads >500,000 copies/mL, virologic failure was more common in RPV-treated than in EFV-treated participants.
  - At Week 96, there were more participants with emergent resistance in the RPV/FTC/TDF arm than in the EFV/FTC/TDF arm (5.3% vs. 1.0%, respectively).
- The STR of RPV/TAF/FTC was approved by the FDA based on results from a bioequivalence study. In this study, plasma concentrations of RPV, FTC, and TAF 25 mg in participants taking

the coformulated drug were similar to those seen in participants who received RPV as the single-drug tablet and TAF/FTC as part of the STR of EVG/c/TAF 10 mg/FTC.[14]

Adverse Effects

- RPV is generally well tolerated. In the ECHO, THRIVE, and STaR trials, fewer instances of CNS adverse events (e.g., abnormal dreams, dizziness, psychiatric side effects), skin rash, and dyslipidemia were reported in the RPV arms than in the EFV arms, and fewer people in the RPV arms discontinued therapy due to adverse events. However, up to 9% of clinical trial participants experienced depressive disorders, including approximately 1% of participants who had suicidal thoughts or who attempted suicide. People receiving RPV who have severe depressive symptoms should be evaluated to assess whether the symptoms may be due to RPV and if the risks of continuing the same regimen outweigh the benefits.

Other Factors and Considerations

- Oral RPV is formulated both as a single-drug tablet and in STRs with TAF/FTC, with TDF/FTC, and with DTG. Among available STRs, RPV/TDF/FTC is no longer recommended by the Panel for initial therapy.
- RPV is also available as part of an LA injectable ARV regimen for use in combination with LA CAB in people with HIV who are virologically suppressed and do not have resistance to these drugs (see Optimizing Antiretroviral Therapy in the Setting of Viral Suppression).
- The STR of RPV/TAF/FTC is given once daily and must be administered with a meal (containing at least 390 kcal).
- RPV is also coformulated as a once-daily FDC tablet with DTG that is used as continuation therapy for people with HIV who have achieved viral suppression.[15] However, this combination has not been studied in people with HIV and no prior ART, and it **is not recommended** for initial therapy (see Optimizing Antiretroviral Therapy in the Setting of Viral Suppression).
- The oral drug absorption of RPV can be significantly reduced in the presence of acid-reducing agents. RPV is **contraindicated** in people who are receiving proton pump inhibitors and should be used with caution in those receiving H2 antagonists or antacids (see Drug–Drug Interactions for dosing recommendations).
- RPV is primarily metabolized in the liver by the CYP3A enzyme; its plasma concentration may be affected in the presence of CYP3A inhibitors or inducers (see Drug–Drug Interactions).
- At doses above the approved dose of 25 mg, RPV may cause QTc interval prolongation. RPV should be used with caution when coadministered with a drug known to increase the risk of Torsades de Pointes.

The Panel's Recommendations

- Given the availability of other effective regimens that do not have virologic and immunologic prerequisites to initiate treatment, substantial drug–drug interactions, and a low genetic barrier to resistance, RPV is **not recommended** for initial therapy in most persons with HIV. RPV/TDF/FTC is no longer recommended as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios*, largely due to the limitations of RPV and the availability of

DOR/TDF/3TC, which has fewer drug–drug interactions and no virologic and immunologic prerequisites. The Panel continues to recommend RPV/TAF/FTC as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (see Table 6b in the Initial Combination Antiretroviral Regimens for People With HIV section), largely to retain an STR option containing an NNRTI and TAF.

- Use of RPV with TAF/FTC **(BII)** should be limited to persons with pre-treatment viral loads <100,000 copies/mL and CD4 counts >200 cells/mm^3.
- Data on RPV plus ABC/3TC are insufficient to consider recommending this regimen.

Protease Inhibitor–Based Regimens

Updated: September 12, 2024
Reviewed: September 12, 2024

Table 8d. Characteristics of Protease Inhibitor Options as Initial Antiretroviral Therapy in Certain Clinical Scenarios

Characteristic	DRV
Dosing Frequency	Once daily for persons with no prior PI experience.
PK Boosting	DRV should only be used with a PK booster (i.e., RTV or COBI).
Fixed-Dose Formulation	• DRV/c • DRV/c/TAF/FTC
Available as a Single-Drug Tablet	Yes
Adverse Effects	• Skin rash • Increase in serum transaminase • Hyperlipidemia • Diarrhea, nausea
CYP3A4 Drug–Drug Interactions	CYP34A substrate, inhibitor
Other Significant Drug Interactions	N/A

Key: COBI = cobicistat; CYP = cytochrome P; DRV = darunavir; DRV/c = darunavir/cobicistat; FTC = emtricitabine; N/A = not applicable; PI = protease inhibitor; PK = pharmacokinetic; RTV = ritonavir; TAF = tenofovir alafenamide

Summary

The U.S. Food and Drug Administration (FDA)–approved protease inhibitors (PIs) include atazanavir (ATV), atazanavirATV/cobicistat (ATV/c), darunavir (DRV), darunavir/cobicistat (DRV/c), fosamprenavir (FPV), indinavir (IDV), lopinavir/ritonavir (LPV/r), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), and tipranavir (TPV). PI-based regimens using pharmacokinetic (PK) enhancement with either cobicistat (COBI) or RTV (also called PK boosting) increase concentration and prolong the half-lives of the PI. These regimens have demonstrated virologic potency, durability in people who are ART-naive, and a high barrier to resistance. Because LPV/r, fosamprenavir/ritonavir (FPV/r), ATV (with or without a PK enhancer), and saquinavir/ritonavir (SQV/r) have disadvantages—such as greater pill burden, lower efficacy, or increased toxicity—only boosted DRV in combination with two nucleoside reverse transcriptase inhibitors (NRTIs) is recommended as initial therapy in certain clinical situations (see Table 6b in Initial Combination Antiretroviral Regimens for People With HIV).

Because transmitted PI resistance is uncommon, boosted DRV-based regimens are preferred over a non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimen as an option for treatment initiation before resistance test results are available. In addition, a boosted DRV-based regimen can be used for rapid antiretroviral therapy (ART) initiation, in the setting of acute HIV infection, and as the preferred option while awaiting resistance test results for people with a history of long-acting cabotegravir (CAB-LA) use as pre-exposure prophylaxis (PrEP). Few or no PI mutations are

detected when a patient's first PI-based regimen fails, which is not the case with non-nucleoside reverse transcriptase inhibitor (NNRTI)–based regimens and regimens with a first-generation integrase strand transfer inhibitor (INSTI) (e.g., raltegravir or elvitegravir).[1] Because of their high barrier to resistance, PI-based regimens may be useful for people at risk for intermittent therapy because of poor adherence.

DRV requires PK boosting with either RTV or COBI to inhibit the cytochrome P3A4 (CYP3A4) isoenzyme, which may lead to significant drug–drug interactions (see Drug–Drug Interactions). The specific characteristics of DRV are listed in Appendix B, Table 5.

Darunavir/Ritonavir

Efficacy in Clinical Trials

Darunavir/ritonavir (DRV/r) has been studied in several large, randomized controlled trials in people with HIV without prior antiretroviral (ARV) experience. These trials compared DRV/r-based regimens to PI-, INSTI-, or NNRTI-based regimens. Summaries of the results from some key trials are listed below.

- The FLAMINGO study compared DRV/r with dolutegravir (DTG), each administered in combination with two NRTIs—either tenofovir disoproxil fumarate (TDF)/emtricitabine (FTC) or abacavir (ABC)/lamivudine (3TC)—in 488 participants who were ART-naive. The rate of virologic suppression at Week 96 was significantly higher among those who received DTG than in those who received DRV/r. The higher rate of virologic failure observed in the DRV/r group was related primarily to the number of failures among those with a viral load >100,000 copies/mL and secondarily to more drug discontinuations in the DRV/r group.[2]
- The AIDS Clinical Trial Group (ACTG) study A5257 (ARDENT), a large, randomized, open-label trial, compared atazanavir/ritonavir (ATV/r) to DRV/r or raltegravir (RAL) over 96 weeks, each given with TDF/FTC. The trial showed similar virologic efficacy for DRV/r, ATV/r, and RAL, but more participants in the ATV/r group discontinued randomized treatment because of adverse events.[3]
- The DRIVE-FORWARD study compared DRV/r to doravirine (DOR), both administered with two investigator-selected NRTIs, in 769 ART-naive participants. At 48 weeks, DOR was found to be non-inferior to DRV/r, with 80% and 84% of participants achieving HIV RNA levels <50 copies/mL, respectively.[4] At Week 96, DOR was superior to DRV/r in terms of virologic suppression (73% vs. 66%).[4] Rates of virologic failure were low and similar in the DOR and DRV/r groups (9% vs. 11%). Treatment-emergent resistance to any study drug was infrequent, occurring in <1% of participants in both the DOR group (2 of 383) and the DRV/r group (1 of 383).

Adverse Effects

- People with HIV who take DRV/r may develop a skin rash, which is usually mild-to-moderate in severity and self-limited. Treatment discontinuation is necessary on rare occasions when severe rash occurs with fever or elevated transaminases.
- ACTG A5257 showed similar lipid changes in participants in the ATV/r and DRV/r arms. Bone mineral density decreased to a greater extent in participants in the ATV/r and DRV/r arms

compared to participants in the RAL arm.[3] The likelihood of developing metabolic syndrome was equivalent among the three arms, although a larger increase in waist circumference was observed at 96 weeks in participants assigned to the RAL arm than in those assigned to the DRV/r arm ($P = 0.023$).[5]

- In the DRIVE-FORWARD study, treatment-related diarrhea was more frequently reported in the DRV/r arm, and greater increases were observed in fasting low-density lipoprotein cholesterol, triglycerides, non–high-density lipoprotein cholesterol, and total cholesterol compared to the DOR arm.[4]

Other Factors and Considerations

- DRV/r is administered once daily with food in people who are ART-naive.
- DRV has a sulfonamide moiety and should be used with caution in people with severe sulfonamide allergies. In clinical trials, the incidence and severity of rash were similar in participants with and without a history of sulfonamide allergy. Most people with sulfonamide allergy can tolerate DRV.
- DRV/r is a potent CYP3A4 inhibitor, which may lead to significant interactions with other medications metabolized through this same pathway (see Drug–Drug Interactions).
- Unlike DRV/c, DRV/r may be used in pregnancy.

The Panel's Recommendations

- Based on efficacy and safety data from clinical trials and clinical experience, the Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) classifies DRV/r with (tenofovir alafenamide [TAF] or TDF) plus (FTC or 3TC) as a *Recommended Initial Regimen for Most People With HIV* who have a history of CAB-LA use as PrEP, pending the results of INSTI genotype testing **(AIII)** (see Table 6a). DRV/r plus (TAF or TDF) plus (FTC or 3TC) **(BI)** and DRV/r plus ABC/3TC **(BII)** are also part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios* (see Table 6b and Table 7).

Darunavir/Cobicistat

Efficacy in Clinical Trials

- The AMBER trial enrolled 725 ART-naive participants in a Phase 3 randomized controlled trial that compared the single-tablet regimen (STR) DRV/c/TAF/FTC with DRV/c plus TDF/FTC. At 48 weeks, similar virologic suppression rates among participants were achieved in both arms of the study (91% and 88% had HIV RNA <50 copies/mL, respectively). No treatment-emergent mutations associated with DRV or TAF/TDF resistance were observed in either group.[6] At 96 weeks, 85% of participants on the STR maintained HIV RNA levels <50 copies/mL compared to 84% in the DRV/c plus TDF/FTC arm.[7]
- The DIAMOND study evaluated DRV/c/TAF/FTC as an STR in 109 participants in a rapid-initiation model of care. At Week 48, 97 (89%) participants completed the study and 92 (84%) achieved HIV-1 RNA <50 copies/mL by the FDA snapshot analysis. No protocol-defined virologic failures occurred, and incidences of adverse events at least possibly related to study

drugs (33%) were low. No study drug-related serious adverse events occurred, and only one (<1%) participant discontinued because of a study drug-related adverse event.[8]

Adverse Effects

- The most common drug-related adverse events were diarrhea, nausea, fatigue, flatulence, rash, and headache.

Other Factors and Considerations

- DRV/c 800 mg/150 mg is available as a coformulated boosted PI or as an STR with TAF/FTC 10 mg/200 mg.
- Both DRV and COBI exposures are reduced markedly during the second and third trimesters of pregnancy, and should be avoided if possible.[9] However, if pregnant women with viral suppression while on DRV/c elect to continue on the drug, frequent viral load monitoring is recommended. For further information, please refer to the Perinatal Guidelines.

The Panel's Recommendations

- The Panel recommends DRV/c plus (TAF or TDF) plus (FTC or 3TC) **(BI)** and DRV/c plus ABC/3TC **(BII)** as part of *Other Initial Antiretroviral Regimens for Certain Clinical Scenarios*.
- Per product label recommendation, DRV/c plus TDF/FTC **is not recommended** for people with creatinine clearance (CrCl) <70 mL/min, whereas DRV/c plus TAF/FTC **is not recommended** for people with CrCl <30 mL/min.
- For people who have a history of CAB-LA use as PrEP, INSTI genotype resistance testing should be performed before starting ART. If ART is to be started before genotypic testing results are available, DRV/c with (TAF or TDF) plus (FTC or 3TC) can be started **(AIII).**

Rating of Recommendations: A = Strong; B = Moderate; C = Weak

Rating of Evidence: I = One or more randomized trials with clinical outcomes and/or validated laboratory endpoints; II = One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion

Antiretroviral Regimens for Initial Therapy When Abacavir, Tenofovir Alafenamide, and Tenofovir Disoproxil Fumarate Cannot Be Used or Are Not Optimal

Updated: September 12, 2024
Reviewed: September 12, 2024

Most of the currently recommended antiretroviral (ARV) regimens for initial therapy consist of two nucleoside reverse transcriptase inhibitors (NRTIs) plus a third active drug. In addition, dolutegravir (DTG)/lamivudine (3TC) is a two-drug, NRTI-limiting regimen that is a recommended option for people with HIV (see Table 6a in Initial Combination Antiretroviral Regimens for People With HIV) and would be preferred over others in situations where it is desirable to avoid abacavir (ABC), tenofovir alafenamide (TAF), and tenofovir disoproxil fumarate (TDF). Several other NRTI-limiting/sparing two-drug regimens have been evaluated in clinical studies, but are not yet recommended by the Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) due to insufficient evidence. Note that two-drug regimens **are not currently recommended** during pregnancy and tenofovir-sparing regimens **are not recommended** in people with hepatitis B virus (HBV)/HIV coinfection unless another HBV-active drug (i.e., entecavir) is added. Clinicians should refer to HBV/HIV Coinfection for guidance on treatment of people with HBV infection when TAF or TDF cannot be used as part of the ARV regimen.

Strategies Supported by Evidence From Clinical Trials

Dolutegravir/Lamivudine

- In the GEMINI-1 and GEMINI-2 trials, 1,433 antiretroviral therapy (ART)–naive participants with baseline HIV RNA <500,000 copies/mL and no evidence of HBV infection were randomized to receive a two-drug regimen of DTG plus 3TC or a three-drug regimen of DTG plus TDF/emtricitabine (FTC). At Week 96, DTG plus 3TC was non-inferior to DTG plus TDF/FTC based on the proportion of participants with viral loads <50 copies/mL (86% in DTG plus 3TC group and 89.5% in DTG plus TDF/FTC group).[1] Virologic nonresponse was uncommon, occurring in 3.1% of participants who received DTG plus 3TC and 2% of participants who received DTG plus TDF/FTC. No instances of treatment-emergent NRTI or integrase strand transfer inhibitor (INSTI) resistance occurred in either treatment group. Among participants who started the study with CD4 counts <200 cells/mm^3, the proportion of participants with HIV RNA <50 copies/mL at Week 96 was lower in the DTG plus 3TC group than in the DTG plus TDF/FTC group; however, the difference was not related to a higher rate of virologic failures in the two-drug group. At Week 144, DTG plus 3TC maintained noninferiority to DTG plus TDF/FTC with 82% versus 84% of participants maintaining viral load <50 copies/mL, respectively. The proportion of participants with viral load ≥50 copies/mL was similar between both treatment groups at 3%. There was a lower risk of drug-related adverse events with DTG plus 3TC versus DTG plus TDF/FTC (19.6% vs. 25.0%; relative risk ratio, 0.78; 95% confidence interval, 0.64–0.95).[1]

The Panel's Recommendation

When ABC, TAF, or TDF cannot be used or are not optimal, the Panel recommends DTG/3TC as an initial regimen for people with HIV **(AI)** who—

- Have a viral load ≤500,000 copies/mL,

- Have a genotype available that demonstrates sensitivity to 3TC,
- Do not have a history of long-acting cabotegravir (CAB-LA) use as pre-exposure prophylaxis, *or*
- Have CAB-LA exposure but with documented INSTI sensitivity on genotypic resistance testing.

HBV status must be determined, and if HBV/HIV coinfection is present, another HBV-active drug should be added (see HBV/HIV Coinfection).

Nucleoside-Limiting Regimens With Some Supporting Data but Not Recommended as Initial Therapy

The Panel **does not recommend** the following nucleoside-limiting or nucleoside-sparing regimens for initial therapy due to insufficient clinical trial data.

Darunavir/Ritonavir Plus Lamivudine

- In the ANDES trial, 336 participants were randomized 1:1 to receive open-label, once-daily dual therapy with darunavir/ritonavir (DRV/r) plus 3TC or triple therapy with DRV/r plus TDF/3TC. This study was conducted in Argentina, and the researchers used an FDC of DRV/r 800 mg/100 mg that is available in that country. The median baseline HIV RNA was 4.5 $\log_{10}$ copies, and 23% of participants had HIV RNA >100,000 copies/mL. At Week 48, 91% of the participants in the dual-therapy group and 93% of the participants in the triple-therapy group achieved an HIV RNA <50 copies/mL, demonstrating that dual therapy was non-inferior to triple therapy.[2] The rates of virologic suppression among study participants who had pre-therapy HIV RNA levels >100,000 copies/mL were similar in the dual- and triple-therapy groups (87% and 90%, respectively). The Panel **does not recommend** this regimen as initial therapy as the results from this study have not yet been published.

Darunavir/Ritonavir Plus Raltegravir

- In the NEAT/ANRS 143 study, 805 treatment-naive participants were randomized to receive twice-daily raltegravir (RAL) or once-daily TDF/FTC, each with DRV/r (800 mg/100 mg once daily). At Week 96, DRV/r plus RAL was non-inferior to DRV/r plus TDF/FTC based on the primary endpoint, the proportion of people with virologic or clinical failure. Among those with baseline CD4 counts <200 cells/mm^3; however, there were more virologic failures in the RAL plus DRV/r arm. A trend towards more failure was also observed among those with pre-treatment HIV RNA ≥100,000 copies/mL.[3] High rates of virologic failure in participants with HIV RNA >100,000 copies/mL were also seen in two smaller studies of DRV/r plus RAL.[4,5] The Panel **does not recommend** DRV/r plus RAL as initial ART because of the higher rate of virologic failure in participants with HIV RNA ≥100,000 copies/mL and the higher pill burden of this regimen compared to other Panel-recommended initial ARV regimens.

Darunavir/Ritonavir Plus Rilpivirine

- In a single-arm, open-label pilot study, 36 ART-naive participants without genotypic evidence of resistance to DRV or rilpivirine (RPV) received DRV/r plus RPV for 48 weeks. Half of the participants (18 of 36) had baseline HIV viral loads >100,000 copies/mL. By Week 36, 97% of participants (35 of 36) achieved HIV RNA <50 copies/mL, and by Week 48, all achieved viral

suppression (HIV RNA < 50 copies/mL).[6] The Panel **does not recommend** this regimen as initial ART given the small sample size of the study described above and the lack of comparative data evaluating DRV/r plus RPV as initial therapy for people with HIV.

Long-Acting Injectable Cabotegravir With Rilpivirine

- The long-acting injectable combination of CAB plus RPV (LA CAB/RPV) has not been studied in ART-naive participants. In the Phase 3 trial FLAIR and Phase IIb trial LATTE-2,[7,8] ART-naive participants were first treated with 20 weeks of DTG/ABC/3TC or oral CAB+ABC/3TC, respectively. Study participants who achieved virologic suppression were eligible for randomization to receive LA CAB/RPV every month or to continue oral daily ART. The Panel **does not recommend** the LA CAB/RPV as initial therapy for people with HIV because of the lack of data supporting the efficacy of this combination in people who are ART-naive **(AIII).** People desiring to use LA CAB/RPV early in their treatment history should first attain viral suppression on a recommended regimen before transitioning to LA CAB/RPV. See Optimizing Antiretroviral Therapy in the Setting of Viral Suppression for more discussion.

Rating of Recommendations: A = Strong; B = Moderate; C = Weak

Rating of Evidence: I = One or more randomized trials with clinical outcomes and/or validated laboratory endpoints; II = One or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion

Table 9. Advantages and Disadvantages of Antiretroviral Components of Initial Antiretroviral Therapy Listed in Table 6a and Table 6b

Updated: September 12, 2024
Reviewed: September 12, 2024

Note: All drugs within an ARV class are listed in alphabetical order. Information based on Table 6a and Table 6b in the Initial Combination Antiretroviral Regimens for People With HIV section.

ARV Class	ARV Agent(s)	Advantage(s)	Disadvantage(s)
Dual-NRTI	**ABC/3TC**	• Coformulated with DTG • Generic formulations are available for ABC/3TC, ABC, and 3TC.	• May cause life-threatening HSRs in people who test positive for the HLA-B*5701 allele. As a result, HLA-B*5701 testing is required before use. • ABC use has been associated with CV disease and cardiac events in some, but not all, observational studies.
	TAF/FTC	• Coformulated with BIC, DRV/c, or RPV • Active against HBV; a recommended dual-NRTI option for people with HBV/HIV coinfection • Smaller decline in renal function, less proteinuria, and smaller reductions in BMD than TDF/FTC • Approved for people with eGFR ≥30 mL/min • Can be used in people on chronic hemodialysis	• See text in the NRTI section regarding weight gain with TAF.
	TDF/3TC	• Coformulated with DOR • Generic formulations are available for TDF, 3TC, or TDF/3TC. • Long-term clinical experience • Active against HBV	• Renal toxicity, including proximal tubulopathy and acute or chronic renal insufficiency, especially when combined with pharmacologic boosters • Osteomalacia has been reported as a consequence of proximal tubulopathy. • Decreased BMD has been associated with use of TDF, especially when combined with pharmacologic boosters.
	TDF/FTC	• Active against HBV; a recommended dual-NRTI option for people with HIV/HBV coinfection • TDF is associated with lower lipid levels than TAF.	• Renal toxicity, including proximal tubulopathy and acute or chronic renal insufficiency, especially when combined with pharmacologic boosters • Osteomalacia has been reported as a consequence of proximal tubulopathy.

Table 9. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy Listed in Table 6a and Table 6b

ARV Class	ARV Agent(s)	Advantage(s)	Disadvantage(s)
			• Decreased BMD has been associated with use of TDF, especially when combined with pharmacologic boosters.
Single NRTI	**3TC**	• Coformulated with DTG as STR • Avoids potential toxicities associated with TDF, TAF, ABC	• DTG/3TC **is not recommended** for individuals with HIV RNA >500,000 copies/mL, HBV coinfection unless on another HBV active drug, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available.
INSTI	**BIC**	• Coformulated with TAF/FTC • Higher barrier to resistance than EVG and RAL • No food requirement	• Oral absorption of BIC can be reduced by simultaneous administration with drugs or supplements containing polyvalent cations (e.g., Al-, Ca-, or Mg-containing antacids or supplements or multivitamin tablets with minerals). See dosing recommendations in Table 24d. • CYP3A4 and UGT1A1 substrate (but not a CYP3A4 inducer or inhibitor); potential for drug–drug interactions. • See text in the INSTI section regarding weight gain and INSTI use.
	DTG	• Higher barrier to resistance than EVG or RAL • Coformulated with ABC/3TC and 3TC as STR • No food requirement • Minimal CYP3A4 interactions • Favorable lipid profile	• Oral absorption of DTG can be reduced by simultaneous administration with drugs containing polyvalent cations (e.g., Al-, Ca-, or Mg-containing antacids or supplements or multivitamin tablets with minerals). See dosing recommendations in Table 24d. • UGT1A1 substrate; potential for drug interactions (see Table 24d) • Depression and suicidal ideation (rare; usually in people with preexisting psychiatric conditions) • See text in the INSTI section regarding weight gain and INSTI use.
NNRTI	**DOR**	• Coformulated with TDF/3TC • Fewer CNS side effects compared to EFV and RPV • No food requirement	• Shorter-term clinical experience than with RPV • Potential for CYP450 drug interactions (see Tables 24b, 25a, and 25b) • Treatment-emergent DOR resistance mutations may confer resistance to certain NNRTIs.

Table 9. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy Listed in Table 6a and Table 6b

ARV Class	ARV Agent(s)	Advantage(s)	Disadvantage(s)

	RPV	• Coformulated with TAF/FTC	• **Not recommended** in people with pre-ART HIV RNA >100,000 copies/mL or CD4 counts <200 cells/mm^3 because of higher rate of virologic failure in these people.
			• Depression and suicidality
			• QTc interval prolongation; consider using an alternative to RPV in people taking medications with known risk of causing Torsades de Pointes or in those at higher risk of Torsades de Pointes.
			• Rash
			• Transmitted resistance is more common than with PIs and INSTIs.
			• More NNRTI-, TDF-, and 3TC-associated mutations at virologic failure than with regimens that contain EFV and two NRTIs
			• Potential for CYP450 drug interactions (see Tables 24b and 25a)
			• Meal requirement (>390 kcal)
			• Requires acid for adequate absorption
			  ○ Contraindicated with PPIs.
			  ○ Use with H2 antagonists or antacids with caution (see Table 24a for detailed dosing information).

PI	**DRV/c** or **DRV/r**	• Higher barrier to resistance than NNRTIs • PI resistance at the time of treatment failure is uncommon with PK-enhanced PIs.	• Skin rash • Food requirement • GI adverse effects • CYP3A4 inhibitors and substrates: potential for drug interactions (see Table 24a) • Increased CV risk reported in one observational cohort study[a] • Hepatotoxicity has been reported, especially in those with preexisting liver disease.
	DRV/c Specific considerations	• Coformulated as DRV/c and DRV/c/TAF/FTC	• COBI inhibits active tubular secretion of Cr and can increase serum Cr without affecting renal glomerular function. • Coadministration with TDF **is not recommended** in people with CrCl <70 mL/min.

Table 9. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy Listed in Table 6a and Table 6b

ARV Class	ARV Agent(s)	Advantage(s)	Disadvantage(s)
			• COBI (like RTV) is a potent CYP3A4 inhibitor, which can result in significant interactions with CYP3A substrates. • COBI should be avoided in pregnancy because levels of COBI and its boosted drugs are lower in the second and third trimesters. If women who are pregnant with suppressed virus on DRV/c elect to continue on the drug, frequent viral load monitoring is recommended.

Management of People With HIV and Antiretroviral Therapy Experience

Virologic Failure

Updated: September 12, 2024
Reviewed: September 12, 2024

Key Considerations and Recommendations
• Assessing and managing a person with HIV who is experiencing antiretroviral therapy (ART) failure can be complex. Expert advice can be critical and should be sought in many instances. • Evaluation of virologic failure should include an assessment of ART adherence, drug–drug and drug–food interactions, drug tolerability, HIV RNA level and CD4 T lymphocyte (CD4) cell count trends over time, ART history, and prior and current drug-resistance test results. • Drug-resistance testing should be performed while the person is taking the failing antiretroviral (ARV) regimen **(AI)** or within 4 weeks of discontinuing a non–long-acting ARV regimen **(AII).** If more than 4 weeks have elapsed since non–long-acting ARV regimens were discontinued, resistance testing still can provide useful information to guide therapy, although it may not detect previously selected resistance mutations **(CIII).** • For people who previously received long-acting (LA) cabotegravir (CAB) plus rilpivirine (RPV), or LA CAB/RPV, and present with virologic failure, resistance testing (including integrase strand transfer inhibitor [INSTI] genotypic testing) should be performed regardless of the time since the last dose of LA CAB/RPV **(AIII).** • The goal of treatment for people with HIV with drug resistance who are experiencing virologic failure is to establish virologic suppression (i.e., HIV RNA levels below the lower limits of detection of currently used assays) **(AI).** • A new ARV regimen should preferably include two fully active drugs if at least one has a high resistance barrier, such as a second-generation INSTI or a boosted protease inhibitor (PI) **(AI).** • A new ARV regimen can also include a second-generation INSTI (i.e., dolutegravir [DTG]) plus a boosted PI (preferably boosted darunavir) without nucleoside reverse transcriptase inhibitors (NRTIs) if both are fully active **(AI)**. • If the above two options are not feasible, a new ARV regimen that includes at least one drug with a high resistance barrier plus two partially active NRTIs—particularly tenofovir alafenamide (TAF) or tenofovir disoproxil fumarate (TDF) with lamivudine (3TC) or emtricitabine (FTC)—can also be considered, although this is a less well-defined strategy and is based on an extrapolation of existing data. Caution with close monitoring of virologic response is advised **(BII),** as discussed below. • If no fully active drug with a high resistance barrier is available, every effort should be made to include three fully active drugs in the new ARV regimen **(AI).** • In general, adding a single ARV drug to a virologically failing regimen **is not recommended,** because this would rarely result in full virologic suppression and may risk the development of resistance to all drugs in the regimen **(BII).** • In some rare instances, it might not be possible to achieve maximal virologic suppression in people with HIV who are highly ART-experienced and have extensive drug resistance. In this case, ART should be continued **(AI)** with regimens that are designed to maintain CD4 counts, preserve treatment options, delay clinical progression, and minimize toxicity. • When it is not possible to construct a viable suppressive regimen for a person with multidrug-resistant HIV, the clinician should consider enrolling the person in a clinical trial of investigational agents or contacting pharmaceutical companies that may have investigational agents available.

- In people with HIV and virologic failure, it is crucial to provide continuous adherence support before and after ARV regimen changes.
- When switching an ARV regimen in a person with hepatitis B virus (HBV)/HIV coinfection, the person should remain on an ARV agent that is active against HBV and has a high resistance barrier to HBV (i.e., TAF, TDF, or entecavir) to avoid HBV rebound and hepatocellular damage **(AII)** (see Hepatitis B Virus/HIV Coinfection for more information).
- Discontinuing or briefly interrupting therapy may lead to a rapid increase in HIV RNA, a decrease in CD4 count, and an increase in the risk of clinical progression. Therefore, discontinuing or interrupting ART **is not recommended** in the setting of virologic failure **(AI).**

Rating of Recommendations: *A = Strong; B = Moderate; C = Weak*

Rating of Evidence: *I = Data from randomized controlled trials; II = Data from well-designed nonrandomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion*

Antiretroviral (ARV) regimens that are currently recommended for initial therapy in people with HIV have a high likelihood of achieving and maintaining plasma HIV RNA levels that are below the lower limits of detection (LLOD) of currently used assays (see Initial Combination Antiretroviral Regimens for People With HIV). People on antiretroviral therapy (ART) who do not achieve this treatment goal or who experience virologic rebound can develop resistance mutations to one or more components of their ARV regimen with possible cross-resistance to other ARVs. Adherence to ARV regimens can be challenging for some people with HIV, and poor adherence can result in detectable HIV RNA levels. The extent of drug resistance varies based on ARV treatment history, with some people having minimal or no resistance and others with extensive resistance. Managing people with extensive resistance is complex and usually requires consultation with an HIV expert. This section of the guidelines defines virologic failure in people on ART and discusses strategies to manage ART in these individuals.

Virologic Response Definitions

The following definitions are used in this section to describe the different levels of virologic response to ART.

- **Virologic suppression:** A confirmed HIV RNA level below the LLOD of available assays.
- **Virologic failure:** The inability to achieve or maintain suppression of viral replication to HIV RNA level <200 copies/mL.
- **Incomplete virologic response:** Two consecutive plasma HIV RNA levels ≥200 copies/mL after 24 weeks on an ARV regimen in a person who has not yet had documented virologic suppression on that regimen. A person's baseline HIV RNA level may affect the time course of response, and some regimens may take longer than others to suppress HIV RNA levels.
- **Virologic rebound:** After virologic suppression, confirmed HIV RNA level ≥200 copies/mL.
- **Virologic blip:** After virologic suppression, an isolated detectable HIV RNA level that is followed by a return to virologic suppression.
- **Low-level viremia:** Confirmed HIV RNA level above the LLOD but <200 copies/mL.

Antiretroviral Therapy Goals and Presence of Viremia While on Antiretroviral Therapy

The goal of ART is to suppress HIV replication to a level below which drug-resistance mutations cannot emerge. Although not conclusive, the evidence suggests that selection of drug-resistance mutations does not occur in people with HIV RNA levels that are persistently suppressed below the LLOD of current assays.[1]

Virologic blips are not usually associated with subsequent virologic failure.[2] In contrast, there is controversy regarding the clinical implications of low-level viremia, i.e., persistent HIV RNA levels between the LLOD and <200 copies/mL in people on ART. Viremia at this threshold is detected with some frequency by commonly used real-time polymerase chain reaction (PCR) assays, which are more sensitive than the PCR-based HIV RNA platforms used in the past.[3-5] Several retrospective studies support the supposition that virologic failure is more likely to occur in people with HIV RNA levels ≥200 copies/mL than in those with low-level viremia between 50 copies/mL and 199 copies/mL.[6-8] However, other studies have suggested that detectable viremia at <200 copies/mL can be predictive of virologic failure[9] and can be associated with the evolution of drug resistance[10] and non-AIDS morbidities.[11]

Persistent HIV RNA levels ≥200 copies/mL are often associated with evidence of viral evolution and accumulation of drug-resistance mutations.[12] This association is particularly common with HIV RNA levels >500 copies/mL.[13] Therefore, people who have persistent HIV RNA levels ≥200 copies/mL are considered to be experiencing virologic failure.

Causes of Virologic Failure

Virologic failure can occur for many reasons. Data from cohorts in the earlier era of combination ART suggested that suboptimal adherence and drug intolerance/toxicity are key contributors to virologic failure and regimen discontinuations.[14,15] Current ARVs are easier to tolerate and have less pill burden, which may improve adherence.[16-18] Virologic failure may be associated with a variety of factors, including the following:

HIV-Related Factors

- Presence of transmitted or acquired drug-resistant virus that may or may not be documented by current or past drug-resistance test results
- Prior ARV treatment failure
- Innate drug resistance to prescribed ARV drugs
- Higher pre-treatment HIV RNA levels (e.g., HIV RNA >100,000 copies/mL; some regimens may be less effective at higher levels)

Antiretroviral Regimen–Related Factors

- Suboptimal pharmacokinetics (PK) (e.g., variable absorption, metabolism, penetration into reservoirs)
- Suboptimal virologic potency

- Low barrier to resistance
- Reduced efficacy due to prior exposure to suboptimal regimens (e.g., monotherapy, dual–nucleoside reverse transcriptase inhibitor [NRTI] therapy, or the sequential introduction of drugs)
- Food requirements
- Drug–drug interactions with concomitant medications, which may reduce concentrations of the ARV drugs
- Adverse drug effects
- High pill burden and/or dosing frequency
- Prescription (prescribing or dispensing) errors

Social and Adherence-Related Factors

Note: Each of the social and adherence-related factors listed below are discussed in the Adherence to the Continuum of Care section.

- Active substance use, mental health disorders, or neurocognitive impairment
- Unstable housing and other psychosocial factors
- Missed clinic appointments
- Interruption of or intermittent access to ART
- Cost and affordability of ARV drugs, which may affect the ability to access or continue therapy (see the Cost Considerations and Antiretroviral Therapy section)

Managing People With HIV and Virologic Failure

If virologic failure is suspected or confirmed, a thorough assessment of whether one or more of the above factors could have been the cause(s) of failure is indicated. The causes of virologic failure can usually be identified but may not be obvious in some cases. Distinguishing among the causes of virologic failure is important, because the approaches to subsequent therapy may differ, depending on the cause. Potential causes of virologic failure should be explored in depth. Once virologic failure is confirmed, steps should be taken to improve virologic outcomes. If a new ARV regimen is needed, approaches to designing a new regimen are discussed below.

Key Factors to Consider When Designing a New Antiretroviral Regimen After Virologic Failure

General Principles on Antiretroviral Use in Virologic Failure

- When designing a new ARV regimen for a person with virologic failure, it is important to consider the factors outlined above on causes of virologic failure and, if possible, consider better tolerated and adherence-friendly regimens.
- A new ARV regimen should be selected based on ART history, current and previous drug-resistance test results, and whether a fully susceptible ARV drug with a high barrier to resistance and other fully active drugs are available.[9,19-31]

- ARV drugs with a high barrier to resistance are those in which emergent resistance is uncommon in people experiencing virologic failure. These include boosted darunavir (DRV), dolutegravir (DTG), and bictegravir (BIC).
- Fully active drugs may include—
  - Drugs in classes for which the person has not previously selected for drug-resistant virus.
  - Newer drugs in existing drug classes that are predicted to be fully active against HIV isolates despite the presence of resistance mutations for some drugs in the same drug class. For example, the non-nucleoside reverse transcriptase inhibitors (NNRTIs) etravirine and possibly doravirine (DOR), the protease inhibitor DRV, and the integrase strand transfer inhibitors (INSTIs) DTG and BIC. However, clinical data supporting the use of DOR or BIC in the setting of virologic failure are limited.
  - Drugs with novel mechanisms of action that the person with HIV has not received before, such as the post-attachment inhibitor ibalizumab (IBA), the gp120 attachment inhibitor fostemsavir (FTR), the capsid inhibitor lenacapavir (LEN), the fusion inhibitor enfuvirtide (T-20), or the CCR5 antagonist maraviroc (MVC) in people with no detectable CXCR4-using virus.
- ARV drugs with partial activity are those predicted to have antiviral activity but to a lesser extent than when there is no underlying drug resistance.
- Administering a drug that a person has never used does not ensure that the drug will be fully or partially active; the potential exists for cross-resistance among drugs from the same class.
- Discontinuing or briefly interrupting therapy in a person with viremia **is not recommended** because it may increase HIV RNA levels, decrease CD4 T lymphocyte (CD4) cell count, and increase the risk of clinical progression **(AI)**[32,33] (see Discontinuation or Interruption of Antiretroviral Therapy).
- The presence of preexisting (transmitted) drug resistance also may lead to virologic failure.[34,35]

Drug-Resistance Testing to Guide New Antiretroviral Regimens

- The Panel on Antiretroviral Guidelines for Adults and Adolescents (the Panel) recommends that drug-resistance testing should be used to guide ARV regimen design and should be performed while the person with HIV is still taking the failing regimen **(AI)** or within 4 weeks of discontinuation of a non–long-acting regimen **(AII).** If more than 4 weeks have elapsed since discontinuation of a non–long-acting regimen, drug-resistance testing still may provide useful information to guide therapy, although it may not detect previously selected resistance mutations **(CIII).**
- Drug-resistance testing is recommended in persons with confirmed virologic failure, i.e., HIV RNA repeatedly >200 copies/mL (**AI** for >1,000 copies/mL, **AIII** for 501–1,000 copies/mL, **CIII** for confirmed 201–500 copies/mL), although at low HIV RNA levels, testing may be difficult to obtain outside of a research setting. In persons with HIV RNA >200 copies/mL but <500 copies/mL, testing may be unsuccessful, but it still should be considered.
- Drug resistance is cumulative, meaning that once a mutation is detected in a resistance assay, it should be considered present in that person's HIV thereafter (this is sometimes referred to as "archived" resistance), regardless of whether it appears on subsequent drug-resistance assays.

Thus, clinicians should evaluate the extent of drug resistance, taking into account all of the person's ART history and, importantly, prior genotypic- or phenotypic-resistance test results.

- Activity of ART based on current and cumulative genotypic mutations can be estimated by tools and interpretation algorithms, such as the Stanford University HIV Drug-Resistance Database. Also see Drug-Resistance Testing.
- Some drug-resistance assays only detect resistance to NRTIs, NNRTIs, or protease inhibitors (PIs); INSTI-resistance testing may need to be ordered separately. INSTI-resistance testing should be ordered in people who experience virologic failure on an INSTI-based regimen. Additional drug-resistance tests for people who experience failure on a fusion inhibitor **(AII),** and viral tropism tests for people who experience failure on a CCR5 antagonist **(BIII)** are also available. There is currently no commercially available resistance test for IBA, FTR, or LEN (see Drug-Resistance Testing).

Strategies for New Antiretroviral Regimen Design

- A new ARV regimen should preferably include two fully active drugs if at least one has a high resistance barrier, such as a second-generation INSTI or a boosted PI **(AI).**[36]
- A new ARV regimen can also include a second-generation INSTI (e.g., DTG) plus a boosted PI (preferably boosted DRV) without NRTIs if both are fully active **(AI);**[37-41] see more detailed discussion in *Managing Virologic Failure in Different Clinical Scenarios* below. If this regimen is used in people with hepatitis B virus (HBV)/HIV coinfection, an HBV-active drug with a high barrier to resistance (e.g., tenofovir alafenamide [TAF], tenofovir disoproxil fumarate [TDF], or entecavir) should be continued or started to avoid HBV rebound and hepatocellular damage.
- If the above two options are not feasible, a new ARV regimen can also include a fully active drug with a high resistance barrier plus two partially active NRTIs—particularly TAF or TDF with lamivudine (3TC) or emtricitabine (FTC)—though this is less well-defined and close monitoring is advised **(BII);** this is discussed in more detail in *Managing Virologic Failure in Different Clinical Scenarios* below.[36,37,42,43]
- If no fully active drug with a high resistance barrier is available, every effort should be made to include three fully active drugs in the regimen **(AI).** See the clinical scenarios below for further guidance on the number of fully active drugs a regimen should contain.
- Despite the presence of drug-resistance mutations, some ARV drugs in the regimen may still have partial activity against the person's HIV and may be retained as part of a salvage regimen. These drugs may include NRTIs, PIs, and second-generation INSTIs, although dosing of some drugs (e.g., DRV and DTG) may need to be increased when treating people with relevant resistance mutations to achieve drug concentrations necessary to be at least partially active against a less sensitive virus.[44-46]
- In contrast, other agents in which resistance may be expected should be discontinued, because their continued use is unlikely to contribute to virologic suppression. These drugs include NNRTIs (especially efavirenz, nevirapine, and rilpivirine [RPV]), the first-generation INSTIs raltegravir (RAL) and elvitegravir (EVG), and T-20.[47-49]
- Long-acting (LA) cabotegravir (CAB)/rilpivirine (RPV) is currently approved as a complete ART regimen for individuals engaged in care who have good adherence to an oral regimen, sustained undetectable HIV RNA levels for >3 months, no known or suspected resistance to

either drug, and no active HBV infection. To date, no large or randomized clinical trials have been published using any INSTI plus NNRTI, including LA CAB/RPV, as a complete regimen for people without viral suppression. However, a few small observational studies have shown that people with viremia despite intensive efforts on oral ART, without resistance to CAB or RPV, can achieve viral suppression with LA CAB/RPV when intensive supportive services are available.[50-53] If considering LA CAB/RPV in this population, it is important to note that data are limited, and this is not an approved indication of the regimen. If the regimen is used in people with inconsistent adherence and virologic failure, there is a high likelihood of developing acquired resistance to CAB and/or RPV, which might limit future treatment options. The approaches and considerations for the use of LA CAB/RPV in people with viremia is further outlined below.

- When changing an ARV regimen in a person with HBV/HIV coinfection, ARV drugs that are active against HBV (especially TAF or TDF) should be continued as part of the new regimen or, if not possible, entecavir should be initiated **(AII).** Using 3TC or FTC as the only drug with HBV activity in a regimen **is not recommended (AII)** because HBV resistance to these drugs can emerge. Discontinuation of these drugs may lead to the reactivation of HBV, which may result in serious hepatocellular damage (see Hepatitis B Virus/HIV Coinfection).
- Virologic responses should be closely monitored after regimen switch (e.g., HIV RNA level testing performed within 4 to 8 weeks), with prompt drug-resistance testing if virologic response is inadequate.

Managing Virologic Failure in Individuals With Different Levels of Viremia

People with HIV and detectable HIV RNA levels while on ART comprise a heterogeneous group of individuals with different ART exposure histories, degrees of drug resistance, durations of virologic failure, and levels of plasma viremia. Management strategies should be individualized. The first steps are to confirm the level of HIV viremia and to assess and address adherence and potential drug–drug interactions (including interactions with over-the-counter products and supplements) and drug–food interactions. Some general approaches based on the level of viremia are addressed below.

- **Low-level viremia (HIV RNA above the LLOD and <200 copies/mL):** People who have these HIV RNA levels do not typically require a change in treatment **(AII).**[4] Although there is no consensus on how to manage these individuals, the risk that drug resistance will emerge is believed to be relatively low. Therefore, these individuals should continue their current regimens and have their HIV RNA levels monitored at least every 3 months to assess the need for changes to ART in the future **(AIII).**
- **HIV RNA ≥200 copies/mL and <1,000 copies/mL:** In contrast to people with detectable HIV RNA levels that are persistently <200 copies/mL, people with levels that are persistently ≥200 copies/mL often develop drug resistance, particularly when HIV RNA levels are >500 copies/mL.[6,7] People who have persistent plasma HIV RNA levels in the range of 200 copies/mL to 1,000 copies/mL are considered to be experiencing virologic failure, and drug-resistance testing should be attempted, particularly in people with HIV RNA levels >500 copies/mL (at <500 copies/mL, testing may not be possible for technical reasons). Management approaches should be the same as for people with HIV RNA >1,000 copies/mL (as outlined below). When drug-resistance testing cannot be performed because of low HIV RNA levels, the decision of whether to empirically change ARV drugs should be made on a case-by-case basis, taking into account whether a new regimen that is expected to fully suppress viremia

can be constructed. If genotypic-resistance test results cannot be obtained because of low HIV RNA levels, proviral DNA genotypic testing may be considered. Results from this test should be interpreted with caution because these assays might miss some or all previously existing drug-resistance mutations. However, mutations that are detected using proviral DNA genotypic testing may be significant and can affect the effectiveness of future regimens (see Drug-Resistance Testing).

- **HIV RNA ≥1,000 copies/mL and no drug-resistance mutations identified using current or previous genotypic-resistance test results:** This scenario is almost always associated with suboptimal adherence. A thorough assessment should be conducted to evaluate the level of adherence, identify and address the underlying cause(s) for incomplete adherence and, if possible, simplify the regimen (e.g., decrease pill count, simplify food requirement or dosing frequency; see Adherence to the Continuum of Care). Assessment includes the following:
    - Assessing the person's access to ART, including access to pharmacy, refills, and copays or patient assistance programs, and seeking assistance to overcome any barriers to consistent access to ART.
    - Assessing social determinants that may impact adherence (e.g., substance use, unstable housing, mental health challenges, etc.).
    - Assessing the person's tolerance of the current ARV regimen and the severity and duration of side effects if intolerance is a concern, while considering that even minor side effects can affect adherence.
    - Addressing intolerance by treating symptoms (e.g., with antiemetics or antidiarrheals), switching one ARV agent in a regimen to another agent in the same drug class, or switching from one drug class to another class (e.g., from an NNRTI to a PI or an INSTI; see Adverse Effects of Antiretroviral Agents).
    - Reviewing food requirements for each medication and assessing whether the person adheres to the requirements.
    - Assessing whether a recent history of gastrointestinal symptoms (e.g., vomiting, diarrhea) may result in short-term malabsorption.
    - Reviewing concomitant medications (including over-the-counter medications and dietary supplements) for possible adverse drug–drug interactions (consult Drug–Drug Interactions and Tables 24a through 25b for common interactions) and, if possible, making appropriate substitutions for ARV agents and/or concomitant medications.
    - Considering therapeutic drug monitoring if PK drug–drug interactions (e.g., when used with rifamycin) or impaired drug absorption (e.g., using polyvalent cations with an INSTI) leading to decreased ARV drug exposure is suspected.
    - Considering the timing of the drug-resistance test (e.g., was the person mostly or completely nonadherent to oral ART for >4 weeks before testing?) (see Drug-Resistance Testing).
    - After a thorough assessment, the following approaches may be considered:
        - If the current regimen is well tolerated, with no significant drug–drug or drug–food interactions, it is reasonable to continue the same regimen while focusing on improving adherence.

  - If the agents are poorly tolerated or have important drug–drug or drug–food interactions, changing the regimen to an equally effective but more tolerable regimen should be considered.
  - HIV RNA level testing should be repeated 4 to 8 weeks after treatment adherence is encouraged or treatment is modified **(AII);** if RNA levels remain >200 copies/mL, genotypic drug-resistance testing should be performed to determine whether a resistant viral strain has emerged (**AI** for >1,000 copies/mL, **AIII** for 501–1,000 copies/mL, **CIII** for 201–500 copies/mL), though at low RNA levels, testing may be difficult to obtain outside of a research setting.

- **HIV RNA >1,000 copies/mL and drug resistance identified:** If new or previously detected resistance mutations compromise the regimen, the regimen should be modified as soon as possible to avoid progressive accumulation of resistance mutations.[54] In addition, several studies have shown that virologic responses to new and fully active regimens are greater in individuals with lower HIV RNA levels and/or higher CD4 counts at the time of regimen changes; thus, the change is best done before viremia worsens or before CD4 count declines.[9,55] The availability of newer ARV drugs, including some with new mechanisms of action, makes it possible to suppress HIV RNA levels to below the LLOD in most people with HIV. The options in this setting depend on the extent of drug resistance and are addressed in the clinical scenarios outlined below.

Managing Virologic Failure in Different Clinical Scenarios

Note: See Table 10 below for a summary of these recommendations.

Virologic Failure on the First Antiretroviral Regimen

The Panel recommends that drug-resistance testing should be performed upon treatment failure to inform regimen design **(AI).**

NNRTI plus NRTI regimen failure: Although an NNRTI plus NRTI regimen is no longer considered a preferred first-line ART option in treatment guidelines, data from clinical trials comparing different ARV regimens after NNRTI plus NRTI failure provide the most robust evidence to inform second-line treatment strategies and, therefore, are included here.

In this setting, people with HIV often have viral resistance to the NNRTI, with or without the M184V/I mutation, which confers high-level resistance to 3TC and FTC. Additional NRTI mutations also may be present. Below are some treatment options.

- **Second-generation INSTI (BIC or DTG) plus NRTIs:** The Panel recommends that fully active DTG plus two NRTIs, at least one of which is fully active, can be a treatment option after failure of a first-line NNRTI-based therapy **(AI).** BIC, which is available only in a combination pill with FTC/TAF, also has a high resistance barrier and may have similar activity to that of DTG in this setting, and is also an option **(AIII);** however, no clinical trial data for this strategy with BIC is available. If at least one fully active NRTI cannot be assured and a clinician wants to avoid using a boosted PI or a drug from other classes, a regimen that includes fully active DTG plus two NRTIs that are estimated to be only partially active (particularly TAF or TDF with 3TC or FTC) can be considered, with caution and close monitoring of viral response, as further discussed below **(BII).**

In the DAWNING trial, participants from 13 countries who experienced virologic failure while on a first-line NNRTI-based regimen were randomized to receive either lopinavir/ritonavir(LPV/r) or DTG, each with two NRTIs, one of which had to be fully active based on real-time drug-resistance testing. The study was stopped early after an interim analysis showed that the DTG arm was superior to the LPV/r arm. The superiority of DTG was somewhat counterbalanced by the finding that 2 of 11 participants in the DTG arm who met virologic withdrawal criteria selected for INSTI resistance, with no PI resistance selected for in the LPV/r arm.[36]

In the NADIA trial, participants in Uganda, Kenya, and Zimbabwe who experienced virologic failure while on a first-line NNRTI plus TDF and 3TC or FTC were randomized to receive either darunavir/ritonavir (DRV/r) or DTG, each with 3TC; participants were assigned by a second randomization to receive a third ARV, either TDF or zidovudine (ZDV). Unlike the DAWNING study, full activity of the NRTIs based on genotype testing at the time of switch was not required.[42,43] The primary study outcome was virologic suppression <400 copies/mL; at 48 and 96 weeks, >85% of participants had HIV RNA levels <400 copies/mL in all arms, and the DTG-based regimens were non-inferior to the DRV/r-based regimens. However, at 96 weeks, 9 of 235 (4%) participants in the DTG group developed DTG resistance. This represented 45% of participants in the DTG group with HIV RNA levels >400 copies/mL, six of whom were assigned to ZDV. In contrast, no PI resistance was selected for in the DRV/r group. When comparing TDF with ZDV, the two NRTIs demonstrated virologic suppression noninferiority at 48 weeks, but TDF was superior to ZDV at 96 weeks. These results included 84 of 92 (91%) participants in the DTG group who had virologic suppression <400 copies/mL despite no predicted active NRTIs at the time of failure of first-line NNRTI-based regimens, and a large proportion of this group had the K65R and M184V/I mutations. Individual-level drug-resistance data would have enabled further examination of specific mutation patterns and their association with patient characteristics and treatment outcomes. Although such data are not available, these results suggest that ZDV should not be used over TDF in a public health approach. The decision to use DTG or DRV/r without another fully active drug should balance the overall efficacy data of these regimens, with considerations for potential emergent drug resistance, drug–drug interactions, convenience, and tolerability. The results from these studies should be interpreted with caution, as individual-level drug-resistance data and their linkage to patient characteristics and outcomes were not available, thus preventing full interpretation of these results. Additionally, these results may not be generalizable to settings and populations outside of the trials due to differences in geography, HIV-1 subtype, study population, ART availability, and treatment monitoring practice.

- **Boosted PI plus NRTIs:** The Panel recommends that a boosted PI (preferably boosted DRV) plus two NRTIs, at least one of which is fully active, can be an option after failure of a first-line NNRTI-based therapy **(AI).** However, if full activity of at least one NRTI in the regimen cannot be assured, fully active boosted DRV plus two NRTIs estimated to be only partially active (particularly TAF or TDF with 3TC or FTC) can be considered, with close monitoring **(BII).** Notably, boosted PIs as monotherapy **are not recommended (AI).**[37,39,40,42,43,56]

  Several large, randomized controlled trials (primarily conducted in resource-limited settings where NNRTI-based regimens have been used as first-line therapy) have explored different second-line regimen options. The studies found that regimens that contained LPV/r or DRV/r plus at least two NRTIs were as effective as regimens that contained LPV/r plus RAL or DTG plus two NRTIs. Participants in some of these studies did not undergo drug-resistance testing before randomization. In the NADIA trial (summarized above), virologic efficacy of DTG and DRV/r-based regimens were non-inferior at 48 and 96 weeks, with TDF being non-inferior at

48 weeks and superior at 96 weeks compared with ZDV. Although there were nine participants in the DTG group who developed DTG resistance (six on ZDV and three on TDF), no participant in the DRV/r group developed PI resistance. Additionally, 74 of 80 (93%) participants in the DRV/r group had virologic suppression <400 copies/mL at 96 weeks despite no predicted active NRTIs at the time of failure of first-line NNRTI-based regimens. As outlined above in the discussion about second-generation INSTI plus no estimated fully active NRTIs based on current drug-resistance algorithms, these results should be interpreted with caution within, and particularly beyond, the study populations and settings.

- **Boosted PI plus an INSTI:** The Panel recommends that boosted DRV plus DTG, both with high barriers to resistance, should be the preferred boosted PI plus INSTI option **(AI).** In a setting where a two-drug boosted PI and INSTI combination are being considered and both boosted DRV and DTG cannot be used, LPV/r plus RAL can be a treatment option for those who experienced virologic failure on an NNRTI-based regimen **(CI).**

  D^2EFT is an open-label multinational randomized controlled trial that assessed the efficacies of DRV/r plus DTG versus DTG plus two NRTIs versus standard of care (DRV/r plus two NRTIs) for participants with first-line failure of an NNRTI-based regimen.[41] In D^2EFT, TDF plus 3TC or FTC were the NRTIs used. At 48 weeks, the proportion of participants who achieved HIV RNA <50 copies/mL was 84% for the DRV/r + DTG arm, 75% for the DRV/r plus two NRTI arm, and 78% for the DTG plus two NRTI arm, showing that the DRV/r + DTG arm was non-inferior to the other two regimens, with more participants achieving viral suppression. Several other small retrospective studies have found that a regimen of boosted DRV plus DTG is effective in achieving viral suppression in people with documented resistance to multiple drug classes.[57-59] Three randomized controlled trials have found that a regimen that consisted of LPV/r plus RAL can be as effective as LPV/r plus at least two NRTIs as second-line therapy for people who failed first-line ART (mostly with an NNRTI-based regimen).[37,39,40]

  If this regimen is used in people with HBV coinfection, an HBV-active drug with a high barrier to resistance (i.e., TAF, TDF, or entecavir) should be continued or started to avoid HBV rebound and hepatocellular damage.

Boosted PI plus NRTI regimen failure: In this scenario, because boosted PI has a high barrier to resistance, most people will have either no resistance or resistance that is limited to 3TC and FTC, though additional NRTI mutations also may be present.[60,61] Failure in this setting is often attributed to poor adherence, drug–drug interactions, or drug–food interactions. Below are some management options.

- **Switch to a second-generation INSTI plus NRTIs regimen:** Second-generation INSTIs have increasingly become preferred options over boosted PIs due to lower drug–drug interaction potential, improved tolerability, comparable efficacy, and a high barrier to resistance. Therefore, consideration should be given to switching to DTG or possibly BIC plus two NRTIs (if at least one of them is fully active) **(AIII).** If only one of the NRTIs is fully active or if adherence is a concern, DTG is currently preferred over BIC **(AIII).** If full activity of at least one NRTI in the regimen cannot be assured, DTG plus two NRTIs estimated to be only partially active based on current drug-resistance algorithms (particularly TAF or TDF with 3TC or FTC) can be considered **(CIII).** As outlined above, results from studies that may suggest such extrapolations should be interpreted with caution, as they did not involve failure of first-line boosted PI plus NRTIs regimens and as individual-level drug-resistance data and their linkage to patient characteristics and outcomes were not available, thus preventing full interpretation of these results. Additionally, these results may not be generalizable to settings and populations

outside of the trials due to differences in geography, HIV-1 subtype, patient population, ART availability, and treatment monitoring practice.

- **Maintain the same regimen:** A systematic review of multiple randomized trials that investigated the failures of first-line ritonavir-boosted PI-based regimens showed that taking actions to improve adherence to the original regimen is as effective as changing to new regimens with or without drugs from new classes **(AII).**[62] If the regimen is well tolerated with no concerns about drug–drug or drug–food interactions or drug resistance, then the regimen can be continued with adherence support and viral monitoring.
- **Switch to another PI-based regimen:** If a regimen with an INSTI plus two NRTIs is not an option and poor tolerability is contributing to virologic failure, the regimen can be modified with a different boosted PI that has no evidence for cross-resistance, plus a second-generation INSTI **(AIII),** or plus two NRTIs (at least one of which is fully active) **(AIII).** If full activity of at least one NRTI in the regimen cannot be assured, another fully active boosted PI plus two NRTIs estimated to be only partially active (particularly TAF or TDF with 3TC or FTC) can be considered, with close monitoring of viral response **(BIII).**

INSTI plus NRTI regimen failure: Virologic failure in people on a regimen that consists of RAL or EVG plus two NRTIs may be associated with emergent resistance to 3TC or FTC (with/without additional NRTI mutations) and, possibly, the INSTI.[63] Viruses with EVG or RAL resistance often remain susceptible to DTG and BIC.[55] However, in the presence of certain INSTI mutations, DTG dose should be increased from once daily to twice daily.[44] The effective dose of BIC in these situations is unknown. In contrast, in clinical trials, people who experienced virologic failure while receiving DTG or BIC plus two NRTIs as first-line therapy were unlikely to develop resistance to DTG or BIC.[63-65] No existing clinical trial data guide therapy for first-line INSTI failures; therefore, treatment strategy should be based on drug-resistance test results and the potential potency of the next regimen. Below are some treatment options, based on drug-resistance pattern considerations.

- **Virologic failure without any resistance mutations:** The person with HIV should be managed as outlined above in the section on virologic failure without drug resistance.
- **Virologic failure without INSTI resistance:** The regimen can be modified to one of the following:
  - A boosted PI plus two NRTIs (preferably at least one of which is fully active) **(AIII);** *or*
  - DTG, or likely BIC, plus two NRTIs (preferably at least one of which is fully active) **(AIII);** *or*
  - A boosted PI plus DTG **(AIII).**
- **Virologic failure with resistance to RAL and/or EVG but susceptibility to DTG:** The regimen can be modified to one of the following:
  - A boosted PI plus two NRTIs (preferably at least one of which is fully active) **(AIII);** *or*
  - DTG (twice daily) plus two NRTIs (at least one of which is fully active) **(BIII);** *or*
  - DTG (twice daily) plus a boosted PI **(AIII).**

Although BIC has a high resistance barrier, there are no data on whether the current BIC dose is efficacious in settings with RAL or EVG resistance and, therefore, it **is not currently recommended (BIII).**

INSTI plus NNRTI regimen failure: Virologic failure in people on a regimen that consists of an INSTI (e.g., DTG or CAB) plus an NNRTI (e.g., RPV) may be associated with resistance to one or both of the medications in the regimen.[66,67] Experience to guide therapy upon failure of these regimens is limited. Therefore, treatment strategies should be based on past treatment history, drug-resistance test results, and the potential potency of the next regimen, based on the guidance provided above.

Second-Line Regimen Failure and Beyond

Drug resistance with fully active commonly used ARV drug options: Using a person's complete ARV treatment history and drug-resistance data, a clinician can decide whether to include a fully active boosted PI or INSTI in future regimens. For example, those who have no documented PI resistance and who have never been treated with an unboosted PI likely harbor virus that is fully susceptible to PIs. Similarly, people who have no documented INSTI resistance and who have never been treated with an INSTI are likely to have virus susceptible to DTG or BIC. In this setting, virologic suppression should be achievable using a boosted PI plus either two NRTIs (preferably at least one of which is fully active), a boosted PI plus an active INSTI, or DTG or BIC plus two NRTIs (preferably at least one of which is fully active). Drugs should be selected based on the likelihood that they will be fully active, as determined by the person's treatment history, past and present drug-resistance testing, and tropism testing if a CCR5 antagonist is being considered.

Multidrug resistance without fully active commonly used ARV drug options: Use of currently available ARV drugs has resulted in a dramatic decline in the number of people with HIV who have few treatment options because of multiclass drug resistance.[68,69] Despite this progress, some people have experienced toxicities with and/or developed resistance to most currently available commonly used ARV drugs. Maximal virologic suppression should remain the goal; however, if it cannot be achieved, the goals of ART will be to preserve immunologic function, prevent clinical progression, and minimize the development of further resistance that may compromise future regimens.

Consensus on the optimal management of people with multidrug-resistant HIV is lacking. If neither a fully active boosted PI nor a second-generation INSTI (e.g., DTG or BIC) is available, the new regimen should include at least two, and preferably three, fully active agents. If less than three fully active drugs are available, the regimen should include as many fully active drugs as possible, along with potentially partially active agents **(BII).** If resistance to NNRTIs, T-20, MVC, BIC, DTG, CAB, EVG, or RAL are identified, there is rarely a reason to continue using these drugs, because there is little evidence that keeping them in the regimen helps delay disease progression **(BII).** Moreover, continuing these drugs (in particular, early-generation INSTIs) may allow selection of additional resistance mutations and development of within-class cross-resistance that may limit future treatment options. It should be noted that even partial virologic suppression of HIV RNA to >0.5 $\log_{10}$ copies/mL from baseline correlates with clinical benefit.[68,70] Cohort studies provide evidence that even in the presence of viremia and no improvement in CD4 count, continuing ART reduces the risk of disease progression.[71] Other cohort studies suggest that even modest reductions in HIV RNA levels continue to confer immunologic and clinical benefits.[72,73] However, these potential benefits must be balanced with the ongoing risk of accumulating additional resistance mutations. In general, adding a single, fully active ARV drug to the regimen **is not recommended** because of the risk of rapid development of resistance **(BII).**

People with HIV and ongoing detectable viremia who lack sufficient treatment options due to an inability to construct a fully suppressive regimen with common ARVs may be candidates for the

first-in-class CD4 post-attachment inhibitor IBA,[74] the gp120-directed attachment inhibitor FTR,[75] and/or the capsid inhibitor LEN.[76]

- **Ibalizumab (IBA)** is a long-acting CD4 post-attachment inhibitor that is given intravenously every 2 weeks. A single-arm, multicenter clinical trial enrolled 40 heavily ART-experienced participants who had multidrug-resistant HIV-1 and who were experiencing virologic failure on an ARV regimen. Subjects received intravenous IBA infusions every 2 weeks, in addition to an optimized background regimen (OBR) that included at least one additional agent to which the subject's virus was susceptible. At Week 24, 43% of participants achieved HIV RNA <50 copies/mL, and 50% achieved HIV RNA <200 copies/mL.[77] Of the 27 participants who continued to the 48-week follow-up study, 59% and 63% had HIV RNA <50 copies/mL and <200 copies/mL, respectively. All 15 participants who had HIV RNA <50 copies/mL at Week 24 maintained virologic suppression up to Week 48.[78]
- **Fostemsavir (FTR)** is a gp120 attachment inhibitor that is given orally twice daily. A Phase 3 multicenter trial enrolled 371 heavily ART-experienced participants who had multidrug-resistant HIV-1 and who were experiencing virologic failure. Participants were enrolled into two cohorts, according to their remaining treatment options. The randomized cohort (n = 272) included those with at least one fully active approved ARV drug in at least one but no more than two classes. These individuals were randomized to FTR (oral 600 mg twice daily) or placebo for 8 days, followed by open-label FTR plus OBR. In the nonrandomized cohort (n = 99), participants with no remaining ARV options were started on open-label FTR (oral 600 mg twice daily) plus OBR on Day 1. The primary endpoint for the randomized cohort was a change in HIV RNA level from baseline at Day 8. In the FTR group, the mean RNA level decrease was 0.79 $\log_{10}$ copies/mL compared to 0.17 $\log_{10}$ copies/mL in the placebo group ($P < 0.001$). At Week 96, 60% of participants in the randomized cohort and 37% of those in the nonrandomized cohort had HIV RNA levels <40 copies/mL, with mean CD4 increases of 205 cells/mm^3 and 119 cells/mm^3, respectively.[79,80] In this study, 15 individuals in the nonrandomized cohort used the CD4 post-attachment inhibitor IBA in combination with FTR and other ARVs. The virological response rate for these participants by snapshot analysis was 53% at Week 48 and 33% at Week 96.
- **Lenacapavir (LEN)** is a LA HIV capsid inhibitor that can be given by one of two initiation schemes (oral plus subcutaneous [SQ] dosing), followed by SQ injections every 6 months (see Appendix B, Table 11 for dosing details).

  A Phase 3 multicenter trial (CAPELLA) enrolled 72 heavily ART-experienced participants who had multidrug-resistant HIV-1 and experienced virologic failure into two cohorts.[81] Cohort 1 (n = 36) included participants who had a <0.5 $\log_{10}$ HIV-1 RNA decline between screening and baseline (i.e., stable viremia at ≥400 copies/mL, confirming lack of response to the failing therapy). The participants were randomized 2:1 to either oral LEN or placebo (on Days 1, 2, and 8) and continued to receive the failing ARV regimen for 14 days to evaluate the virologic effect of LEN functional monotherapy. Starting on Day 15, all participants began on an OBR; those randomized to oral LEN began SQ LEN every 6 months, whereas participants in the placebo arm received oral LEN on Days 15, 16, and 22 followed by SQ LEN on Day 29 (14 days after the first oral LEN dose) and then every 6 months. On Day 15, 88% of participants in the LEN arm and 17% in the placebo arm had HIV RNA level reduction of ≥0.5 $\log_{10}$ copies/mL, with least-squares mean change in HIV RNA level of −2.1 $\log_{10}$ copies/mL versus −0.07 $\log_{10}$ copies/mL for the LEN and placebo arms, respectively ($P < 0.001$). At the end of 26 weeks (i.e., after one dose of SQ LEN), 81% of participants had RNA levels <50 copies/mL, and 89% had RNA levels <200 copies/mL, with a mean change in RNA level of −2.58 ± 1.04 $\log_{10}$ copies/mL.[81] At the end

of 52 weeks (i.e., after two doses of SQ LEN), 83% of participants had RNA levels <50 copies/mL, with 94% of those with at least two active OBR drugs and 67% with no active OBR drugs. The mean CD4 cell count change at 52 weeks[76] was +82 cells/mm^3.

Cohort 2 (n = 36) was a nonrandomized cohort that included participants who either had a ≥0.5 $\log_{10}$ HIV-1 RNA decline from screening to baseline visit or were enrolled after Cohort 1 reached its planned sample size. All participants were started on an OBR and received oral LEN on Days 1, 2, and 8; on Day 15, SQ LEN was started and given every 6 months. After 26 weeks, 83% of the participants had HIV RNA levels <50 copies/mL, and 86% had HIV RNA levels <200 copies/mL. At Week 52, 72% had RNA levels <50 copies/mL, and the mean CD4 cell count change was +113 cells/mm^3.

Oral lead-in therapy was well tolerated overall, with nausea reported in 13% of participants who received LEN. Injection site reactions, which were generally mild and transient, were reported in 63% of the participants.[81]

Twenty-two of 72 (31%) participants met the criteria for resistance testing at confirmed virologic failure through Week 52.[76] LEN-associated capsid resistance mutations were found in 9 of the 22 (41%) participants with confirmed virologic failure. The M66I mutation was the most common mutation, reported in six participants. Four of the nine participants with LEN-associated capsid resistance mutations had no active agent in the OBR. Four others had low plasma concentrations of the OBR drugs at Week 26, suggesting poor adherence of the self-administered OBR, resulting in an unfavorable LEN functional monotherapy.[82]

Taken together, these data[76,82,83] highlight the importance of selecting a robust OBR to support LEN and counseling about adherence to the OBR. Additionally, LEN is a moderate CYP3A4 inhibitor and may increase concentrations of some coadministered drugs, whereas LEN concentration may be significantly decreased in the presence of a strong CYP3A4 inducer (see Table 24g. Drug Interactions Between the Capsid Inhibitor Lenacapavir and Other Drugs for further details). Therefore, people with HIV should be routinely counseled to inform all their health care providers of all medications they are taking, including LEN, even though it is not taken daily. Potential drug–drug interactions should be discussed, particularly before a new drug is started, to minimize the risk of toxicities, nonadherence, and drug resistance.

People with HIV who continue to have detectable viremia and who lack sufficient treatment options to construct a fully suppressive regimen also may be candidates for research studies or expanded access programs, or they may qualify for single-person access to an investigational new drug, as specified in the U.S. Food and Drug Administration's Physician Request for a Single Patient Investigational New Drug for Compassionate or Emergency Use. Information about ARV agents that are in clinical studies can be found in the drug database available on the Clinicalinfo website.

People With HIV on ART With Suspected Drug Resistance Who Present With Limited Information (Incomplete or No Self-Reported ARV History, Medical Records, or Drug-Resistance Test Results)

Every effort should be made to obtain the person's ARV history and prior drug-resistance test results; however, this may not always be possible. One strategy is to restart the most recent ARV regimen and assess drug resistance in 2 to 4 weeks to guide the selection of the next regimen. Another strategy is to start two or three drugs that are predicted to be fully active based on the person's treatment history. If no ARV history is available, a clinician may consider using agents with a high barrier to resistance—such as twice-daily DTG, BIC (which is available only in a combination pill

with FTC/TAF and for which dosage in this setting is unclear), and/or twice-daily boosted DRV—as part of the regimen. Regardless of which strategy is employed, people should be closely monitored for virologic response (e.g., HIV RNA level testing approximately 4 to 8 weeks after reinitiation of therapy), with prompt drug-resistance testing performed if virologic response is inadequate.

People With HIV Who Are Unable to Achieve Viral Suppression Due to Poor Adherence to Oral ART and Who Do Not Have Resistance to Cabotegravir and Rilpivirine

Based on very limited data discussed below, the Panel recommends the use of LA CAB/RPV on a case-by-case basis in select individuals with persistent virologic failure despite intensive adherence support on oral ART, who have no evidence of resistance to RPV or CAB, and with shared decision-making between providers and people with HIV **(CIII).**

Some people with HIV cannot reach or maintain viral suppression on oral ART despite intensive adherence support. Although a complete LA injectable regimen may overcome some adherence obstacles for people with viremia, long-term clinical efficacy data are limited in these circumstances and the regimen is only approved for people who are virologically suppressed for at least 3 months. No large, published randomized controlled trial has demonstrated the efficacy of a complete regimen of any INSTI plus NNRTI, including LA CAB/RPV, in people with viremia. However, cohort data are emerging, resulting in two possible approaches to use LA CAB/RPV in this population. If achieving viral suppression with oral ART is possible with intensive adherence support to oral ART, switching to LA CAB/RPV after viral suppression can serve as a goal to incentivize the person to adhere to the oral regimen. Data from the Long-Acting Therapy to Improve Treatment Success in Daily Life (LATITUDE) AIDS Clinical Trial Group (ACTG) A5359 study using this strategy is discussed in Approach #1 below.[84] If achieving viral suppression with oral ART is not possible despite intensive adherence support to oral ART, switching to LA CAB/RPV without viral suppression may be an option in certain circumstances, as discussed in Approach #2 below.

Approach #1: Intensive efforts to achieve viral suppression prior to switching to LA CAB/RPV

Because all of the large LA CAB/RPV studies enrolled participants who were adherent to ART with sustained viral suppression, every effort should be made to achieve viral suppression before considering a switch to LA CAB/RPV, even in people with poor adherence. The Phase 3 prospective, randomized, open-label LATITUDE study was designed to assess this strategy in people who faced challenges with ART adherence. Preliminary data have been presented from this study that enrolled individuals without resistance to CAB or RPV from 33 sites in the United States and Puerto Rico.[84] Participants received adherence support and conditional economic incentives to assist in achieving viral suppression on oral ART. Study participants who experienced viral suppression were randomized to continue oral ART or switch to LA CAB/RPV every 4 weeks. At a planned data safety monitoring board (DSMB) interim efficacy analysis, only 294 (68%) of the 434 participants enrolled achieved viral suppression and were eligible for randomization, with 146 assigned LA CAB/RPV and 148 continuing standard of care (SOC) oral ART. At randomization, it was noted that despite the intensive adherence support, 17% in the LA CAB/RPV arm and 7% in the SOC arm had HIV RNA >200 copies/mL. At Week 48 of the randomized phase, 24% in the LA CAB/RPV arm and 39% in the SOC arm met the primary endpoint of earliest confirmed virologic failure or treatment discontinuation, which did not meet the predefined stringent stopping criteria. However,

two secondary endpoints—virologic failure alone (7% in LA CAB/RPV vs. 25% in SOC) and treatment-related failure (defined as first virologic failure or discontinuation due to adverse events) (10% in LA CAB/RPV vs. 26% in SOC)—met the predefined stopping criteria and were statistically significant. Based upon the totality of the data, in February 2024, the DSMB recommended halting randomization and offering all eligible participants LA CAB/RPV. Of the six participants with virologic failure on LA CAB/RPV, two had new drug-resistance mutations (one conferring high-level resistance to CAB and one conferring high-level resistance to both CAB and RPV). The available data suggest that an intensive effort to achieve viral suppression followed by a switch to LA CAB/RPV may be a viable option for individuals who cannot adhere to an oral ARV regimen. Further analyses and formal publication of LATITUDE study results are pending.

Approach #2: Administer LA CAB/RPV in people with viremia who are unable to achieve viral suppression despite intensive adherence support

Emerging data show that select people with HIV who are unable to achieve viral suppression on an oral ARV regimen despite intensive support might benefit from use of LA CAB/RPV, which is currently not approved for use in this population. Available data with this strategy include an initial case report,[85] followed by outcome data from a compassionate use program,[86] showing that 16 of 28 (57%) people with viremia achieved virologic suppression after a median of 5 months with LA CAB/RPV. Among those with virologic failure and for whom resistance data were available, all had new NNRTI mutations conferring RPV resistance and 50% had new integrase mutations, two of which conferred CAB resistance. Since then, three small observational studies have suggested that LA CAB/RPV may achieve viral suppression in select people with viremia and poor adherence to oral ART.[50-52] In these studies, select people with viremia who were unable to adhere to daily oral ART were initiated on monthly or twice-monthly LA CAB/RPV with or without oral lead-in therapy. At up to 10 months of follow-up, 95% achieved HIV RNA <50 copies/mL. Of those with virologic failure for whom genotypes were available, new reverse transcriptase (e.g., L100I, E138K, Y181I) and/or integrase (e.g., G140S, Q148R, R263K) mutations were detected, conferring intermediate to high resistance to RPV and/or CAB, respectively. Various levels of multidisciplinary support and intensive case management were utilized throughout these studies (e.g., provision of injections in field sites, financial incentives, appointment reminders, and transportation assistance). Despite the intensive support, not all injections were given on time.

In the multisite U.S. Observational Pharmacoepidemiology Research and Analysis (OPERA) cohort,[87] clinical data on the use of LA CAB/RPV were prospectively captured from electronic health records from 84 clinics in 18 U.S. states and territories. Among the 36 individuals who had HIV RNA >200 copies/mL before starting LA CAB/RPV and had at least one follow-up HIV RNA test, 94% had an HIV RNA <200 copies/mL at their last follow-up visit.

Taken together, until additional data are available, these approaches may provide alternatives for individuals with viremia and difficulties with adherence to oral ART, especially for those at the highest risk for disease progression or death. If either of the above approaches are employed, close monitoring is recommended with drug-resistance testing performed if virologic response is inadequate. Importantly, beyond conventional and intensive multidisciplinary team involvement, case management and outreach support are needed to ensure adherence and adequate monitoring while on LA CAB/RPV (see the Adherence to the Continuum of Care section for discussion on strategies to improve adherence in these situations). Caution with close monitoring is advised, as data are unavailable for detailed guidance regarding the need for specific adherence or intensive case management services or whether every 4- or every 8-week LA CAB/RPV will yield similar virologic

outcomes in people with viremia before switching. Every 4-week dosing was used in the LATITUDE study. In the published case series to date in people with viremia, every 4-week dosing was prescribed for most, with the option of switching to every 8 weeks after achieving viral suppression. Until further data are available, it may be prudent to use similar strategies when LA CAB/RPV is being considered. People with HIV and providers need to be aware of the significant risk of developing resistance to NNRTIs, and particularly INSTIs if virologic failure occurs on LA CAB/RPV. Such resistance may limit future treatment options and may also lead to its transmission, which should be balanced with the individual's HIV-related risk for disease progression and death.[88] Closely monitoring for viral responses is advised if LA CAB/RPV is used in people with viremia and who have challenges with adherence.

Summary

The goal of treatment for people with HIV and virologic failure is to establish virologic suppression. The management of people with virologic failure often requires expert advice to construct virologically suppressive regimens. Before modifying a regimen, it is critical to carefully evaluate the potential cause(s) of virologic failure, including incomplete adherence, poor tolerability, and drug–drug and drug–food interactions, as well as review HIV RNA and CD4 count changes over time, complete treatment history, and current and previous drug-resistance test results. If HIV RNA suppression is not possible with currently approved agents, consider the use of investigational agents through participation in clinical trials or expanded/single-patient access programs. If virologic suppression is still not achievable, the choice of regimens should focus on minimizing toxicity and preserving treatment options while maintaining CD4 counts to delay clinical progression.

Table 10. Antiretroviral Options for People With HIV and Virologic Failure

Designing a new regimen for people with HIV who are experiencing treatment failure should always be guided by ARV history and results from current and past resistance testing. This table summarizes the text above and displays the most common or likely clinical scenarios seen in people with virologic failure. For more detailed descriptions, please refer to the texts above and/or consult an expert in HIV drug resistance to assist in the design of a new regimen. It is also crucial to provide continuous adherence support before and after regimen changes.

Clinical Scenario	Type of Failing Regimen	Resistance Considerations	New Regimen Options[a]	Goal
First Regimen Failure	NNRTI plus two NRTIs	Most likely resistant to NNRTI +/– 3TC or FTC (i.e., NNRTI mutations +/– M184V/I).[b] Additional NRTI mutations also may be present.	DTG (or possibly BIC) plus two NRTIs (preferably at least one fully active[c]) **(AI);** *or* Boosted PI plus two NRTIs (preferably at least one fully active) **(AI);** *or* Boosted PI plus INSTI (boosted DRV plus DTG **[AI]**; LPV/r plus RAL **[CI]**)	Resuppression
	Boosted PI plus two NRTIs	Most likely no resistance or resistance only to 3TC or FTC (i.e., M184V/I, without resistance to other NRTIs)[b]	DTG, or possibly BIC, plus two NRTIs (preferably at least one fully active; if only one of the NRTIs is fully active[c] or if adherence is a concern, DTG is currently preferred over other INSTIs) **(AIII);** *or* Continue same regimen **(AII);** *or* Boosted PI plus INSTI (boosted DRV plus DTG **[AIII]**; LPV/r plus RAL **[CI]**); *or* Another boosted PI plus two NRTIs (at least one fully active[c]) **(AIII).**	Resuppression
	INSTI plus two NRTIs	If failure with no INSTI resistance	Boosted PI plus two NRTIs (preferably at least one fully active[c]) **(AIII);** *or* DTG, or likely BIC, plus two NRTIs (preferably at least one fully active[c]) **(AIII);** *or* DRV/r plus DTG **(AIII)**	Resuppression
		If failure on EVG or RAL, often have INSTI resistance, but potentially susceptible to DTG	Boosted PI plus two NRTIs (preferably at least one fully active[c]) **(AIII);** *or*	Resuppression

Table 10. Antiretroviral Options for People with HIV and Virologic Failure

Clinical Scenario	Type of Failing Regimen	Resistance Considerations	New Regimen Options[a]	Goal
		Can have 3TC or FTC resistance.	DTG[d] twice daily or possibly BIC (if HIV is sensitive) plus two fully active NRTIs **(BIII);** *or* DTG[d] twice daily or possibly BIC (if HIV is sensitive) plus a boosted PI (preferably DRV/r) **(AIII).**	
	INSTI plus NNRTI (DTG/RPV or LA CAB/RPV)	INSTI and/or NNRTI resistance possible	Use ART history and past and current resistance testing to design a new regimen. Consult an expert in drug resistance as needed.	Resuppression
Second Regimen Failure and Beyond	Drug resistance with fully active treatment options—	Use past and current genotypic- +/– phenotypic-resistance testing and ART history when designing new regimen.	New regimen according to original treatment type—	Resuppression
	(i) Boosted PI, but not second-generation INSTI, fully active		(i) Boosted PI with two NRTIs (preferably at least one fully active)	
	(ii) Second-generation INSTI, but not boosted PI, fully active		(ii) DTG or BIC with two NRTIs (preferably at least one fully active)	
	(iii) Both PI and INSTI fully active		(iii) The two options above or boosted PI with INSTI	
	Multiple or extensive drug resistance with few treatment options (e.g., fully active boosted PI or second-generation INSTI unavailable)	Use past and current genotypic- and phenotypic-resistance testing to guide therapy. Confirm with a viral tropism assay when use of MVC is considered. Consult an expert in drug resistance if needed.	New regimen should include at least two, and preferably three, fully active agents, including those with novel mechanisms of action (e.g., IBA, FTR, LEN). If fewer than three fully active drugs, include as many fully active drugs as possible, along with potentially partially active drugs **(BII).** Consider enrollment into clinical trials or expanded access programs for investigational agents if available. Discontinuation of all ARV drugs **is not recommended (AI).**	Resuppression if possible; otherwise, keep viral RNA levels as low as possible and CD4 count as high as possible.

Table 10. Antiretroviral Options for People with HIV and Virologic Failure

Clinical Scenario	Type of Failing Regimen	Resistance Considerations	New Regimen Options[a]	Goal
People With Suspected Drug Resistance and Limited or Incomplete ARV and Resistance History	Unknown	Obtain medical records if possible. Resistance testing may be helpful in identifying drug-resistance mutations, even if the person has been off ART. Keep in mind that resistance mutations may not be detected in the absence of drug pressure.	Consider restarting the old regimen with careful monitoring of virologic response and early resistance testing if inadequate virologic suppression. If no ARV history is available, consider initiating a regimen with drugs with high genetic barriers to resistance (e.g., DTG, BIC, and/or boosted DRV) with careful monitoring of virologic response and early resistance testing, if inadequate virologic suppression.	Resuppression

[a] When switching an ARV regimen in a person with HBV/HIV coinfection, ARV drugs that are active against HBV and have a high resistance barrier to HBV (i.e., tenofovir) should be continued as part of the new regimen, or another HBV drug (i.e., entecavir) should be started. Discontinuation of these drugs may lead to the reactivation of HBV, which may result in serious hepatocellular damage.

[b] If other NRTI-resistance mutations are present, use resistance test results to guide NRTI usage in the new regimen.

[c] See text for details and additional options in special settings.

[d] Response to DTG depends on the type and number of INSTI mutations.

Key: 3TC = lamivudine; ART = antiretroviral therapy; ARV = antiretroviral; BIC = bictegravir; CD4 = CD4 T lymphocyte; DRV = darunavir; DRV/r = darunavir/ritonavir; DTG = dolutegravir; EVG = elvitegravir; FTC = emtricitabine; FTR = fostemsavir; HBV = hepatitis B virus; IBA = ibalizumab; INSTI = integrase strand transfer inhibitor; LEN = lenacapavir; LPV/r = lopinavir/ritonavir; MVC = maraviroc; NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; RAL = raltegravir

Isolated Central Nervous System Virologic Failure and Neurologic Symptoms

Cerebrospinal Fluid Viral Escape

Presentation with new-onset central nervous system (CNS) signs and symptoms has been reported as a rare form of "compartmentalized" virologic failure. People experiencing this present with new, usually subacute, neurological symptoms that are associated with a breakthrough of HIV replication within the CNS compartment, despite relative plasma HIV RNA suppression. In this case, cerebrospinal fluid (CSF) HIV RNA shows higher concentrations than in plasma.[89-91] Clinical evaluation frequently shows abnormalities on magnetic resonance imaging (MRI) and abnormal CSF findings with characteristic lymphocytic pleocytosis.[92] In most (though not all) people, drug-resistant CSF virus is evident.[93] Consensus among experts is that this "neurosymptomatic" form of CNS viral escape should be treated through optimization of ARV regimens based on drug-resistance testing results if available **(CIII).**[94] Although drug-resistance testing of HIV in CSF can be used to guide changes in the ARV regimen, according to the principles outlined above for plasma HIV RNA resistance, such testing typically needs to be conducted in a research setting. If CSF HIV drug-resistance testing is not available, the regimen may be changed based on the person's treatment history or on predicted drug penetration into the CNS **(CIII).**[95-98]

This "neurosymptomatic" CNS viral escape should be distinguished from "neuroasymptomatic" escape, defined as—

- The incidental detection of asymptomatic and mild CSF HIV RNA elevation, which is similar to plasma viral blips in that it is usually transient with low levels of CSF HIV RNA and has been associated with PI-based regimens[99-101]; *or*
- A transient increase in CSF HIV RNA that is related to other CNS infections that can induce a brief increase in CSF HIV RNA (e.g., herpes zoster).[102]

There is not clear evidence to support a change in an ARV regimen for incidentally detected "neuroasymptomatic" escape, although careful clinical review and follow-up of each person with this condition are recommended to monitor for the emergence of neurologic symptoms or systemic viremia.[94] There does not appear to be an association between these asymptomatic CSF HIV RNA elevations and the relatively common chronic, usually mild, neurocognitive impairment in people with HIV who show no evidence of CNS viral breakthrough.[103]

Neurological Symptoms in People With HIV on Antiretroviral Therapy

Evidence is currently not available to support empiric intensification or switch of ARV regimens in people on systemically suppressive ART with mild neurological and/or cognitive symptoms who do not have documented CSF escape. Such individuals should be referred for neurological evaluation to determine if further evaluation is indicated. This may include blood laboratory testing, lumbar puncture, neuropsychological testing, and MRI to evaluate for CSF escape, as well as other causes of neurological symptoms. A recent multinational randomized, double-blinded, placebo-controlled trial randomized 191 ART-experienced participants—with cognitive impairment and suppressed plasma HIV RNA level and not taking an INSTI—to one of three arms: dual placebo, addition of DTG plus placebo, or DTG plus MVC. Compared with placebo, ART intensification with DTG or DTG plus MVC did not alter neuropsychological performance or depressive symptoms over time in participants with cognitive impairment.[104]
