- Discuss safer sex (review specifics appropriate to the patient's sexual practices and infections) to prevent the patient's exposure to herpes, hepatitis B, hepatitis C, and other STDs, and to prevent the patient from exposing others to HIV or other pathogens. In addition, remind the patient that safer sex practices will limit the risk of reinfection with HIV. (See chapters *Preventing HIV Transmission/Prevention with Positives* and *Preventing Exposure to Opportunistic and Other Infections*.)
- If *Toxoplasma* IgG test result is negative, see chapter *Preventing Exposure to Opportunistic and Other Infections*.
- If CMV test result is negative, counsel the patient that CMV is shed in semen, vaginal and cervical secretions, saliva, and urine of infected people. Latex condoms will help reduce risk. For women considering childbearing, CMV should be avoided to prevent severe disease and even death of the neonate. (See chapter *Preventing Exposure to Opportunistic and Other Infections*.)
- For patients who are hepatitis C negative and are using injection drugs, offer referral to a drug treatment program or a clean needle exchange program. (See chapters *Preventing HIV Transmission/Prevention with Positives* and *Preventing Exposure to Opportunistic and Other Infections*.)

Interim History and Physical Examination

Background

This chapter shows the suggested frequency and follow-up intervals of the history and physical examination for monitoring HIV-infected patients, as well as specific areas to assess in an ongoing manner. With this information, the clinician can track disease progression and formulate and maintain an appropriate care plan. Note that information gathered in the history or physical examination may indicate a need for additional directed explorations.

It is important to document new or ongoing symptoms and functional limitations at each visit. This information is particularly useful when outside agencies must determine the patient's disability status. (See chapter *Karnofsky Performance Scale*.)

See chapter *Initial and Interim Laboratory and Other Tests* for recommended screening tests.

HRSA HAB Performance Measures

Percentage of patients, regardless of age, with a diagnosis of HIV who had at least **one medical visit in each 6-month period** of the 24-month measurement period with a minimum of 60 days between medical visits
(Core measure)

Percentage of female patients with a diagnosis of HIV who have a **Pap screening** in the measurement year
(Adult and Adolescent measure)

Percentage of patients with a diagnosis of HIV who received **HIV risk counseling** in the measurement year
(Adult and Adolescent measure)

Percentage of new patients with a diagnosis of HIV who have been **screened for substance use** (alcohol and drugs) in the measurement year
(Adult and Adolescent measure)

Percentage of patients aged 12 years and older **screened for clinical depression** on the date of the encounter using an age-appropriate standardized depression screening tool AND, if positive, a follow-up plan is documented on the date of the positive screen
(Adult and Adolescent measure)

Table 1. History and Physical Examinations

History	Physical Examination
Every visit (at least every 3-4 months)	
• New symptoms • Medications • HIV-related medications • Medications for other conditions • Over-the-counter medications • Herbs or vitamins • Adherence to medications and clinical care visits • Antiretroviral (ARV) doses missed in the past 3 days, in the past month • Knowledge of HIV regimen • HIV transmission risk behaviors and risk reduction methods • Sexual history (risk factors for STDs) • Mood • Alcohol and recreational drug use • Tobacco use • Allergies • Pain • Social supports • Housing • Insurance • Intimate partner violence	• Vital signs (temperature, blood pressure, heart rate, respiratory rate, and oxygen saturation) • Weight • General appearance and body habitus (including evaluation for lipodystrophy) • Skin • Oropharynx • Lymph nodes • Heart and lungs • Abdomen • Neurologic • Psychiatric (e.g., mood, affect, and attention)
Every 6 months	
As above	As above, plus: • Vision and funduscopic examination (if CD4 count <100 cells/μL) • Ears/nose
Every 6 months (twice), and, if both are normal, annually thereafter (see chapters <i>Cervical Dysplasia</i> and <i>Anal Dysplasia</i>)	
As above	• Women: pelvic examination; cervical Papanicolaou (Pap) test; consider anorectal examination, anal Pap test • Men: consider anal examination, anal Pap test
Annually	
Update initial history: HIV-related symptoms, hospitalizations, major illnesses, and family history	Complete physical to include: • Genitorectal examination • Testicular examination • Prostate examination • Breast examination

HIV Classification: CDC and WHO Staging Systems

Background

HIV disease staging and classification systems are critical tools for tracking and monitoring the HIV epidemic and for providing clinicians and patients with important information about HIV disease stage and clinical management. Two major classification systems currently are in use: the U.S. Centers for Disease Control and Prevention (CDC) classification system and the World Health Organization (WHO) Clinical Staging and Disease Classification System.

The CDC disease staging system (most recently revised in 1993) assesses the severity of HIV disease by CD4 cell counts and by the presence of specific HIV-related conditions. The definition of AIDS includes all HIV-infected individuals with CD4 counts of <200 cells/ μL (or CD4 percentage $<14\%$) as well as those with certain HIV-related conditions and symptoms. Although the fine points of the classification system rarely are used in the routine clinical management of HIV-infected patients, a working knowledge of the staging criteria (in particular, the definition of AIDS) is useful in patient care. In addition, the CDC system is used in clinical and epidemiologic research.

In contrast to the CDC system, the WHO Clinical Staging and Disease Classification System (revised in 2007) can be used readily in resource-constrained settings without access to CD4 cell count measurements or other diagnostic and laboratory testing methods. The WHO system classifies HIV disease on the basis of clinical manifestations that can be recognized and treated by clinicians in diverse settings, including resource-constrained settings, and by clinicians with varying levels of HIV expertise and training.

S: Subjective

When a patient presents with a diagnosis of HIV infection, review the patient's history to elicit and document any HIV-related illnesses or symptoms (see chapter *Initial History*).

O: Objective

Perform a complete physical examination and appropriate laboratory studies (see chapters *Initial Physical Examination* and *Initial and Interim Laboratory and Other Tests*).

A: Assessment

Confirm HIV infection and perform staging.

P: Plan

Evaluate symptoms, history, physical examination results, and laboratory results, and make a staging classification according to the CDC or WHO criteria (see below).

CDC Classification System for HIV Infection

The CDC categorization of HIV/AIDS is based on the lowest documented CD4 cell count and on previously diagnosed HIV-related conditions (see Table 1). For example, if a patient had a condition that once met the criteria for category B but now is asymptomatic, the patient would remain in category B. Additionally, categorization is based on specific conditions, as indicated below. Patients in categories A3, B3, and C1-C3 are considered to have AIDS.

Table 1. CDC Classification System for HIV-Infected Adults and Adolescents

CD4 Cell Count Categories	Clinical Categories		
	A Asymptomatic, Acute HIV, or PGL	B* Symptomatic Conditions, not A or C	C# AIDS-Indicator Conditions
(1) ≥ 500 cells/ μ L	A1	B1	C1
(2) 200–499 cells/ μ L	A2	B2	C2
(3) <200 cells/ μ L	A3	B3	C3

Abbreviations: PGL = persistent generalized lymphadenopathy

* Category B Symptomatic Conditions

Category B symptomatic conditions are defined as symptomatic conditions occurring in an HIV-infected adolescent or adult that meet at least one of the following criteria:

- They are attributed to HIV infection or indicate a defect in cell-mediated immunity.
- They are considered to have a clinical course or management that is complicated by HIV infection.

Examples include, but are not limited to, the following:

- Bacillary angiomatosis
- Oropharyngeal candidiasis (thrush)
- Vulvovaginal candidiasis, persistent or resistant
- Pelvic inflammatory disease (PID)
- Cervical dysplasia (moderate or severe)/cervical carcinoma in situ
- Hairy leukoplakia, oral
- Herpes zoster (shingles), involving two or more episodes or at least one dermatome
- Idiopathic thrombocytopenic purpura
- Constitutional symptoms, such as fever ($>38.5^{\circ}\text{C}$) or diarrhea lasting >1 month
- Peripheral neuropathy

Category C AIDS-Indicator Conditions

- Bacterial pneumonia, recurrent (two or more episodes in 12 months)
- Candidiasis of the bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical carcinoma, invasive, confirmed by biopsy
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month in duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Encephalopathy, HIV-related
- Herpes simplex: chronic ulcers (>1 month in duration), or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 -month in duration)
- Kaposi sarcoma
- Lymphoma, Burkitt, immunoblastic, or primary central nervous system
- *Mycobacterium avium* complex (MAC) or *Mycobacterium kansasii*, disseminated or extrapulmonary

- *Mycobacterium tuberculosis*, pulmonary or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jiroveci* (formerly *carinii*) pneumonia (PCP)
- Progressive multifocal leukoencephalopathy (PML)
- *Salmonella* septicemia, recurrent (nontyphoid)
- Toxoplasmosis of brain
- Wasting syndrome caused by HIV (involuntary weight loss >10% of baseline body weight) associated with either chronic diarrhea (two or more loose stools per day for ≥ 1 month) or chronic weakness and documented fever for ≥ 1 month

WHO Clinical Staging of HIV/AIDS and Case Definition

The clinical staging and case definition of HIV for resource-constrained settings were developed by the WHO in 1990 and revised in 2007. Staging is based on clinical findings that guide the diagnosis, evaluation, and management of HIV/AIDS, and it does not require a CD4 cell count. This staging system is used in many countries to determine eligibility for antiretroviral therapy, particularly in settings in which CD4 testing is not available. Clinical stages are categorized as 1 through 4, progressing from primary HIV infection to advanced HIV/AIDS (see Table 2). These stages are defined by specific clinical conditions or symptoms. For the purpose of the WHO staging system, adolescents and adults are defined as individuals aged ≥ 15 years.

Table 2. WHO Clinical Staging of HIV/AIDS for Adults and Adolescents

Primary HIV Infection	
• Asymptomatic	• Acute retroviral syndrome
Clinical Stage 1	
• Asymptomatic	• Persistent generalized lymphadenopathy
Clinical Stage 2	
• Moderate unexplained weight loss (<10% of presumed or measured body weight) • Recurrent respiratory infections (sinusitis, tonsillitis, otitis media, and pharyngitis) • Herpes zoster	• Angular cheilitis • Recurrent oral ulceration • Papular pruritic eruptions • Seborrheic dermatitis • Fungal nail infections
Clinical Stage 3	
• Unexplained severe weight loss (>10% of presumed or measured body weight) • Unexplained chronic diarrhea for >1 month • Unexplained persistent fever for >1 month (>37.6°C, intermittent or constant) • Persistent oral candidiasis (thrush) • Oral hairy leukoplakia • Pulmonary tuberculosis (current)	• Severe presumed bacterial infections (e.g., pneumonia, empyema, pyomyositis, bone or joint infection, meningitis, bacteremia) • Acute necrotizing ulcerative stomatitis, gingivitis, or periodontitis • Unexplained anemia (hemoglobin <8 g/dL) • Neutropenia (neutrophils <500 cells/μL) • Chronic thrombocytopenia (platelets <50,000 cells/μL)

Clinical Stage 4	
• HIV wasting syndrome, as defined by the CDC (see Table 1, above) • <i>Pneumocystis</i> pneumonia • Recurrent severe bacterial pneumonia • Chronic herpes simplex infection (orolabial, genital, or anorectal site for >1 month or visceral herpes at any site) • Esophageal candidiasis (or candidiasis of trachea, bronchi, or lungs) • Extrapulmonary tuberculosis • Kaposi sarcoma • Cytomegalovirus infection (retinitis or infection of other organs) • Central nervous system toxoplasmosis • HIV encephalopathy • Cryptococcosis, extrapulmonary (including meningitis)	• Disseminated nontuberculosis mycobacteria infection • Progressive multifocal leukoencephalopathy • Candida of the trachea, bronchi, or lungs • Chronic cryptosporidiosis (with diarrhea) • Chronic isosporiasis • Disseminated mycosis (e.g., histoplasmosis, coccidioidomycosis, penicilliosis) • Recurrent nontyphoidal <i>Salmonella</i> bacteremia • Lymphoma (cerebral or B-cell non-Hodgkin) • Invasive cervical carcinoma • Atypical disseminated leishmaniasis • Symptomatic HIV-associated nephropathy • Symptomatic HIV-associated cardiomyopathy • Reactivation of American trypanosomiasis (meningoencephalitis or myocarditis)

CD4 and Viral Load Monitoring

Background

The CD4 cell count and HIV viral load (RNA level) are closely linked to HIV-related illness and mortality. They give prognostic information on HIV progression and on response to therapy.

HRSA HAB Performance Measures

Percentage of patients, aged 6 months and older with a diagnosis of HIV/AIDS, with at least two **CD4 cell counts or percentages** performed during the measurement year at least 3 months apart

(All-Age measure)

Percentage of patients, regardless of age, with a diagnosis of HIV with a **viral load test** performed at least every 6 months during the measurement year

(All-Age measure)

CD4 Monitoring

CD4 lymphocyte cells (also called T-cells or T-helper cells) are the primary targets of HIV. The CD4 count and the CD4 percentage mark the degree of immunocompromise. The CD4 count is the number of CD4 cells per microliter (μL) of blood. It is used to stage the patient's disease, determine the risk of opportunistic illnesses, assess prognosis, and guide decisions about the urgency of starting antiretroviral therapy (ART) (see chapters *Risk of HIV Progression/Indications for ART* and *Antiretroviral Therapy*). The CD4 percentage is the percentage of the lymphocyte population that is CD4+; it is measured directly by flow cytometry. A CD4 percentage of <14% is considered to correspond to the same degree of immunosuppression as an absolute CD4 count of <200 cells/ μL . The absolute CD4 count is calculated from the CD4 cell percentage and the total white blood cell count.

The normal values for CD4 count vary considerably among different laboratories. The mean normal value for most laboratories is approximately 500-1,300 cells/ μL . This calculated value is subject to more fluctuations than the CD4 cell percentage. Illness, vaccination, diurnal variation, laboratory error, and some medications can result in transient CD4 cell count changes, whereas

the CD4 percentage remains more stable. Because CD4 counts may vary, treatment decisions generally should not be made on the basis of a single CD4 value. When results are inconsistent with previous trends, tests should be repeated, and treatment decisions usually should be based on two or more similar values. A change between two test results is considered significant if it is a 30% change in absolute CD4 count or 3 percentage point change in CD4 percentage.

In persons with untreated HIV infection, the CD4 count declines by approximately 50-80 cells/ μL per year, on average. The pattern of decline may be slow and steady, or the CD4 count may level off for an extended period of time (as in long-term nonprogressors) and then decrease. Although it takes an average of 10 years for a newly infected person to progress to AIDS, there is great variation among patients. For some patients, disease progression occurs within a year or two. For others, it takes more than 20 years, and a small number of patients appear to maintain high CD4 counts and undetectable HIV RNA levels without ART (aviremic or “elite” controllers).

Among asymptomatic individuals, the CD4 count until recent years was the major factor that guided the decision to initiate therapy, and it remains so in resource-limited areas of

the world. Current United States guidelines recommend treatment for all HIV-infected individuals regardless of CD4 count. The CD4 count, though, can help clinicians and patients decide how quickly to start therapy. Clinical status, viral load, pregnancy, comorbidities, patient adherence to medications, and risk of HIV transmission are among the other factors that should be taken into consideration (see chapters *Risk of HIV Progression/Indications for ART* and *Antiretroviral Therapy*).

Prophylaxis against opportunistic infections is based on CD4 count, and sometimes on CD4 percentage. For example, a CD4 count of <200 cells/ μ L or a CD4 percentage of <14% is an indication for prophylaxis against *Pneumocystis jiroveci* pneumonia; a CD4 count of <50 cells/ μ L is an indication for prophylaxis against *Mycobacterium avium* complex. (See chapters *Opportunistic Infection Prophylaxis* and *Risk of HIV Progression/Indications for ART*.) The CD4 count also guides decision making in determining when to stop prophylaxis against opportunistic infections with patients whose CD4 counts rise in response to ART.

Effective ART typically results in CD4 count increases of >50 cells/ μ L within weeks after viral suppression, and increases of 50-100 cells/ μ L per year thereafter. For some patients, CD4 counts may not increase that quickly or steadily, even with durable viral load suppression. Patients who are older (age >50) and those with lower baseline CD4 cell counts are more likely to have blunted CD4 count responses. For monitoring purposes, the CD4 count should be repeated approximately every 3-6 months both in stable untreated patients and in patients on ART. For patients on ART with persistently suppressed HIV RNA and CD4 counts solidly above thresholds for opportunistic infection risk, current guidelines suggest monitoring every 6-12 months, and some data demonstrate that even less frequent CD4 checks in such patients is safe. The CD4

count should be checked more often if clinically indicated (e.g., switching therapy, ART failure, rapidly declining CD4 count) (see Table 1).

Viral Load Monitoring

The HIV-1 viral load measurement indicates the number of copies of HIV-1 RNA per milliliter of plasma. Although HIV ultimately resides within cells, the plasma measurement is an accurate reflection of the burden of infection and the magnitude of viral replication. It is used to assess the risk of disease progression and can help guide initiation of therapy. It is critical in monitoring virologic response to ART.

There are several commercially available HIV-1 viral load assays and numerous institution-specific assays. The range of detectable virus differs somewhat with each test, but the lowest level of detection generally is 20-75 copies/mL. A viral load below this “undetectable” level indicates the inability of the assay to detect HIV in the plasma, but does not indicate absence or clearance of the virus from the body. The highest levels of detection of the viral load assays typically are between 500,000 copies/mL and 750,000 copies/mL. Viral loads higher than these levels are reported, for example, as >500,000 copies/mL. Note that commercially available assays may not detect HIV-2, and they do not accurately quantify it.

After initial infection with HIV, the viral load quickly peaks to very high levels, usually >100,000 copies/mL (see chapter *Early HIV Infection*). During the period of acute infection, when HIV antibody testing may indicate negative results, the viral load test may be used to detect HIV infection. Generally, 3-6 months after primary infection, the viral load declines and then levels off, remaining in a steady state. Among patients who are not taking ARV medications, a small number maintain a low or even undetectable viral load (aviremic or “elite” controllers), but the vast majority of those patients have relatively high HIV RNA levels.

Higher plasma viral loads are associated with more rapid declines in CD4 cells and with increased risk of progression to symptomatic disease and AIDS; they also are associated with higher risk of HIV transmission (see chapter *Risk of HIV Progression/Indications for ART*). In untreated persons, the CD4 cell count is more useful in determining the urgency of ART initiation, but once a patient has started ART, the viral load is used to monitor the response to therapy. A key goal of ART is to achieve a viral load that is below the level of quantitation (e.g., <40 copies/mL). Because CD4 and clinical responses may lag behind changes in viral load, viral load testing is essential for detecting virologic failure in a timely manner. With an effective ARV regimen, a decline of at least 10-fold (1 logarithm) is expected within the first month, and suppression to undetectable levels should be achieved within 3-6 months after initiation of therapy. Isolated low-level elevations (typically <400 copies/mL) in viral load may occur in patients on ART; these “blips” generally do not predict subsequent virologic failure. (Additionally, some viral load assays appear to produce low-level positive results [<200 copies/mL] more commonly

than others; as with blips, these do not in general appear to increase the risk of virologic failure.) To avoid confusing virologic failure with blips or test variability, current guidelines define virologic failure as repeated HIV RNA levels >200 copies/mL. If the viral load does not reduce to an undetectable level (or at least <200 copies/mL), or if it rebounds after suppression, virologic failure has occurred, and possible causes should be investigated (e.g., poor ARV adherence, resistance to ARVs, or reduced drug exposure).

The HIV viral load should be checked at least twice at baseline, before the patient starts an ART regimen. Follow-up viral load measurement should be performed at regular intervals, depending on the patient’s clinical situation (see Table 1). For stable patients, viral load usually should be monitored every 3-4 months; for highly adherent and stable patients with suppressed viral loads for at least several years, monitoring every 6 months is adequate. With new therapy or changes in therapy, significant change in viral load or CD4 count, or declining clinical status, the viral load should be measured at more frequent intervals.

Table 1. CD4 and HIV Viral Load Monitoring Schedule

	Baseline	Follow-Up Before ART Initiation	At ART Initiation or Switch	After ART Initiation or Switch	Follow-Up on Effective ART	Treatment Failure or Clinical Indications
CD4 Count	√	Every 3-6 months	√	3-6 months	Every 3-6 months*	√
HIV Viral Load	√	Every 3-6 months	√	2-8 weeks, then every 4-8 weeks until HIV RNA is undetectable	Every 3-4 months**	√

* Clinically stable patients on ART with sustained viral suppression and CD4 counts above threshold for opportunistic infection risk: may monitor every 6-12 months.

**Adherent patients on stable ART with viral suppression and stable immunologic status for >2-3 years: can consider monitoring every 6 months.

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents. *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. Department of Health and Human Services. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Viral loads, like CD4 counts, are affected by laboratory variation, assay fluctuations, and patient variables such as acute illness and recent vaccinations. Variations of $<0.5 \log_{10}$ copies/mL (threefold) usually are not clinically significant. Viral load results that are inconsistent with previous trends should be repeated, and treatment decisions usually should be based on two or more similar values. Recent illnesses or vaccinations can transiently increase viral load. If a patient has had a recent illness or vaccination, the viral load measurement should be deferred for 4 weeks, if possible.

Patient Education

- The CD4 cell count is the best indicator for gauging the strength of the immune system and for determining whether a person is at risk of infection with certain organisms. The higher the CD4 count, the stronger the immune system.
- CD4 counts are variable. Caution patients not to pin emotions and hopes to a single laboratory result. A change of $<30\%$ may not be significant.
- The HIV viral load is the best indicator of the level of HIV activity in the patient's body.
- The CD4 count and HIV viral load may be used to help determine how urgently therapy is needed (note, though, that current guidelines recommend ART for all persons with HIV infection, regardless of CD4 or viral load).
- A key goal of therapy is to suppress the viral load to below the level of detectability by laboratory tests. An undetectable viral load does not mean HIV has been completely eradicated or that the patient is not infectious to others.

- For most patients on effective ART, the CD4 count will rise as the virus is suppressed. This indicates an improvement in the immune system.
- In stable patients on ART, the CD4 count and HIV viral load usually should be monitored every 3-6 months.

Risk of HIV Progression/ Indications for ART

Background

The CD4 cell count and HIV viral load (RNA level) are closely linked to HIV-related illness and mortality, and are the laboratory measures that are followed in clinical practice. They are the primary markers that give prognostic information on disease progression and on response to antiretroviral therapy (ART) (see chapter *CD4 and Viral Load Monitoring*). However, it is increasingly recognized that a number of other factors are involved in HIV disease progression. These include individual HIV-specific immune responses, immune activation, viral factors, host genetics, and age. The role of these factors and their interplay is complex and incompletely understood.

CD4 Count

The CD4 count (and CD4 percentage) marks the degree of immunocompromise. The CD4 count is used to stage the patient's disease progression, determine the risk of opportunistic illnesses, and assess prognosis (see chapter *CD4 and Viral Load Monitoring*). The CD4 count also helps to determine the urgency and the timing of ART initiation, and the need for prophylaxis against opportunistic infections. It also helps in formulating differential diagnoses for symptomatic patients

(see Table 1, Figure 1, and chapters *CD4 and Viral Load Monitoring* and *Opportunistic Infection Prophylaxis*).

Persons with HIV infection are at increased risk of complications at lower CD4 counts. A CD4 count of <200 cells/ μ L (or CD4 percentage of <14%) indicates severe immunosuppression, and is an AIDS-defining condition. Persons with CD4 counts below this level are at greater risk of a number of opportunistic illnesses and death, increasingly so at lower CD4 counts (see Table 1).

Table 1. Correlation Between CD4 Cell Counts and Complications of HIV Infection

CD4 Count* (cells/ μ L)	Infectious Complications	Noninfectious Complications [#]
>500	- Acute retroviral syndrome - Candidal vaginitis	- Persistent generalized lymphadenopathy (PGL) - Guillain-Barré syndrome - Myopathy - Aseptic meningitis
200-500	- Pneumococcal and other bacterial pneumonias - Pulmonary tuberculosis - Herpes zoster - Oropharyngeal candidiasis (thrush) - Cryptosporidiosis (self-limited) - Kaposi sarcoma (cutaneous) - Oral hairy leukoplakia - Herpes simplex (oral/genital)	- Cervical intraepithelial neoplasia - Cervical cancer - B-cell lymphoma - Anemia - Mononeuropathy multiplex - Idiopathic thrombocytopenic purpura - Hodgkin lymphoma - Lymphocytic interstitial pneumonitis - Fatigue
<200	<i>Pneumocystis jiroveci</i> pneumonia (PCP) - Disseminated histoplasmosis and coccidioidomycosis - Miliary/extrapulmonary tuberculosis - Progressive multifocal leukoencephalopathy (PML)	- Wasting - Peripheral neuropathy - HIV-associated dementia - Cardiomyopathy - Vacuolar myelopathy - Progressive polyradiculopathy - Non-Hodgkin lymphoma
<100	- Disseminated herpes simplex virus - Toxoplasmosis - Cryptococcosis - Cryptosporidiosis, chronic - Microsporidiosis - Candidal esophagitis - Kaposi sarcoma (visceral/pulmonary)	
<50	- Disseminated cytomegalovirus (CMV) - Disseminated <i>Mycobacterium avium</i> complex (MAC)	Central nervous system (CNS) lymphoma

* Most complications occur with increasing frequency at lower CD4 cell counts.

[#] Some conditions listed as “noninfectious” are associated with transmissible microbes. Examples include lymphoma (Epstein-Barr virus) and anal and cervical cancers (human papillomavirus).

Adapted from Bartlett JG, Gallant JE, Pham P. 2012 *Medical Management of HIV Infection*. Baltimore: Johns Hopkins University School of Medicine; 2012. Used with permission.

Increasing evidence suggests that the risk of complications from HIV infection occurs across a broad spectrum of CD4 counts, and that patients with relatively high counts (those with counts of >350 cells/ μ L and even those with counts of >500 cells/ μ L) also have increased rates of morbidities compared with HIV-uninfected persons. The complications

in persons with higher CD4 counts typically are not the classic AIDS-related opportunistic illnesses but are “non-AIDS” illnesses such as cardiovascular disease, neurocognitive decline, and non-AIDS-associated cancers.

In asymptomatic individuals, CD4 count has been used as the main indicator of need for ART. It is well established that ART is extremely effective

at reducing HIV-related illness in persons with lower CD4 counts. In recent years, accumulating data have suggested that ART also is beneficial for persons with high pretreatment CD4 counts.

Randomized trials have shown that starting ART for asymptomatic patients with pretreatment CD4 counts of 200-350 cells/ μ L results in decreased morbidity and mortality compared with starting therapy for persons with CD4 counts of <200 cells/ μ L. For patients with pretreatment CD4 counts of >350 cells/ μ L, data from several randomized controlled studies and cohort studies have found decreased rates of complications and death among persons who initiated ART at CD4 counts of $\geq$ 350 cells/ μ L, compared with persons who initiated treatment at lower CD4 counts. Additionally, some (though not all) observational evidence suggests a mortality benefit of ART even among persons with pretreatment CD4 counts of >500 cells/ μ L. These cohort studies are complemented by a

number of investigations that demonstrate ongoing and adverse effects of HIV and associated inflammation on various organ systems. A randomized controlled trial to evaluate the strategy of starting treatment at CD4 counts >500 cells/ μ L is under way.

These lines of evidence, along with studies showing a substantial impact of ART in decreasing HIV transmission, and the availability of ARVs that generally are safe, tolerable, and effective, support the rationale for earlier initiation of treatment. The current U.S. Department of Health and Human Services (HHS) adult and adolescent treatment guidelines recommend starting ART for all HIV-infected persons regardless of CD4 count, both to enhance the health of the infected individual and to prevent transmission of HIV. The strength of this recommendation is greater if the CD4 count is lower or the clinical status is poorer, and according to transmission risk groups (see Table 2 and chapter *Antiretroviral Therapy*).

Table 2. HHS Recommendations on Initiation of Antiretroviral Therapy

The HHS guidelines state that, "*Antiretroviral therapy (ART) is recommended for all HIV-infected individuals to reduce the risk of disease progression.*" The strength and evidence for this recommendation vary by pretreatment CD4 cell count, as follows:

CD4 Criteria	Strength of Recommendation*
- CD4 count <350 cells/μL - CD4 count 350-500 cells/μL - CD4 count >500 cells/μL	- Strongly recommended (AI) - Strongly recommended (AII) - Moderately recommended (BIII)

Additionally, the guidelines state that, "*ART also is recommended for HIV-infected individuals for the prevention of transmission of HIV.*" The strength and evidence for this recommendation vary by transmission risk, as follows:

Transmission Risk Group	Strength of Recommendation*
- Perinatal transmission - Heterosexual transmission - Other transmission risk groups	- Strongly recommended (AI) - Strongly recommended (AI) - Strongly recommended (AIII)

* **Rating of recommendation:** A = strong; B = moderate; C = optional

Rating of evidence: I = data from randomized controlled trials; II = data from well-designed nonrandomized trials or observational cohort studies; III = expert opinion

Considerations
Patients starting ART should be willing and able to commit to treatment and understand the benefits and risks of therapy and the importance of adherence (AIII). Patients may choose to postpone therapy, and providers, on a case-by-case basis, may elect to defer therapy on the basis of clinical and/or psychosocial factors.

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents. *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. Department of Health and Human Services. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

A number of factors and coexisting conditions signal the need for speedier initiation of therapy, if possible. According to the HHS guidelines, these include the following:

- Pregnancy
- History of AIDS-defining illness
- Acute opportunistic infection
- Lower CD4 cell count
- Acute/recent HIV infection
- HIV-associated nephropathy
- Hepatitis B coinfection
- Hepatitis C coinfection
- Rapidly declining CD4 counts (e.g., >100 cells/ μ L per year)
- Higher HIV RNA (e.g., >100,000 copies/mL)

HIV Viral Load

Whereas the CD4 count is an indicator of immune system function, the HIV viral load (RNA level) gives prognostic information on how quickly the CD4 count is likely to decline and, consequently, the risk of disease progression. Patients with high HIV viral loads generally demonstrate a faster decline in CD4 count and progression to AIDS-related illnesses; they also may have a higher rate of non-AIDS-related events even with relatively high CD4 counts (e.g., >350 cells/ μ L). Those with low viral loads usually have higher CD4 counts and remain asymptomatic for prolonged periods. A small percentage of persons with HIV infection may have very low or undetectable viral loads for extended periods of time.

By themselves, CD4 count and HIV viral load are useful, albeit rough, prognostic indicators. When considered together, they constitute a finer tool to estimate the risk of progression (see Figure 1).

Other Factors Associated with HIV Progression

Although the CD4 count and HIV viral load are the most important predictors of HIV progression, it is increasingly recognized that a number of other factors, and likely others that remain unknown, contribute to disease progression in HIV infection.

Viral factors

Variations in the HIV genome have been associated with an altered rate of disease progression. For example, deletions in the *nef* gene have been associated with a slow rate of progression. On the other hand, virus that uses the CXCR4 protein as a coreceptor for entry (termed X4 virus or syncytia-inducing virus) has been associated with accelerated progression. As another example, drug-resistance mutations may

affect how efficiently the virus replicates (viral fitness). Patients who have virus with decreased fitness have slower immune deterioration than those with wild-type virus.

Host immune factors

Host genetic factors have been shown to alter the rate of HIV progression. Various human leukocyte antigen (HLA) alleles have been associated with faster or slower progression rates. Genetic polymorphisms also play a role. For example, CCR5 is a chemokine receptor that can serve as a coreceptor for HIV entry into the CD4 cell. A naturally occurring variant allele for CCR5 has a 32 base pair deletion. Individuals who are heterozygous for this allele have slower progression of HIV disease.

Increased immune activation and elevated markers of inflammation, such as IL-6 and D-dimer, also have been associated with risk of disease progression and death. They also may be involved in the ongoing damage seen in a number of end organs. Although T-cell activation and levels of inflammation decrease with ART, they often do not return to normal.

Age

Several studies have shown a higher risk of morbidity and mortality in older patients. When followed from seroconversion, older patients demonstrate faster disease progression compared with younger patients (see Table 3). Older patients also are found to have a less robust increase in the CD4 count in response to ART and may have a higher rate of non-AIDS-related morbidities.

Table 3. Median Survival and Time to AIDS by Age at Seroconversion

Age at Seroconversion (years)	Median (95% CI) Survival (years)	Median (95% CI) Time to AIDS (years)
15-24	12.5 (12.1-12.9)	11.0 (10.7-11.7)
25-34	10.9 (10.6-11.3)	9.8 (9.5-10.1)
35-44	9.1 (8.7-9.5)	8.6 (8.2-9.0)
45-54	7.9 (7.4-8.5)	7.7 (7.1-8.6)
55-64	6.1 (5.5-7.0)	6.3 (5.5-7.2)
≥65	4.0 (3.4-4.6)	5.0 (4.0-6.2)

Adapted from *Concerted Action on SeroConversion to AIDS and Death in Europe. Time from HIV-1 seroconversion to AIDS and death before widespread use of highly-active antiretroviral therapy: a collaborative re-analysis. Collaborative Group on AIDS Incubation and HIV Survival including the CASCADE EU Concerted Action. Lancet.* 2000 Apr 1;355(9210):1131-7.

Patient Education

- The CD4 cell count and HIV viral load are the two markers that provide information on the degree of current immunocompromise and the risk of disease progression.
- The lower the CD4 count, the higher the risk of AIDS-related illness.
- Current United States guidelines recommend ART for all HIV-infected individuals. In areas where treatment resources are limited, the CD4 count is the major indicator for initiation of ART.
- A low HIV viral load is associated with slower immune deterioration; a high viral load is associated with quicker immune deterioration.
- Older individuals may have a poorer response to therapy; earlier initiation of therapy may be considered for older patients.

Early HIV Infection

Background

Acute HIV infection refers to the very early stages of HIV infection, or the interval from initial infection to the time that antibody to HIV is detectable; early HIV infection usually includes the first 6 months of infection. During the acute stage of HIV infection, patients typically have symptoms of acute retroviral illness, very high HIV RNA levels (>100,000 copies/mL) and detectable p24 antigen, and negative or indeterminate HIV antibody test results.

Diagnosing patients with acute HIV infection is a clinical challenge. The symptoms of acute HIV are nonspecific, and although many patients seek medical care for symptoms of acute retroviral syndrome, the diagnosis commonly is missed at initial presentation. The difficulties involve recognizing the clinical presentation of acute HIV infection and testing patients appropriately. In HIV treatment facilities, clinicians generally do not see patients with primary HIV infection unless they are referred with the diagnosis already established. In other health care settings, clinicians may not be familiar with the signs and symptoms of acute HIV infection and often do not consider this diagnosis. Despite the difficulties, recognizing early HIV infection in symptomatic patients is essential. Early diagnosis provides an opportunity for early linkage to HIV care and treatment and may decrease future HIV transmission by newly identified patients, who are particularly infectious during early untreated HIV infection.

After infection with HIV, it takes a median of about 25 days before the HIV antibodies are detectable in most people; in some individuals, it may be several months before seroconversion occurs. HIV RNA may be detectable within 10 days of infection and p24 antigen in about 15-20 days. Persons with known exposures to HIV, whether occupational or not, should be monitored closely beginning at about 3 weeks after exposure (routine monitoring at 6 weeks, 3 months, and 6 months after exposure to HIV is likely to result in delayed diagnosis of HIV infection). For information on postexposure prophylaxis, see chapters *Nonoccupational Postexposure Prophylaxis* and *Occupational Postexposure Prophylaxis*.

S: Subjective

Approximately two thirds of patients infected with HIV develop symptoms of acute HIV infection, a condition known as acute retroviral syndrome. Symptoms typically appear 2-6 weeks after exposure to HIV and generally include several of the following:

- Fever (present in 80-90%)
- Rash, often erythematous and maculopapular
- Fatigue
- Pharyngitis (with or without exudate)
- Generalized lymphadenopathy
- Urticaria

- Myalgia/arthralgia
- Anorexia
- Mucocutaneous ulceration
- Headache, retroorbital pain
- Neurologic symptoms (e.g., aseptic meningitis, radiculitis, myelitis, cranial nerve palsies)

This symptomatic phase usually persists for 2-4 weeks or less, although lymphadenopathy may last longer. Symptoms and signs are similar to those of many other illnesses, including other viral syndromes, influenza, and mononucleosis. However, generalized lymphadenopathy, rash, thrush, and mucosal ulceration are sufficiently uncommon in most adult febrile illnesses that, when present, they

should trigger suspicion of acute HIV infection. It is important to obtain a history of recent risk behaviors from all patients who present with symptoms consistent with acute HIV infection and to have a low threshold for testing for acute HIV infection. Common laboratory findings include leukopenia, thrombocytopenia, and mild transaminase elevations.

O: Objective

The 3rd-generation assays may detect HIV infection within 4 weeks, but new 4th-generation HIV antigen/antibody tests usually show positive results within 2-3 weeks after an infection occurs. During the symptomatic phase of HIV seroconversion, HIV antibody tests may still indicate negative or indeterminate serostatus. For patients who have negative or indeterminate antibody results but symptoms consistent with seroconversion illness and a recent risk history for HIV exposure, an HIV RNA (viral load) test should be performed. Patients with negative or indeterminate antibody test results but detectable HIV viral loads (particularly >10,000 copies/mL) can be considered to be infected with HIV, although the antibody test should be repeated later to confirm seroconversion. A low viral load (<10,000 copies/mL) may indicate a false-positive result, because viral loads typically run very high (i.e., >100,000 copies/mL and, often, millions of copies/mL) during the acute infection stage. For patients who have negative or indeterminate HIV antibody test results and low positive HIV viral loads, the HIV RNA test should be repeated on a different blood specimen.

The 4th-generation HIV tests do not distinguish between antigen positivity and antibody positivity. Patients with a positive result should be retested with an antibody test; if the result is negative or indeterminate and acute HIV is suspected, an HIV RNA test should be sent, as above (see chapter *Expedited HIV Testing*).

A/P: Assessment/Plan

Patients with early HIV infection will need additional medical evaluation, baseline laboratory testing, and intensive support, counseling, and education about HIV infection. See chapters *Initial History*, *Initial Physical Examination*, and *Initial and Interim Laboratory and Other Tests* for detailed information on the initial evaluation of HIV-infected patients.

Laboratory

The initial laboratory work should include the following:

- CD4 cell count and HIV viral load.
- A baseline HIV genotype test for all patients with early HIV infection, even those who do not choose to start antiretroviral treatment (ART). In some cities in the United States and Europe, 6-16% of infected individuals have acquired HIV virus strains with mutations that confer resistance to antiretroviral medications. These resistance mutations may be identified by early resistance testing, but may not be detectable later. (See chapter *Resistance Testing*.)
- Patients diagnosed on the basis of HIV RNA should have an HIV antibody test repeated in 3-6 months to document seroconversion.

Treatment

ART is recommended for all persons with HIV, including those with early HIV infection. Some limited evidence suggests that treatment initiated during primary HIV infection may have particular benefits, including preserving HIV-specific immune function that would otherwise be lost as the infection progresses, limiting the size of the HIV viral reservoir, and decreasing the loss of gastrointestinal lymphoid tissue. In addition, early treatment is expected to decrease rates of HIV transmission during a time of heightened infectiousness.

The potential advantages of ART for primary infection must be weighed against

the possibility of short- and long-term toxicities, the possibility of developing drug resistance, and the adherence challenges associated with starting ART quickly for newly diagnosed patients. Issues concerning the possible treatment of primary HIV infection are reviewed in the U.S. Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents* (available at aidsinfo.nih.gov/guidelines).

For pregnant women with acute or recent HIV, the risk of perinatal HIV transmission is very high; thus, ART should be started as early as possible to try to prevent infection of the infant (see chapter *Reducing Perinatal HIV Transmission*).

For patients who opt to start therapy during primary HIV infection, the choice of agents and the recommendations for monitoring are the same as those for the treatment of patients with chronic HIV infection (see chapter *Antiretroviral Therapy*). The initial goal of therapy in primary HIV infection is to suppress the HIV viral load to undetectable levels.

Patient Education

- Patients with early HIV infection need support and counseling, as do all newly diagnosed patients.
- Intensive education about HIV infection, the course of disease progression, prognosis, and the benefits and risks of ART must be undertaken.
- Counseling patients about safer sex and drug injection techniques, as indicated, is especially important because these patients may have ongoing high-risk behaviors for HIV transmission and because they may be highly infectious during the primary infection period. (See chapter *Preventing HIV Transmission/Prevention with Positives* for more information about patient support and counseling in these areas.)

Expedited HIV Testing

John Nelson, PhD, CPNP

Background

According to the U.S. Centers for Disease Control and Prevention (CDC), about 1.15 million people are living with HIV in the United States, and it has been estimated that about 18% of these individuals are unaware of their HIV serostatus. Additionally, it is estimated that 50,000 new HIV infections occur in the United States each year. It is important to identify persons who are infected with HIV as soon as possible after infection, in order both to link them to health care services and to reduce the risk that they will unknowingly transmit HIV to others.

In order to identify those with HIV infection, the CDC recommends routine voluntary HIV screening for all adults, adolescents, and pregnant women. Nevertheless, many people are reluctant to be tested, and many clinics do not offer routine testing. With expedited HIV testing, clients can be tested and receive their preliminary results during a single visit. The goals of expedited testing are to identify HIV infection as early as possible after initial infection and to do so in as little time as possible (negative results, indeterminate results, and confirmed positive test results are available during the same visit that testing is done). This makes it possible to link persons testing HIV positive to HIV medical care and other supports as quickly as possible. Expedited testing also allows for the efficient management of clients in need of urgent medical treatment (such as pregnant women) and situations requiring quick clinical decision making (such as assessment for postexposure prophylaxis).

Expedited HIV tests include both traditional nonlaboratory-performed rapid tests and antigen/antibody (Ag/Ab) laboratory-based tests. The Ag/Ab 4th-generation tests detect both HIV p24 antigen and anti-HIV antibodies (for HIV-1 and/or HIV-2). The 4th-generation tests are more sensitive during the acute phase of HIV infection than are the previous-generation screening immunoassay tests (including nonlaboratory-based rapid tests), so they are capable of diagnosing HIV infection at an earlier stage (as early as 2-3 weeks after infection). One laboratory-based 4th-generation test is capable of delivering the preliminary results within 1 hour.

Because of the greater sensitivity of 4th-generation laboratory-based immunoassays in identifying HIV at earlier stages of infection, it is now recommended that these tests be done whenever possible for HIV screening. Interestingly, 4th-generation testing is less expensive per test than the point-of-care (POC) rapid tests in the United States.

Clients and Settings for Expedited Testing

Expedited HIV testing is important in settings in which the availability of HIV test results would influence medical care immediately, or in routine screening in settings where HIV prevalence is high or clients are not likely to return for the test results. Settings in which the use of highly sensitive 4th-generation HIV Ag/Ab testing from a laboratory is preferable include labor and delivery facilities (where

identification of HIV infection is critical in preventing perinatal transmission), prenatal care facilities, hospital emergency departments, urgent care and acute care clinics, sexually transmitted disease clinics, drug treatment clinics, hospitals, and other clinical care or testing sites in communities with a high prevalence of HIV. In high-risk jurisdiction settings such as jails and mobile health service vans, and in community outreach programs where access to an on-site laboratory does not exist, nonlaboratory-based rapid testing is still recommended.

Expedited HIV Tests

The U.S. Food and Drug Administration (FDA) has approved three 4th-generation HIV Ag/Ab tests for use in the United States (see Table 1). Federal regulations under the Clinical Laboratory Improvement Amendments (CLIA) program categorize tests as waived, moderate complexity, or high complexity. Many rapid tests are approved as CLIA-waived tests (see Table 2), meaning that they may be performed at the POC after appropriate staff training and with procedures in place to ensure quality control. These tests use whole blood or oral fluid and require a few simple steps to perform.

Other rapid tests are “nonwaived” tests and must be performed in laboratories. Results for rapid tests performed at the POC are available in less than 30 minutes; results for expedited tests done in a laboratory should be available within 1 hour.

As mentioned above, 4th-generation laboratory-based tests are recommended for HIV screening. In cases wherein laboratory-based 4th-generation HIV testing is not available, then 2nd- or 3rd-generation antibody POC rapid testing may be done with the knowledge that a person in seroconversion may test falsely negative.

Table 1. FDA-Approved 4th-Generation HIV Tests for Laboratory Use Only (CLIA Moderate- or High-Complexity Tests)

Test Name	Time to Test Result	Target Analyte (Test Generation)	Sensitivity for Established HIV-1 Infection & Sensitivity for HIV-2 Infection (%) (95% Confidence Interval)	Specificity for Established HIV-1 Infection (%) (95% Confidence Interval)	Approved Specimen Types & Volume	Assay Format
Abbott Architect HIV Ag/Ab Combo Assay (fully automated CLIA moderate-complexity assay) (Expedited)	<30 min	HIV-1 p24 antigen and antibodies to HIV-1/2 (4th generation)	Plasma/Serum HIV-1 p24: 100 (94.3-100)/HIV-1: 100 (99.63-100) HIV-2: 100 (98.2-100)	Plasma/Serum 99.8 (99.6-99.9)	Plasma/Serum 150 µL	Chemiluminescent micro-particle immuno-assay
Bio-Rad GS HIV Combo Ag/Ab EIA (manual or semi-automated CLIA high-complexity assay)	>3 hours	HIV-1 p24 antigen and antibodies to HIV-1/2 (4th generation)	Plasma/Serum HIV-1: 100 (99.7-100); HIV-2: 100 (98.1-100)	Plasma/Serum 99.87 (99.76-99.93)	Plasma/Serum 75 µL	Enzyme immuno-assay micro-well format
Alere Determine HIV-1/2 Ag/Ab Combo	20 minutes	HIV p24 antigen and antibodies to HIV-1 and/or HIV-2 (4th generation)	Whole Blood 99.9 (99.4-100)	Whole Blood 99.6 (99.2-99.8)	Plasma/Serum Whole Blood	Immuno-assay
MultiSpot HIV-1/HIV-2 Rapid Test	15 minutes	Antibodies to HIV-1 and HIV-2 (detection and differentiation) (3rd generation)	100% (99.9-100)	99.9% (99.8-100)	Plasma/Serum	Immuno-assay

Interpreting Test Results

All FDA-approved tests are highly sensitive and specific. As previously mentioned, 4th-generation HIV Ag/Ab tests have significantly greater sensitivity to very recent (acute) HIV infection. The negative predictive value of all rapid and expedited HIV tests is close to 100%. That means a client who receives a negative rapid test result almost assuredly is not infected, barring recent exposures (e.g., sexual contact or needle sharing with an infected person within the past 1-3 months, depending on the test used).

For clients who test reactive (positive) on a rapid or expedited test, the result is considered preliminary and must be confirmed. Traditionally, confirmation has been done by use of either a Western blot (WB) or immunofluorescence assay (IFA). However, neither of these confirmatory tests is expedited, and neither is able to differentiate HIV-1 and HIV-2 infections simultaneously. The confirmatory test currently recommended by the CDC is one that is able to differentiate HIV-1 and HIV-2 antibodies and is expedited (e.g., MultiSpot HIV-1/HIV-2 Rapid Test). If the confirmatory test result is positive, the client is considered to be infected with HIV. If the confirmatory test result is negative (no HIV Ab bands with a WB test or no visible reaction on the MultiSpot in the HIV-1 and/or HIV-2 Ab areas) or indeterminate (with the WB test, greater than 0 bands but too few bands to be considered positive), then an HIV RNA-1 test should be done immediately to check for early infection (Figure 1). In this case, a detectable HIV RNA (unless very low) will indicate early HIV infection – the client is most likely HIV infected and is seroconverting from antibody negative to positive status. The HIV-1 RNA test should be done regardless of the original HIV screening test (4th-generation Ag/Ab or earlier-generation Ab). With detectable HIV RNA, the client

should be considered infected, but an HIV confirmatory (WB or IFA) antibody test should be repeated in roughly 2-4 weeks to determine HIV antibody status. In the case of possible HIV-2 infection, consultation with an HIV specialist is recommended.

The positive predictive value of a single positive rapid or expedited HIV test result depends on the specificity of the test and the HIV prevalence in the community. The high specificity of the rapid or expedited tests means that, if a test result is positive, the likelihood that a client is truly HIV infected depends on the local HIV prevalence. In a population with a high HIV prevalence, a positive test result is likely a true positive, but in a population with a low HIV prevalence, that result has a greater chance of being a false positive.

Figure 3. 4th-Generation HIV Testing Algorithm

Centers for Disease Control and Prevention. *Detection of acute HIV infection in two evaluations of a new HIV diagnostic testing algorithm – United States, 2011–2013.* MMWR Morb Mortal Wkly Rep. 2013 Jun 21;62(24):489–94.

Information for the Client

Educating the Client Before Testing

It is important to offer expedited HIV testing as part of a broader health screening, to educate clients about HIV infection and about the test, and to give them an opportunity to ask questions and to decline testing. The provider should emphasize that a second test is always performed in order to confirm a positive preliminary screening (laboratory or POC) test result. When possible, expedited or rapid testing should be made available during a regular visit so that clients do not face additional waiting time, and so that HIV infection can be detected as early as possible.

Giving Reactive (Preliminary Positive) Rapid Test Results

Example of simple language to use outside labor and delivery settings

The following wording is suggested when the client's rapid (nonconfirmed) test result is positive (or the expedited confirmatory testing is negative [and therefore the final result is "indeterminate"]):

"Your preliminary screening test result was positive, but we won't know for sure if you are infected with HIV until we get the results from your confirmatory test. In the meantime, you should take precautions to avoid transmitting the virus. This means protecting all sex partners from possible exposure (using condoms, for example), not sharing needles or syringes for any purpose, and not sharing razors."

Emphasize the importance of a confirmatory test, arrange for the confirmatory test to be done immediately. If an expedited, confirmatory test is available (MultiSpot Rapid), the client should not leave until that test has been completed and the result given. If an expedited confirmatory test is not available, then schedule a return visit for the client to receive the test result. It is important to develop a plan for follow-up with

this client during this waiting period (by phone or in-person) and to reinforce the importance of following up. (Be sure to have the client's contact information in case he or she does not return for confirmatory results.)

Example of language to use in labor and delivery settings

The following wording is suggested when the client's nonconfirmed expedited or rapid test result is positive:

"Your preliminary HIV screening result was positive. You may have HIV infection. We need to do confirmatory tests to verify this first result, but it is important to start medication immediately to reduce the risk of passing HIV to your baby while we wait for the result. It is important to delay breast-feeding until we have the confirmatory test results."

Follow-Up for Results of Confirmatory Tests

Clinical sites that offer expedited or rapid HIV testing should have a protocol for conveying the results of preliminary and confirmatory positive HIV test results to clients. With rapid tests and expedited laboratory-based testing, the client may be given the confirmatory results on the same day tested. If expedited laboratory-based confirmatory testing (MultiSpot Rapid), is not available, blood for confirmatory WB or IFA must be collected. In this case, results generally will not be available the same day, but appropriate specimen collection and test ordering should be done before the client leaves on the day the preliminary positive result is given.

If the confirmatory result is negative or indeterminate (after a positive preliminary result), testing for HIV-1 RNA must be done.

Sites should either provide confirmatory notification services in-house or have mechanisms in place for notifying clients of

their test results. All clients with confirmed positive HIV test results should be referred immediately for HIV care, community-based HIV services, or health department disease intervention specialists (who are trained to link people to care). Testing sites should establish reliable referral pathways to qualified HIV care providers with follow-up policies and procedures in place to make sure that linkage to care actually occurred.

Client Education

In general settings and in situations not involving labor and delivery, advise clients of the following:

- Expedited laboratory and rapid nonlaboratory HIV testing is an important component of health screening. Learning early that they have HIV infection can help clients better maintain their health.
- Knowing that they have HIV infection can help clients start treatment as soon as possible, and to take precautions to prevent transmission of HIV to others.
- Clients can refuse an HIV test, and it will not affect the care they receive.
- The results from expedited or rapid tests are available at the same visit, usually in less than 1 hour.
- The expedited 4th-generation Ag/Ab tests are very accurate and are better at identifying newly infected persons than the 2nd- and 3rd-generation rapid and laboratory screening tests.
- If the expedited or rapid test result is positive, a second, confirmatory test always is done in order to provide assurance that the screening test result was accurate; and, if the confirmatory test is either negative or indeterminate, a third test (HIV viral load) needs to be done to determine whether the client is infected.
- It is important that clients return for the results of all confirmatory tests.
- If a client's expedited or rapid test result is negative, that client is most likely not infected with HIV, *unless* the infection occurred within the past month – the test may not detect very recent infection.
- Test results are kept confidential. However, if a confirmatory test result is positive, most state laws require that information to be reported to the health department.
- There are clinics and other resources to help clients obtain more information as well as counseling, care, or treatment. The provider should provide specific referrals to these as well as assist the client in linkage to the referral site as soon as possible.

Resistance Testing

Background

Genotype and phenotype testing for resistance currently is commercially available for all nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and integrase inhibitors that have been approved by the U.S. Food and Drug Administration (FDA). In addition, standardized genotype testing is commercially available for enfuvirtide (a fusion inhibitor).

Neither genotype nor phenotype predicts which antiretroviral (ARV) drugs will be active in a particular patient, only ARVs that are not likely to be active. Nevertheless, studies comparing the use of resistance testing with expert opinion alone have shown that resistance testing can improve virologic control of HIV. Resistance testing is used to guide subsequent treatment for patients whose antiretroviral therapy (ART) is failing and for those whose viral load is not completely suppressed after starting therapy. It also is used to select an initial regimen that is likely to be effective for patients who have never been treated, and it is recommended for all patients with HIV infection (both acute and chronic) upon entry into care, whether or not ART is to be initiated. In addition, resistance testing is recommended for pregnant women who are not on ART and for those who are on ART but have a detectable HIV viral load.

HRSA HAB Performance Measures

Percentage Percentage of patients, regardless of age, with a diagnosis of HIV who had an **HIV drug resistance test** performed before initiation of HIV antiretroviral therapy if therapy started during the measurement year

(All-Age measure)

Genotype Tests

Genotype testing works by amplifying and sequencing HIV taken from a patient to look for mutations in the HIV reverse transcriptase, protease, integrase, or envelope genes that are known to correlate with clinical resistance to ARV drugs. Genotype tests generally can detect mutations in plasma samples with HIV RNA levels of >1,000 copies/mL, but sometimes are successful with viral loads of 500-1,000 copies/mL. Species representing 20% or more of the amplified product usually can be detected by current techniques, but minor species may not be detected. Resistance mutations that developed in the past during treatment with certain ARV medications may be archived as minor species and become invisible to genotype testing (as early as 4-6 weeks) after the drug is discontinued. These resistance mutations may reemerge and cause drug failure, however, if the previous drug is used again. By contrast, mutations acquired at the time of infection (from a transmitted virus

that was already resistant) appear to persist for years, although the duration is not known precisely and may vary by mutation.

A genotype test takes 1-2 weeks to complete. The results are reported as a list of the mutations detected; most reports also include an interpretation that indicates the drug resistance likely to be conferred by those mutations (see “Limits of Resistance Testing,” below).

Note that the standard genotype tests detect only mutations that may affect reverse transcriptase inhibitors and PIs; a specific genotype for the integrase inhibitor (or fusion inhibitor) class must be ordered if there is concern for resistance to this class. Resistance to CCR5 antagonists is uncommon; a change in coreceptor tropism is a more likely cause of virologic failure for patients taking maraviroc. For such patients, a coreceptor tropism assay should be obtained. Afterwards, if resistance to CCR5 antagonists is still suspected, a resistance test can be obtained.

Genotype results must be interpreted carefully. Because mutations can become invisible to the genotype testing process when the selective pressure of a drug is removed, a thorough ARV history, a review of any past resistance tests, and expert clinical assessment are necessary to put the results of a genotype test in proper perspective and to identify options for further treatment (see “Limits of Resistance Testing,” below). A compilation of the most common HIV mutations selected by the three classes of antiretroviral agents is available at www.hiv.lanl.gov/content/index. Other resources useful in understanding resistance testing and interpreting test results include the information compiled by the International Antiviral Society-USA and the Stanford University HIV Drug Resistance Database (hivdb.stanford.edu).

A “virtual phenotype” is a genotype that is compared with a databank of patient samples that have been analyzed by paired genotype and phenotype testing. The patient’s genotype is matched to a banked genotype, and the patient’s phenotype is then predicted on the basis of the phenotypes paired to the banked genotype. A virtual phenotype can be completed in the same amount of time as a genotype. Results are reported as a genotype (listing the mutations detected) as well as a predicted fold change in the 50% inhibitory concentration (IC50) of each drug to the patient’s virus (see “Phenotype Tests,” below). The predicted susceptibility of the patient’s virus to each drug is then reported, based on biologic and clinical cutoffs.

Phenotype Tests

Phenotype testing works by splicing the HIV reverse transcriptase and HIV protease genes from a patient’s virus into a standardized laboratory strain, which is then grown in the presence of escalating concentrations of ARV drugs. The test measures the IC50 of each drug against the virus in vitro. Results are reported as fold change in IC50, as compared with a drug-susceptible control strain or with a previous test of the same patient’s blood. The predicted susceptibility of the patient’s virus to each drug is then reported, based on what is known about the correlation between fold change in IC50 of that drug and clinical resistance. As with genotype testing, the phenotype may not be able to detect resistance if the HIV RNA level is low (<1,000 copies/mL) and may not detect minor species. Therefore, a thorough history of ARV use and resistance tests, as well as expert interpretation, are essential for determining the significance of the results (see “Limits of Resistance Testing,” below). A phenotype takes 2-3 weeks to complete.

Choosing Between Genotype and Phenotype

Genotype testing is faster and cheaper than phenotype testing, and it can detect emerging resistance, that is, virus with a mixture of strains of which some may be sensitive and some may be resistant to a given drug, as long as they are present in sufficient quantity. It is therefore generally recommended (including by the U.S. Department of Health and Human Services [HHS]) for ART-naïve patients and for patients whose first or second ART regimens are failing. Additionally, in some instances it is very important to know the exact viral mutation pattern in order to predict the virus's response to subsequent therapy, particularly in patients with virologic failure on a regimen containing an NNRTI or integrase inhibitor. HHS recommends phenotype testing when patients are suspected of having complicated or multidrug resistance patterns (for example, in the setting of extensive prior ART), or when patients are found to have such patterns on genotype testing (especially resistance to PIs).

Using Genotype and Phenotype Tests at the Same Time

Genotype and phenotype tests have a few complementary properties that may, in some circumstances, make it desirable to use both tests at the same time. This strategy is especially advantageous when trying to devise a regimen for patients who have been exposed to many ARV agents and have few remaining treatment options, and for whom the development of additional resistance could be particularly dangerous. For example, early mutations may appear on a genotype before increases in inhibitory concentrations are detectable on a phenotype. Phenotype testing can detect loss or gain of drug efficacy caused by complex interactions of mutations that, by themselves, would not be predictive. In some cases, results of the genotype and the phenotype may be discordant; in these cases, consultation with an expert is recommended.

Recommendations for Resistance Testing

An overview of when genotype and phenotype testing is and is not recommended is presented in Table 1.

Table 1. Resistance Testing Recommendations

Clinical Setting/Recommendation	Rationale
Recommended	
Acute HIV infection Genotype	- Determine whether drug-resistant virus was transmitted, to help design an initial regimen or to change a regimen accordingly. - If ART is deferred, consider repeating genotype at the time of ART initiation.
Chronic HIV infection before starting ART - Genotype - Coreceptor tropism assay	- Determine whether drug-resistant virus was transmitted to help design an initial regimen. - Perform upon entry to care (as close to the time of infection as possible), because transmitted drug-resistant virus is more likely to be detected earlier in the course of HIV infection. - If ART is deferred, consider repeating genotype at the time of ART initiation. - Consider integrase genotypic resistance assay if integrase inhibitor resistance is a concern. - Perform coreceptor tropism assay if use of a CCR5 antagonist is being considered.
Virologic failure during ART - Genotype if failure of 1st or 2nd regimen - Both phenotype and genotype if multiple prior regimens, suspicion of mutations to multiple ARVs (especially PIs), or evidence of such mutations on genotype - Coreceptor tropism assay	- Determine the role of resistance in drug failure and optimize the selection of active drugs for the new regimen, if indicated. - Perform while patient is taking ARVs, or ≤ 4 weeks after discontinuing ARVs. - If virologic failure on integrase inhibitor or fusion inhibitor, obtain specific genotypic testing for resistance to these to determine whether to continue them. - Perform coreceptor tropism assay if use of a CCR5 antagonist is being considered.
Suboptimal suppression or viral load Genotype or phenotype, depending on clinical situation (as above)	Determine role of resistance: identify active drugs for new regimen.
Pregnant women Genotype or phenotype, depending on treatment history (as above)	- Perform before initiation of ART or prophylaxis. - Perform for all on ART with detectable HIV RNA levels. - Optimize the selection of active drugs for ARV regimen.
Not Usually Recommended	
After discontinuation (>4 weeks) of ARVs	- Assist in selecting optimal regimen to achieve maximal viral suppression. - Drug-resistance mutations may decrease in number and become undetectable on assays.
Plasma viral load <500 HIV RNA copies/mL	Resistance assays are likely to be unsuccessful in patients with HIV RNA <500 copies/mL, because of the low number of RNA copies. In those with levels >500 but $<1,000$ copies/mL, testing may fail but can be considered.

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents. *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. Department of Health and Human Services. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Antiretroviral-Naive Patients

With treatment-naive patients, resistance testing may reveal resistance mutations that were acquired at the time of infection, through infection with a strain of HIV that had already developed ARV resistance. Current guidelines recommend genotype testing for recently infected patients and for ARV-naive, chronically infected patients before initiation of therapy. It is important to test as early as possible in the course of HIV infection, to increase the likelihood of detecting transmitted mutations. The rationale for resistance testing in ARV-naive patients is twofold: 1) The prevalence of primary resistance is substantial, particularly in locations with a high prevalence of persons taking ART; and 2) Unknowingly starting a patient on ARV medications to which his or her virus is already resistant may risk failure of the initial regimen, rapid acquisition of additional resistance mutations, and curtailment of future treatment options.

Limits of Resistance Testing

As discussed above, drug-resistant HIV evolves in response to selective pressure applied by the ARV drugs in the patient's system. Specific resistance mutations develop in response to the pressure exerted by specific drugs (M184V, for example, evolves in response to lamivudine or emtricitabine). The presence of viral resistance suggests that a particular drug (and drugs with similar resistance patterns, or cross-resistance) is unlikely to be successful in suppressing viral replication.

In contrast, the absence of resistance to a drug on a genotype or phenotype test does not necessarily indicate that the drug will be effective, particularly if that drug (or drugs sharing cross-resistance) has been used previously. If a particular drug is discontinued, the viral strains harboring the mutations that confer resistance to that drug may decrease below the threshold of detection by the resistance assay, so the resistance test may not reveal certain resistance mutations. In such situations, minority populations of resistant viruses may exist in reservoirs and may emerge rapidly under selective pressure if that drug is restarted, or if drugs with similar or overlapping resistance patterns are used. The implications of archived mutations are twofold: 1) Resistance tests are most reliable when the patient is still taking the failing regimen; and 2) Resistance testing should be interpreted in the context of both the drugs that the patient was taking at the time of the test and the drugs that the patient had been exposed to previously (i.e., the patient's ARV history). In addition, it is important to review any previous resistance tests, which may show resistance mutations that were not revealed on subsequent testing.

Resistance Testing in Patients with Virologic Failure

As discussed in the chapter *Antiretroviral Therapy*, factors other than resistance may cause failure of ART; these include nonadherence, drug-drug interactions, and malabsorption. Therefore, before assuming drug failure, it is important to assess the causes of ARV regimen failure. If resistance is suspected, resistance testing should be done while the patient is taking the failing regimen, for the reasons noted above.

Patient Education

Advise patients of the following:

- Resistance testing can improve the likelihood of virologic control of HIV.
- Most treatment guidelines recommend resistance testing in certain circumstances.
- Both genotype and phenotype testing can detect resistance only if it exists in at least 20% of the viral species present in a patient (known as the dominant species). Minor species may harbor resistance that remains undetected by either test.
- In general, a patient's viral load must be at least 1,000 copies/mL for either test to be reliable, although samples with >500 copies/mL sometimes can be analyzed.
- Resistance tests are most reliable when performed while a patient is still taking a failing regimen, or within 4 weeks after stopping.
- Neither test predicts which drugs will be active in a particular patient, only drugs that are not likely to be active.

Karnofsky Performance Scale

Background

The Karnofsky Performance Scale is an assessment tool intended to assist clinicians and caretakers in gauging a patient’s functional status and ability to carry out activities of daily living.

It is important to assess a patient’s performance on a regular basis, especially as the effects of HIV progress. Documentation of Karnofsky scores over time may be very useful in following a patient’s course of illness, and can help a disabled patient in his/her application for disability benefits. It also is used for some research applications.

The Karnofsky Performance Scale

Description	Percent (%)
Normal; no complaints; no evidence of disease	100
Able to carry on normal activity; minor signs or symptoms of disease	90
Normal activity with effort; some signs or symptoms of disease	80
Cares for self; unable to carry on normal activity or do work	70
Requires occasional assistance, but is able to care for most personal needs	60
Requires considerable assistance and frequent medical care	50
Disabled; requires special care and assistance	40
Severely disabled; hospitalization indicated although death not imminent	30
Very sick; hospitalization necessary; requires active support treatment	20
Moribund; fatal processes progressing rapidly	10
Dead	0

Occupational Postexposure Prophylaxis

Background

Health care personnel (HCP) and other individuals working in medical, public safety, sanitation, and laboratory settings are at risk of occupational exposure to HIV. Although avoiding exposure to HIV is the only reliable way of preventing HIV infection, postexposure prophylaxis (PEP), can reduce the risk of HIV infection in exposed HCP. PEP is defined as antiretroviral (ARV) therapy that is initiated soon after exposure to HIV with the intention of preventing HIV infection.

This chapter examines the general issues involved with PEP in occupational settings. The information is based on 2013 U.S. Public Health Service (USPHS) guidelines for occupational PEP (see “References,” below). For information on PEP for *nonoccupational* HIV exposures (such as sexual exposure), see chapter *Nonoccupational Postexposure Prophylaxis*. Note that other bloodborne pathogens, particularly hepatitis B virus (HBV) and hepatitis C virus (HCV), also may be transmitted through occupational exposure; it is important to consider these potential infections when assessing occupational exposures. For information on the management of occupational exposures to HBV and HCV, refer to the 2001 USPHS PEP guidelines (see “References,” below). In addition, the National Clinicians’ Post-Exposure Prophylaxis Hotline (PEPline) is available for telephone consultation at 888-HIV-4911 (888-448-4911).

The risk of HIV infection after exposure depends on several factors that are related to the exposure itself and to the source patient (see below). To make sound PEP recommendations, the clinician must assess the risk of HIV infection from the particular exposure. After this, the clinician and the exposed worker must discuss the possible benefit of PEP (given the risk of HIV transmission from the injury) in relation to the willingness of the exposed worker to adhere to a 28-day course of ARV medicines, the potential toxicity of the regimen, and drug interactions. HCP who are pregnant at the time of their exposure must weigh the risk of fetal exposure to HIV against the potential teratogenic and other risks of the ARV drugs (it should be noted that pregnancy is not a contraindication to PEP, and that a number of ARVs are recommended for use during pregnancy, based on safety and efficacy data) (see chapter *Reducing Perinatal HIV Transmission*).

The efficacy of PEP is related to the specific PEP regimen, the timing of PEP, and the exposed worker’s level of adherence to the PEP regimen. PEP is most likely to be effective if it is started within hours of an exposure, and outcomes may be compromised as the time from exposure increases. Nevertheless, it may be reasonable to offer PEP up to 72 hours after exposure. Adherence to PEP is strongly affected by factors such as the tolerability of the ARVs, the number of pills in the regimen, and the frequency of dosing. As current guidelines emphasize, it is very important to select a PEP regimen that is expected to be tolerated and that is convenient to take; any side effects or adherence difficulties should be managed promptly. The guidelines recommend the use of 3 (or more) PEP drugs for all exposures. Although the optimal duration of PEP is not known; studies support ARV treatment for 28 days.

In the work setting, HIV infection may occur through percutaneous injuries (e.g., needlesticks) or mucocutaneous exposures (e.g., mucous membrane or nonintact skin exposure) to blood or other potentially infectious body fluids. The risk of HIV seroconversion after occupational exposure with an HIV-contaminated hollow-bore needle is best described as 0.3%, on average. Another way of describing this to an exposed HCP is that, without PEP, HIV transmission occurs about

once in 300 instances of needlestick from a known HIV-infected source patient. In a retrospective case-control study of HCP with percutaneous exposure to HIV, the following exposure and source patient factors were associated with an increased risk of HIV transmission:

- Large-gauge (<18-gauge) hollow-bore needle
- Deep injury
- Visible blood on the device
- Procedure with needle in a blood vessel
- Terminal AIDS in the source patient
- High HIV viral load of the source patient

The factor described as “terminal AIDS in the source patient” is considered a surrogate for a source patient with a high HIV viral load (this study was done prior to the routine use of HIV viral load assays); high HIV viral load is known to be a substantial risk factor for HIV transmission. On the other hand, although an undetectable HIV viral load is thought to indicate a low risk of HIV transmission, transmission still is possible, and cases of perinatal and sexual transmission from sources with undetectable serum HIV RNA have been reported.

Compared with percutaneous injury, exposure of infectious body fluids to mucous membranes (e.g., eye or mouth) or to skin with an obvious impairment of integrity (e.g., abrasion or wound) typically involves a lower risk of HIV transmission (the transmission risk for mucous membrane exposure to HIV is approximately 1 in 1,000, and less than 1 in 1,000 for cutaneous exposure). However, mucocutaneous exposures that involve large volumes of blood or other infectious fluid from an HIV-infected patient with a high HIV RNA level or prolonged duration of contact are considered increased-risk exposures.

S: Subjective

An HCP reports possible exposure to HIV through a needlestick injury or mucocutaneous exposure.

Ideally, the HCP should immediately decontaminate the injured or exposed skin with soap and water, or flush the exposed mucous membranes with copious amounts of water or saline. The HCP should report the exposure immediately to appropriate authorities in the health care institution (e.g., the institution’s needlestick hotline).

Take a thorough history of the specific exposure, including the type of exposure, the type and amount of body fluid involved, the point of entry or exposure, the time it occurred, the HIV status of the source patient (if known), and HIV risk factors of the source patient (if HIV status is not known).

A: Assessment

Assess potential exposure to HIV (and to HBV and HCV). Consider the HIV status of the source and the characteristics of the exposure in deciding whether PEP should be offered. The guidelines recommend the use of PEP following percutaneous or mucous membrane exposures to potentially infectious body fluids. They note that PEP should be offered even in the case of an exposure to a source patient with an undetectable HIV viral load. Consult with experts if there is uncertainty about whether a particular exposure poses sufficient risk to warrant PEP.

P: Plan**Laboratory Testing****For the exposed HCP**

- Perform a baseline HIV antibody test.
- Test for other infections transmitted through occupational exposure, particularly hepatitis B (HBV surface antigen, surface antibody, core antibody), and hepatitis C (HCV antibody).
- Obtain complete blood count (CBC), creatinine and estimated glomerular filtration rate (GFR), and hepatic transaminases at baseline, before treatment with ARV medications.
- For women who may be pregnant, perform a pregnancy test.

For the source person

- The institution should perform appropriate testing of the source person for bloodborne pathogens (e.g., HIV, HBV, and HCV) if the person's status is unknown.
- The use of rapid or expedited HIV tests makes it possible to render quick decisions about the need for HIV PEP, and the 4th-generation Ag/Ab tests identify most cases of HIV during the window period of acute HIV infection (see chapter *Expedited HIV Testing*).
- Although a positive expedited test result requires confirmation before the individual is diagnosed as HIV infected, for the purposes of PEP, it should be considered a true positive until proven otherwise, and the exposed worker should be counseled accordingly. If, upon further testing, the source patient is determined to be HIV uninfected, PEP should be discontinued. A negative expedited test result is considered reliable unless the source has signs or symptoms of acute HIV (see chapters *Expedited HIV Testing* and *Early HIV Infection*).

- PEP should not be delayed (beyond 1-2 hours) while source patient HIV testing is under way.

Treatment

A regimen consisting of at least 3 ARV drugs is recommended for all occupational HIV exposures (the U.S. guidelines no longer recommend evaluation of the severity of exposure to determine the number of drugs in a PEP regimen). Recommendations for PEP regimens are based on expert opinion and largely follow the principles of HIV treatment regimens, but the PEP guidelines place particular emphasis on optimizing the tolerability and convenience of the regimen to facilitate adherence for 28 days.

Considerations in choosing the medications for a PEP regimen include:

- Possible ARV adverse effects
- Dosing schedule
- Drug-drug interactions with other medications the HCP may be taking
- The likelihood that the source patient's virus is resistant to 1 or more ARV medications

Provide counseling about the potential risks and benefits of PEP drugs, including possible adverse effects, drug-drug interactions, and the importance of close adherence. Recommended regimens are shown in Table 1; select one that is likely to be effective, tolerable, and convenient. Note that although these regimens are potent in treating HIV infection, their efficacy as prophylaxis has not been demonstrated. Consultation with experts is recommended (see "Expert Consultation," below).

These recommendations are drawn from the 2013 guidelines for occupational PEP; consult the most recently updated version of the guidelines for current information.

Table 1. Antiretroviral Regimens for Occupational Postexposure Prophylaxis of HIV Infection

Preferred Regimen	
• Raltegravir 400 mg BID + tenofovir 300 mg/emtricitabine 200 mg QD (Truvada)	
Alternative Regimens (combine 1 drug or drug pair from left column with 1 NRTI pair from right column)	
• Raltegravir 400 mg BID • Darunavir 800 mg QD + ritonavir 100 mg QD • Etravirine 200 mg BID • Rilpivirine 25 mg QD • Atazanavir 300 mg QD + ritonavir 100 mg QD • Lopinavir/ritonavir 400/100 mg BID	+ • Tenofovir + emtricitabine (Truvada), 1 tablet QD • Tenofovir 300 mg QD + lamivudine 300 mg QD • Zidovudine + lamivudine (Combivir), 1 tablet BID • Zidovudine 300 mg BID + emtricitabine 200 mg QD
OR	
• Elvitegravir/cobicistat/tenofovir/emtricitabine (Stribild) (complete regimen; no additional NRTIs needed)	

Adapted from Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to Human Immunodeficiency Virus and Recommendations for Postexposure Prophylaxis (2013). Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Refer to the appendix in the updated PEP guidelines for more complete information on the advantages, and disadvantages of the various ARV agents available for PEP, and to the adult and adolescent ARV treatment guidelines (reference below) for more information about ARV adverse effects and drug-drug interactions.

Certain ARVs generally are not recommended for PEP because of elevated risk of toxicities; these include nevirapine (which is contraindicated as PEP), abacavir (testing for HLA-B*5701 must be done), didanosine, enfuvirtide, and tipranavir. Efavirenz may have a higher rate of significant adverse effects than other listed agents. Additionally, efavirenz should not be used with women who are in the first trimester of pregnancy or who may become pregnant while on PEP, because of possible teratogenicity. Some “alternative” ARVs may be considered for use based on consultation with experts.

If the source person is known or suspected to have infection with HIV that is resistant to ARV medications, seek expert consultation in selecting an appropriate PEP regimen.

However, PEP should not be delayed while consultation is being solicited, and it is possible to adjust regimens based on expert advice.

Begin ARV prophylaxis as soon as possible after the exposure occurs, preferably within a few hours and no later than 72 hours postexposure. Treatment should be continued for 28 days unless the source person is determined to be HIV uninfected.

Provide counseling about the efficacy of PEP, including timely initiation of PEP medications, the importance of adherence to the regimen for 28 days, and management of common adverse effects. Counsel exposed workers to avoid possible transmission of HIV, e.g., by using use latex barriers with their sex partners, avoiding breast feeding if possible, avoiding pregnancy, and avoiding blood/tissue donations, until transmission of HIV infection has been ruled out.

Follow-Up

Exposed workers should be reevaluated within 72 hours after exposure to review any available new information about the exposure and the source person as well as test results. For HCP taking PEP, early reevaluation

offers the opportunity for further education and counseling, including assessment and support of PEP adherence and evaluation and management of any side effects. In addition to health education counseling, many exposed workers need emotional support during their follow-up visits.

For persons on PEP, monitoring for adherence and adverse effects should be conducted again at 2 weeks. Blood testing (e.g., CBC, creatinine and electrolytes, liver function tests, others as indicated) should be done to monitor for PEP toxicity, as indicated by the particular ARV regimen.

PEP is discontinued after 4 weeks, and monitoring for ARV toxicity generally should not be repeated unless there is a need to recheck an abnormal result.

Follow-up HIV antibody testing should be done at 6 weeks, 3 months, and 6 months after the exposure. If a 4th-generation HIV Ag/Ab assay is used, the final HIV test can be done at 4 months rather than 6 months. Follow-up for 12 months is recommended for HCP who acquired hepatitis C via exposure to a source who was coinfecting with HIV and HCV.

Symptoms of acute HIV infection such as fever, rash, and lymphadenopathy (see chapter *Early HIV Infection*) may occur in HCP who are infected with HIV through occupational exposure. Exposed HCP should be counseled about the symptoms of acute HIV infection and instructed to return for reevaluation as soon as possible if symptoms develop. If symptoms consistent with acute HIV appear within 4-6 weeks after an occupational exposure, the HCP should be evaluated immediately; an HIV RNA test should be performed if acute HIV infection is suspected. If an HCP is found to be infected with HIV, that individual should be referred immediately to an HIV specialist for further evaluation and care.

Expert Consultation

Consultation with experts in PEP and in ARVs is recommended for assistance with managing all occupational exposures. This is particularly important if the source person is known or suspected to have ARV-resistant virus or if there are unusual or perplexing elements about the case (e.g., if the exposed HCP is pregnant or breast feeding, has significant medical illness, or takes medications that may interact with PEP ARVs). Consultation on the treatment of occupational exposures to HIV and other bloodborne pathogens is available to the clinician managing the exposed person on the National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at 888-HIV-4911 (888-448-4911). This service is available 7 days a week, at no charge (additional information is available on the PEPline website at www.nccc.ucsf.edu).

Prophylaxis Against HBV and HCV

Prophylaxis against HBV is recommended for patients with potential exposure to HBV who do not have immunity against HBV. Give hepatitis B immune globulin (HBIG) as a 0.06 mL/kg IM injection and initiate the vaccination series. For patients who received the vaccination series but did not develop protective antibodies (HBV sAb+), give HBIG at the time of the postexposure workup and initiate revaccination; consider repeat of HBIG in 1 month. For patients with immunity to HBV, no treatment is indicated.

For HCV, no prophylactic treatments are recommended. After potential exposure, perform a baseline HCV antibody test. If the source is known to have HCV infection, consider alanine aminotransferase (ALT) and HCV viral load testing at 4-6 weeks. HCV antibody testing should be repeated at 4-6 months. If HCV seroconversion occurs (indicated by ALT elevation, detectable HCV viral load, or confirmed positive HCV

antibody test result), refer the patient to a hepatitis C expert because early treatment of HCV may be indicated.

Addendum: Workplace Obligations

The health care institution has certain obligations to an exposed employee.* The institution should do the following:

- Evaluate the circumstances of the exposure, the type of fluid, and possible entry points.
- Evaluate the source patient.
- Perform baseline HIV antibody testing of the exposed HCP.
- Counsel the exposed HCP about the possible risks and benefits of PEP.
- Offer or recommend PEP as soon as possible after the exposure, preferably within the first several hours.
- Counsel the HCP about avoiding secondary transmission to others (safer sex and other risk-reduction practices, as indicated).
- Support and maintain the confidentiality of the HCP.
- For an HCP who is taking PEP, monitor for medication toxicity and adherence, and check for drug-drug interactions with other medications the HCP may be taking.
- Repeat HIV testing at 6 weeks, 3 months, and 6 months (if a 4th-generation HIV Ag/Ab assay is used, the final HIV test can be performed at 4 months).
- Report the exposure as required by federal and state regulations (including U.S. Occupational Safety and Health Administration requirements).

The PEP guidelines recommend that health care institutions have a formal mechanism for consultation about occupational HIV exposures, appropriate initial lab testing for source patients and exposed HCP, counseling for exposed HCP, availability of initial PEP regimens (e.g., starter packs), and a mechanism for outpatient follow-up. The protocols should

be readily available to emergency department providers and others who manage exposure incidents.

* Legal issues vary from state to state. In many states, institutions and clinics have no obligation toward nonemployees or students who are exposed to HIV in their settings. In such situations, clinical supervisors or school or university officials often are the first contact for notification. However, everyone working in a health care setting should be familiar with the procedures and financial responsibilities for HIV exposure management to avoid delays in HIV PEP treatment.

Patient Education

- Persons who have possible exposures to HIV in the work setting should contact the PEP service of their employer or a qualified medical provider as soon as possible after the exposure, or they should go to an emergency department. Although PEP may be effective if it is started within 72 hours of exposure, the sooner medications are initiated, the better the chance for preventing HIV transmission.
- PEP medications should be taken as directed for the full 28-day course. Adherence to PEP medications is essential for successful treatment.
- PEP recipients should be advised to contact their providers if they experience uncomfortable side effects. Providers may prescribe medications to alleviate the side effects, or they may prescribe different PEP medications.
- Until HIV infection has been ruled out, exposed workers should be advised to use latex or polyurethane barriers to prevent transmission of HIV to their sex partners, to avoid pregnancy, and to avoid breast feeding if possible.
- Exposed HCP should be counseled about the symptoms of primary HIV infection and instructed to contact their care providers immediately if symptoms develop.

Nonoccupational Postexposure Prophylaxis

Background

Although avoiding exposure to HIV is the only reliable way of preventing HIV infection, postexposure prophylaxis (PEP) can decrease the risk of infection after exposure to HIV. Antiretroviral (ARV) therapy is an important prophylactic intervention for appropriate persons with nonoccupational exposures (e.g., sexual contact; sharing of injection drug needles or other equipment) as well as those with occupational exposures (e.g., needlesticks). The U.S. Department of Health and Human Services (HHS) has developed recommendations for nonoccupational PEP (nPEP) based on data from animal models, perinatal clinical trials, and observational studies. Efficacy of nPEP remains hypothetical, and randomized clinical trials are not possible, but nPEP appears to be safe.

Overall, nPEP is more likely to be effective when the exposure is a single episode and nPEP is initiated in a timely manner. It is not appropriate for cases of multiple sexual exposures or injection drug use (IDU) exposures over time or for exposures that occurred >72 hours before starting nPEP treatment (see Figure 1).

The model for nPEP is derived in part from protocols for occupational PEP (e.g., in terms of risk assessment, pretreatment testing, timing of treatment, treatment regimens, and duration of treatment). (For information on occupational PEP, see chapter *Occupational Postexposure Prophylaxis*.) One significant difference between the protocols is that nPEP protocols should include interventions to reduce the risk of future HIV acquisition. Although exposed individuals usually seek care because they are interested specifically in antiretroviral prophylaxis, the nPEP model takes advantage of a critical opportunity to provide risk-reduction counseling and education.

See chapter *Occupational Postexposure Prophylaxis* for further discussion of evaluating possible benefits and risks of PEP.

S: Subjective

The patient reports potential exposure to HIV through a sexual encounter or the sharing of needles or other equipment for IDU.

Take a thorough history of the specific sexual or drug-use activities, the time the exposure occurred, the HIV status of the source person (if known), and HIV risk factors of the source person (if HIV status is not known). In cases of sexual assault, evidence collection and specific paperwork may be required as well.

O: Objective

Examine for trauma and for signs or symptoms of sexually transmitted diseases (STDs), which may increase the risk of HIV transmission. In injection drug users, examine for abscesses and signs or symptoms of infection. For women who may be pregnant, perform a pregnancy test.

A: Assessment

Assess for potential exposures to HIV and other bloodborne pathogens and for the presence of other STDs. The risk of HIV infection depends on the HIV status of the source and on the characteristics of the exposure (e.g., HIV viral load) and of the exposure (see Figure 1). Note that, although an undetectable HIV viral load is thought to indicate a low risk of HIV transmission, transmission still is possible, and cases of sexual transmission from sources with undetectable serum HIV RNA have been reported.

The estimated risk of HIV exposure will determine whether nPEP should be offered. An algorithm for risk evaluation and treatment decisions is presented in Figure 1.

P: Plan

Laboratory Testing

- Perform a baseline HIV antibody test.
- Evaluate and test for other infections transmitted through sexual or IDU exposures, including chlamydia, gonorrhea, syphilis, herpes simplex virus, hepatitis B (HBV surface antigen, surface antibody, and core antibody), and hepatitis C (HCV antibody).
- Obtain complete blood count (CBC), liver function tests (LFTs), and creatinine and estimated glomerular filtration rate (GFR) at baseline before treatment with ARV medications.

Treatment

Follow the algorithm in Figure 1 to determine whether the patient should be offered nPEP medications. If the patient is a candidate for treatment, provide counseling about the potential risks and benefits of nPEP.

Select an nPEP regimen that is likely to be effective but tolerable; consider the potential

Figure 1. Exposure Risk Algorithm

adverse effects and drug interactions of ARV agents (Table 1). Adherence to nPEP is strongly affected by factors such as the tolerability of the ARVs, the number of pills in the regimen, and the frequency of dosing. It is very important to select a regimen that is expected to be tolerated and that is convenient to take; any side effects or adherence difficulties should be managed promptly.

In general, the recommendations for nPEP involve 3-drug combination therapy. In some circumstances, more than 3 ARVs may be appropriate (e.g., if the source virus is resistant to ARVs), and in some cases, 2-drug PEP may be considered (e.g., if the HIV status of the source person is unknown, the exposure is thought to be of relatively low risk, or there is a need to minimize possible toxicity); consultation with experts is recommended.

Note that the HHS nPEP guidelines were last updated in 2005 and do not reflect current practice. **The recommendations presented here have been adapted to reflect current nPEP strategies, current guidelines for occupational PEP, and the availability of newer ARVs** (see Table 1). Note that a number of ARVs that were included in “preferred” or “alternative” regimens in the 2005 guidelines are no longer recommended in current practice, based on factors such as higher likelihood of causing adverse effects, greater pill burden, or inconvenient dosing. A number of alternatives to the recommendations listed below are available; consult with an expert. Note that, although these regimens are effective in treating HIV infection, their efficacy as prophylaxis has not been demonstrated.

If the source person is known or suspected to have infection with HIV that is resistant to ARV medications, seek expert consultation in selecting an appropriate nPEP regimen.

Certain ARVs are not currently recommended for PEP, including nevirapine (which is contraindicated for PEP), abacavir (testing for HLA-B*5701 must be done), didanosine, enfuvirtide, and tipranavir. Although the 2005 nPEP guidelines designate it as a preferred agent, efavirenz may have a higher rate of significant adverse effects than other agents listed in Table 1. Additionally, efavirenz should not be used during the first trimester of pregnancy or for women who may become pregnant while taking PEP, because of possible teratogenicity. Refer to the updated occupational PEP guidelines and to the adult and adolescent ARV treatment guidelines for more complete information on the advantages and disadvantages, adverse effects, and drug-drug interactions of the various ARV agents available for PEP (references below). Consider consultation with experts (see “Expert Consultation,” below).

Table 1. Antiretroviral Regimens for Nonoccupational Postexposure Prophylaxis of HIV Infection*

Preferred Regimens	
• Raltegravir 400 mg BID + tenofovir 300 mg/emtricitabine 200 mg QD (Truvada)	
Alternative Regimens (combine 1 drug or drug pair from left column with 1 NRTI pair from right column)	
• Raltegravir 400 mg BID • Darunavir 800 mg QD + ritonavir 100 mg QD • Etravirine 200 mg BID • Rilpivirine 25 mg QD • Atazanavir 300 mg QD + ritonavir 100 mg QD • Lopinavir/ritonavir 400/100 mg BID + • Tenofovir + emtricitabine (Truvada), 1 tablet QD • Tenofovir 300 mg QD + lamivudine 300 mg QD • Zidovudine + lamivudine (Combivir), 1 tablet BID • Zidovudine 300 mg BID + emtricitabine 200 mg QD	
OR	
• Elvitegravir/cobicistat/tenofovir/emtricitabine (Stribild) (complete regimen; no additional NRTIs needed)	

* Forthcoming HHS guidelines on nPEP may differ from these recommendations; check current recommendations.

Abbreviations: NNRTI = nonnucleoside reverse transcriptase inhibitor; NRTI = nucleoside analogue reverse transcriptase inhibitor; PI = protease inhibitor

Adapted from Kuhar DT, Henderson DK, Struble KA, et al; U.S. Public Health Service Working Group. *Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to Human Immunodeficiency Virus and Recommendations for Postexposure Prophylaxis*. Infect Control Hosp Epidemiol. 2013 Sep;34(9):875-92; and U.S. Department of Health and Human Services. *Antiretroviral Postexposure Prophylaxis After Sexual, Injection-Drug Use, or Other Nonoccupational Exposure to HIV in the United States—January 21, 2013*. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Once the decision is made to institute nPEP, do the following:

- Begin ARV prophylaxis as soon as possible after the exposure, but always within 72 hours. Treatment should be continued for 28 days, unless the source person is determined to be HIV negative.
- Provide counseling about the efficacy of nPEP, timely initiation of nPEP medications, adherence to the regimen for 28 days, and the importance of preventing additional HIV exposures during this time.
- Counsel exposed patients to use latex barriers with their sex partners until transmission of HIV infection has been ruled out.
- Counsel patients, as appropriate, about ways to reduce risks of future exposure to HIV.
- In cases of sexual assault, refer the patient to a rape counselor.

Follow-Up

Patients should be evaluated within 1 week for review of all test results and further risk-reduction counseling. For patients taking nPEP, this follow-up should include adherence assessment and evaluation of any adverse effects. Side effects should be managed aggressively in order to maximize the likelihood of adherence to nPEP. A 2-week blood screening (CBC, LFTs, and creatinine) should be performed for patients on the 28-day nPEP regimen to monitor for nPEP toxicity.

Follow-up testing for HIV antibody in patients with a negative baseline HIV antibody test should be done at 6 weeks, 3 months, and 6 months after the exposure. If a 4th-generation HIV Ag/Ab assay is used, the final HIV test can be done at 4 months rather than 6 months.

Patients need health education and risk-reduction counseling and emotional support during their follow-up visits. Nonoccupational PEP programs should focus efforts on

risk-reduction counseling rather than the continued use of medicines for prevention. To this end, many programs have case managers, social workers, and health educators as the key providers of follow-up and counseling after an exposure, with referral to clinicians as needed.

If patients develop acute HIV infection or are discovered to be HIV seropositive at follow-up testing, immediately refer to an HIV specialist for evaluation and care (see chapter *Early HIV Infection*).

Expert Consultation

For consultation on the treatment of exposures to HIV (and HBV and HCV), the clinician managing the exposed person can call the National HIV/AIDS Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at 888-HIV-4911 (888-448-4911). This service is available 7 days a week at no charge. Additional information on the Internet is available at www.nccc.ucsf.edu. PEPline support may be especially useful in challenging situations, such as when drug-resistant HIV strains are suspected to be involved in the exposure or when the exposed person is pregnant.

Prophylaxis Against HBV and HCV

Prophylaxis against HBV is recommended for patients with potential exposure to HBV who do not have not have immunity against HBV. Give HBV immune globulin (HBIG) as a 0.06 mL/kg IM injection and initiate the vaccination series. For patients who previously received the vaccine series but did not develop protective antibody (HBV sAb+), give HBIG at the time of the postexposure workup and initiate revaccination; consider repeat of HBIG in 1 month. For patients with immunity to HBV (HBV sAb+), no treatment is indicated.

For HCV, no prophylactic treatments are recommended. After potential exposure, perform a baseline HCV antibody test. If the source is known to have HCV infection, consider alanine aminotransferase (ALT)

and HCV viral load testing at 4–6 weeks. HCV antibody testing should be repeated at 4–6 months. If HCV seroconversion occurs (indicated by ALT elevation, detectable HCV viral load, or confirmed positive HCV antibody test result), refer the patient to a hepatitis C specialist because early treatment of acute HCV may be indicated.

Patient Education

- Persons who have possible exposures to HIV should contact a medical provider or go to an emergency room as soon as possible after the potential exposure has occurred. PEP may be effective if it is started within 72 hours of exposure, but the sooner medications are initiated, the better the chance for preventing HIV transmission.
- PEP medications should be taken as directed for a full 28-day course. Adherence to PEP medications is essential for successful treatment.
- If patients are experiencing uncomfortable adverse effects, they should contact their care provider right away. Providers may prescribe medications to alleviate the adverse effects or select other PEP medications.
- Until HIV infection has been ruled out, exposed persons should be advised to use latex barriers to prevent transmission of HIV to their sex partners.
- Exposed persons should be counseled about the symptoms of primary HIV infection and instructed to contact their care provider immediately if symptoms develop.
- The most effective way to prevent HIV infection is to prevent exposure to HIV by practicing safer sex and safer IDU techniques. Use of condoms and other latex or polyurethane barriers and avoidance of needle sharing are successful preventive measures. If patients have questions about access to condoms or clean needles, they should contact their care provider for assistance.

Preventing HIV Transmission/ Prevention with Positives

Background

In recent years, the rate of new HIV infections in the United States has remained stable in the range of 50,000 per year. Antiretroviral therapy (ART) not only improves the health of individuals on treatment but also substantially reduces the risk of transmitting HIV infection. It has become a critical component of efforts to prevent new infections (hence the saying, “treatment is prevention”), but it is not fully effective. Additionally, it remains true that only a minority of persons living with HIV infection in the United States is taking ART and a smaller proportion has maximal suppression of HIV viral load. Thus, behavioral and other risk-reduction interventions remain important aspects of HIV prevention. This chapter will focus primarily on interacting with patients around transmission risk behaviors, with the goal of reducing HIV transmission. This aspect of care is often referred to as “prevention with positives” (PWP).

For many years HIV, prevention efforts have been targeted primarily at HIV-uninfected individuals, but HIV-infected persons also must be a crucial focus for HIV prevention. Helping HIV-infected persons reduce their risks of transmitting HIV to others is an important aspect of medical care for HIV-infected patients. Most people with HIV infection want to prevent others from being infected with HIV, but they may practice sexual or injection-drug behaviors that put others at risk of infection.

Health care providers for HIV-infected patients can play a crucial role in prevention efforts, including but not limited to provision and monitoring of ART. Many HIV-infected individuals report that they want to discuss prevention with their health care providers; however, (according to multiple studies), one third to three fourths of HIV medical providers do not ask their patients about sexual behavior or drug use. Each patient visit presents an opportunity to provide effective prevention interventions, even in busy clinical settings.

It is clear that information alone, especially on subjects such as sexual activity and drug use, cannot be expected to change patients’ behavior. However, health care providers can help patients understand the transmission risk of certain types of behavior and help patients establish personal prevention strategies (sometimes based on a harm-reduction approach) for themselves and their partners. Some patients may have difficulty adhering to their safer sex goals. In these cases, referrals to mental health clinicians or other professional resources such as prevention case management may be helpful.

Patient-education needs are variable and must be customized. Providers must assess the individual patient’s current level of knowledge as part of developing a prevention plan. All the information that a patient needs cannot be covered during a single visit. A patient’s prevention strategy should be reinforced and refined at each visit with the clinician. Clinicians also should ask patients questions to determine life changes (e.g., a new relationship, a breakup, or loss of a job) that may affect the patient’s sexual or substance-use practices. If the patient can read well, printed material can be given to reinforce education in key areas, but it cannot replace a direct conversation with the clinician.

HRSA HAB Performance Measures

Percentage of patients with a diagnosis of HIV who received **HIV risk counseling** in the measurement year

(Adult and Adolescent measure)

Note: The U.S. Department of Health and Human Services is expected to publish guidelines on HIV prevention in the near future; those may contain recommendations that differ from the ones presented here.

National Prevention Intervention Efforts

The U.S. Centers for Disease Control and Prevention (CDC) has developed a prevention approach called High-Impact Prevention that focuses on populations at greatest risk of acquiring or transmitting HIV, using proven, scalable, and cost-effective interventions. Proven interventions include:

- HIV testing and linkage to care
- ART
- Prevention programs for people living with HIV and their partners
- Prevention programs for people at high risk of HIV infection
- Access to condoms and sterile syringes
- Screening and treatment for sexually transmitted diseases (STDs)
- Substance abuse treatment

The CDC has identified a number of evidence-based behavioral prevention interventions aimed at persons with HIV infection that meet criteria for efficacy and scientific rigor. These are conducted on the individual, group, or community level, and a number of them may be implemented in the treatment setting. A Compendium of these interventions can be accessed online at the CDC website (see www.cdc.gov/hiv/prevention/research/compendium/rr/index.html). Training and educational materials for effective intervention models can be found on the CDC-supported Diffusion of Effective Behavioral Interventions (DEBI) website (www.effectiveinterventions.org/en/Home.aspx).

Among the many examples of Prevention Intervention Programs with Demonstrated Efficacy in Treatment Settings on the CDC website are the following:

- **Options/Opciones Program:** The program features brief, 5-10 minute patient-centered discussions between patients and providers at each clinic visit using motivational interviewing techniques. Providers evaluate sexual and drug-use behaviors, assess the patient's readiness to change, and elicit methods from the patient on moving toward and maintaining safer behaviors. The provider and the patient develop an individually tailored plan, which the provider writes out on a prescription pad and gives to the patient.
- **Partnership for Health:** This intervention involves brief, 3-5 minute, one-on-one counseling sessions between the provider and the patient on self-protection, partner-protection, and disclosure. The approach features loss-framed messages that emphasize the risks or negative consequences of risky behavior. The provider then helps the patient develop a plan for risk reduction.
- **Positive Choice – Interactive Video Doctor:** This program involves an approximately 24-minute session during which HIV-infected patients complete the Positive Choice risk assessment on a laptop computer while waiting for scheduled visits with their providers. Based on the risk-assessment results, a video clip appears with the actor-portrayed Video Doctor who delivers interactive risk-reduction messages that are tailored to the patient's gender, risk profile, and readiness to change. The messages are delivered with motivational interviewing principles, using a patient-centered, empathetic and nonjudgmental approach. After the video session, the computer prints out an individualized educational sheet for the patient and an assessment sheet for the patient and the provider to use for follow-up.

The U.S. Preventive Services Task Force (USPSTF) has recommended high-intensity behavioral counseling to prevent STDs (including HIV) in persons at risk of these infections; these approaches also are being used in persons with HIV infection to reduce their risk of transmitting HIV. Effective high-intensity behavioral counseling typically comprises multiple sessions with either groups or individuals. Examples of these are included amongst the models presented on the CDC and DEBI websites.

Strategies for Brief, Effective Interventions by Providers

A number of strategies have been shown to be more effective than providing information alone. Effective and brief provider-initiated interventions often include the following elements:

- **Establish rapport** and provide services in an understanding, nonjudgmental manner. Patient educators, nurses, peer counselors, social workers, and mental health providers may be effective in discussing prevention strategies with patients.
- **Conduct a quick, detailed behavioral risk assessment:**
 - See the key areas of risk assessment and intervention listed in Table 1, below.
 - Assess where the patient's risk behavior lies along the risk continuum (described in chapter *Smoking Cessation*).
 - Correct misinformation and answer questions.
 - Assess the patient's readiness for behavior change (see "Stages of Change model," below).
 - Screen for and treat STDs: a positive STD test result can be a biologic marker of behavioral risk, and STDs may facilitate HIV transmission (see chapter *Initial and Interim Laboratory and Other Tests*).
 - Supply medications, condoms, and lubricant as needed.
- **Assess the patient's readiness for change** and approach any high-risk behavior in a step-wise manner, recognizing when the patient is ready for next steps. Such interventions may be carried out for 5-10 minutes per visit over a series of visits. The "Stages of Change" model and appropriate strategies include the following:
 - **Precontemplation:** The patient is not ready to change; reassess at subsequent visits.
 - **Contemplation:** The patient is considering a change in the future; discuss and help the patient to identify concrete next steps, such as a date for initiating change.
 - **Preparation:** The patient is ready to change soon; discuss a concrete action plan and connect the patient with appropriate resources as needed.
 - **Action:** The patient is actively engaged in changing behavior; continue to discuss and address challenges; offer encouragement.
 - **Maintenance:** The patient has made behavioral changes; continue to discuss and address challenges, offer encouragement and congratulations.
 - **(Relapse):** The patient has relapsed to previous risky behaviors; recognize the triggers and difficulties the patient had with maintenance and offer support and encouragement to try again when the patient is ready.
- **Customize messages**, as each individual patient's needs are variable.
- **Understand** that patients often have competing priorities and pressures involving mental health needs, relationships, finances, housing, employment, and other issues that may result in risky sexual and drug-use behaviors.

Prevention with Positives: Key Areas of Assessment and Intervention

These topics should be explored over time. Some sample questions and areas for intervention are presented in Table 1. More detailed discussions of topics follow this table.

Table 1. Components of a Detailed Risk Assessment, with Key Areas for Intervention

Topic	Sample Questions, Assessment, and Plan
General Risk Assessment	Subjective/objective questions to ask: 1. What do you know about HIV transmission? 2. What, if anything, are you doing that could result in transmitting HIV to another person? Assessment and plan: • Use this as an opportunity to help educate the patient on HIV transmission and to correct misinformation. • Place the patient's behaviors on a risk spectrum and try to prioritize the behaviors that are riskiest or the behaviors that the patient is most willing to address.
Sexual Practices	Subjective/objective questions to ask: 1. Tell me about any sexual activity since your last clinic visit. 2. What do you know about the HIV status of each sex partner? 3. Tell me about condom use during any sexual activity. 4. What has made it more difficult for you to use condoms during this sexual encounter or with this partner? 5. Do your sex practices differ with HIV-infected versus HIV-uninfected partners ("sexual positioning")? See below for more on partner notification. Other information: • Number of sex partners in the past 6 months • Gender of each partner • Type of relationship with each partner (main, casual, anonymous) • Type of sexual activity engaged with each partner • Safer and less-safe sexual practices with each partner • Substance use, including alcohol, associated with sex • Circumstances of risky sex behaviors (e.g., bars/clubs, anonymous partners, intoxication) Assessment and plan: • Assess the patient's level of risk of sexual transmission. • Assess the patient's willingness and ability to use condoms during each sexual encounter, particularly with partners who are HIV uninfected or of unknown HIV serostatus. • Assess the patient's ability to use condoms (male and/or female) and correct any misinformation. See information on how to use condoms below. • Supply the patient with condoms and lubricant. • If the patient is unwilling to use condoms, counsel that risk of transmission can be reduced by screening for and treating STDs, using abundant amounts of lubrication, avoiding concurrent drug use, avoiding the use of spermicides and douching, and by choosing less risky sexual activities. Additionally, serosorting, in which the HIV-infected person has sex only with other HIV-infected individuals, can prevent transmission to uninfected persons (note: this is <i>not</i> an effective strategy for persons who are HIV uninfected or are unsure of their serostatus).

Partner Notification	Subjective/objective questions to ask: 1. What are your thoughts and experiences talking with your partner(s) about your HIV infection? This may be one of the hardest things you have to do. 2. (If the patient has not disclosed to main partner[s]): How might you approach this? 3. Are you afraid for your safety if you tell your partner(s)? Assessment and plan: ways to offer help for disclosure • Local health departments may have partner services programs that help locate and notify partners in a confidential manner. • Providers and support staff can help disclose to partners with the patient present. • Providers and support staff can help disclose to partners without the patient present.
Antiretroviral Therapy (ART)	• ART has been shown to reduce the rate of HIV transmission in serodiscordant heterosexual couples by 96%. In other studies, lower levels of HIV in the blood (in particular, complete suppression of the HIV RNA through ART) have been associated with lower levels of HIV virus in genital secretions and with reductions in the rate of sexual transmission of HIV. • Current HHS guidelines recommend ART for all HIV-infected persons, both for their own health and to reduce risk of HIV transmission. • Close adherence to ART and continuous HIV suppression are likely to be key factors in making this an effective prevention tool; assess and reinforce adherence at every visit. • For a number of reasons, ART alone is not completely effective in preventing transmission; it should be viewed as one important tool in a broader approach to prevention. Be watchful for attitude shifts away from safer sexual and needle-sharing behaviors among patients who believe that ART protects them from transmitting HIV.
STD Screening and Treatment	• The presence of an STD suggests behaviors that can increase HIV transmission, and it is detrimental to the patient's health. • Additionally, some STDs may increase the risk of HIV transmission. • Screen all patients at baseline and regularly afterward, depending on their risk factors according to CDC and USPSTF guidelines. For example, screen men who have sex with men (MSM) every 3-6 months if multiple sex partners. • Routinely ask patients if they have symptoms of an STD and educate about the importance of seeking care if symptoms are present. • Depending on risk, it is recommended to screen for the following STDs (see chapters <i>Initial History</i> and <i>Initial and Interim Laboratory and Other Tests</i> for screening questions and lab tests): • Syphilis: Serologic test (e.g., RPR, VDRL) • Gonorrhea: For pharyngeal infections, use nucleic acid amplification test (NAAT) or culture of oral swab*; for rectal infections, use NAAT or culture of rectal swab*; for urethral or cervical or vaginal infections, use first-catch urine or urethral (male) or cervical (female) specimen for NAAT, or culture of urethral (male) or cervical (female) specimen • Chlamydia: For rectal infections, use NAAT or culture of rectal swab*; for urethral or cervical infections, use first-catch urine or urethral (men) or cervical or vaginal (women) specimen for NAAT; testing for pharyngeal chlamydial infection is not recommended although the test result often accompanies the GC pharyngeal NAAT result • Trichomonas: Wet mount (insensitive), culture, or NAAT on vaginal secretion • Herpes simplex virus (HSV): Type-specific HSV-2 antibody testing Although hepatitis B and hepatitis C are not known to increase the risk of HIV infection, they may be transmitted sexually, and persons with risk factors (particularly MSM with risky sexual practices) should be screened regularly (see chapter <i>Initial and Interim Laboratory and Other Tests</i>). * NAAT is not yet approved for this indication by the U.S. Food and Drug Administration (FDA), though there is evidence that NAAT can accurately diagnose pharyngeal and rectal gonorrhea and chlamydia infections. Many local public health departments and other laboratories have received Clinical Laboratory Improvement Amendments (CLIA) waivers to perform these tests.

Drug and Alcohol Risk Assessment	Subjective/objective questions to ask: 1. Tell me about any drug or alcohol use since your last clinic visit. 2. How do you think your drug or alcohol use affects your sexual behaviors? 3. What are your thoughts about quitting or cutting down on drug and alcohol use, and about separating it from sex? See below for follow-up on needle-sharing practices. Assessment and plan: • Assess the patient's level and circumstances of risk to target your intervention. • Emphasize that nasal straws or sniffers (e.g., for cocaine) should not be shared. • Assess the patient's readiness to quit or cut down on drug and alcohol use, and to separate these activities from sex. • Deliver messages tailored to the patient's readiness; for example, educate on the risks of harming oneself or others, facilitate a plan for harm reduction, or refer to rehabilitation/detoxification programs and centers.
Needle-Use Practices	Subjective/objective question to ask: 1. Tell me about any needle sharing since your last clinic visit. Assessment and plan: • After assessing the patient's risks and readiness, and if the patient is not ready for treatment (e.g., referral to detoxification programs or to buprenorphine and methadone programs for heroin users), the following messages for harm reduction can be offered: • Use only sterile needles and syringes, e.g., from pharmacies or syringe service (needle exchange) programs. (Provide information about local syringe service programs. Some are listed on the North American Syringe Exchange Network website at www.nasen.org.) • Never reuse or share needles, syringes, or drug preparation equipment because it leads not only to transmission of HIV, hepatitis B, and hepatitis C, but also to bacterial infections and abscesses. • Use new or disinfected cookers and new cotton filters to prepare drugs. • Clean the skin with a new alcohol swab before injecting. • If equipment must be reused, it should be cleaned properly with bleach or water. • Safely dispose of syringes in a sharps container (which can be a clean detergent or other container), then take them to a needle exchange program or pharmacy for disposal.
Mental Health Assessment	Mental illnesses such as bipolar disorder, depression, and post-traumatic stress disorder can increase the chances of risky sexual and drug-use behaviors. Ask about mental health illnesses directly and pay attention to any symptoms that may indicate a psychiatric illness (e.g., manic episodes, depressive episodes, hallucinations). Subjective/objective questions to ask: 1. Tell me about any previous diagnoses or hospitalizations for mental health illnesses. 2. Have you taken any medications for mental health illnesses? 3. Perform a depression screen: see chapter <i>Major Depression and Other Depressive Disorders</i>. Assessment and plan: See section <i>Neuropsychiatric Disorders</i> for more information.

Pregnancy Screening	Subjective/objective questions to ask: For women of childbearing potential: 1. Are you currently pregnant or wanting to become pregnant at some point in the future? 2. Have you missed any periods recently? Are you having any symptoms of pregnancy? 3. What are your thoughts and plans about birth control? For men with female sex partners: 1. What are your thoughts on having a baby with your partner? What are your thoughts about fathering? 2. What are your thoughts on using birth control with your partner? Assessment and plan: See chapter <i>Health Care of HIV-Infected Women Through the Life Cycle</i>.
----------------------------	--

Sexual Transmission and Prevention of HIV

Begin the education process by learning what the patient and his or her immediate family members (if the family is aware of the patient's HIV status) believe about HIV transmission. Also be sure the patient understands how the virus is not transmitted (e.g., via sharing plates and eating utensils or using the same bathrooms) to allay any unnecessary fear.

Advise the patient not to share toothbrushes, razors, douche equipment, or sex toys to avoid transmitting HIV via blood or sexual secretions. This also will help prevent the transmission of other bloodborne or sexually transmitted diseases, including hepatitis C, from coinfecting patients. The patient should not donate blood, plasma, tissue, organs, or semen because these can transmit HIV to the recipient.

There is no reason why a person with HIV cannot have an active, fulfilling, and intimate sex life. However, the patient must be counseled properly about the risk of transmission. This discussion between the provider and patient should be client centered. This means that the provider should let the patient guide the discussion, starting from the patient's current point of knowledge and practice, always addressing any presenting concerns the patient may have prior to proceeding with a discussion about sexual

transmission and risk. The provider should ask open-ended questions, in a nonjudgmental manner, to elicit information about the patient's relationships, sexual behaviors, and current means of reducing transmission risk.

It is important to recognize that not every patient seeks the complete elimination of risk (e.g., via abstinence) but rather a reduction in risk, chosen after the options are discussed with the provider. The clinician may help the patient select and practice behaviors that are likely to be less risky. There are many methods for reducing risk, including the following:

- Disclosing HIV status
- Maintaining maximal suppression of HIV through ART
- Reducing the number of sex partners
- Using condoms, particularly for anal or vaginal intercourse (insertive or receptive)
- Avoiding drug use in conjunction with sex
- Using adequate lubrication to avoid trauma to genital or rectal mucosa

If the patient requires more extensive counseling to support behavioral changes, the provider should refer the patient to support groups or prevention case management to meet those needs. Certainly, if the patient is dealing with a dual or triple diagnosis (including substance abuse or mental illness), a referral to address those needs is indicated.

Partner Notification and Partner Services

A good way to begin a discussion about HIV prevention and transmission is with an inquiry about any previous experiences disclosing to partners. The provider then can ask whether the patient currently has a need to disclose to one or more partners and whether he or she is ready and motivated to share information about HIV status. The provider should prompt patients to consider several questions about disclosure, including how they might approach the discussion, how their partners might react, what information they might offer their partners, whether partners are likely to keep their status confidential, and whether they have any concerns about personal safety (e.g., owing to fear of a violent reaction). If patients fear violence or retaliation or are not ready to share their status but want their partners to know, the provider may offer assistance with partner services, for example through the local health department, through which partners can be notified and linked to services in a confidential manner. As an alternative, patients may want the provider to talk with their partners, and that option can be offered as well. See the CDC website (www.cdc.gov/nchhstp/partners/Partner-Services.html) for information on partner services.

Antiretroviral Therapy

ART that results in maximal HIV suppression is an important means of HIV prevention. In serodiscordant heterosexual couples, one randomized controlled trial showed that ART reduced the risk of sexual transmission of HIV by 96%. Similar study data for MSM, injection drug users, and other HIV risk groups do not exist, but multiple other lines of evidence suggest that effective ART sharply reduces risk of HIV transmission. Thus, ART should be offered to all HIV-infected persons, both to benefit their own health and to reduce risk of HIV transmission to others, as recommended

in HHS guidelines. Support patients' adherence to ARVs in order to optimize the effectiveness of ART as both treatment and prevention.

Note that ART does not eliminate HIV transmission risk. In some individuals, there can be substantial discrepancies between HIV RNA levels in the serum and the sexual fluids. There have been case reports of HIV transmission from HIV-infected individuals who had maximal virologic suppression on ART. Thus, other behavioral and biologic risk-reduction approaches (e.g., screening for and offering interventions or treatment for risky sexual behaviors, substance use, depression, STDs, and other factors listed in Table 1) are important aspects of prevention in patients taking ART, as in patients not taking ART.

Helping Patients Reduce the Risk of Sexual Transmission Standard Condom Use

Make sure that the patient understands how HIV is transmitted and which types of sexual acts are more and less risky than others. For vaginal or anal sex, correct use of latex or polyurethane condoms reduces the risk of HIV transmission considerably. Patients should be encouraged to use condoms as much as possible. For HIV-infected individuals, condom use is effective in reducing the risk of contracting another illness (such as hepatitis C or another STD) and the (apparently low) risk of becoming reinfected with another strain of HIV. It should be noted that condoms are less effective in reducing the transmission of organisms such as human papillomavirus (HPV) and HSV, which may result from viral shedding from skin. In the event of allergy to latex or other difficulty with latex condoms, polyurethane male or female condoms may be substituted. "Natural skin" or "lambskin" condoms are not recommended for HIV prevention.

Of course, condoms must be used correctly to be highly effective in preventing HIV transmission. Be sure that the patient knows exactly how to use a condom. Table 2, in the Appendix, provides instructions for condom use.

Advise patients to avoid using nonoxynol-9 (N-9) spermicides. Data suggest that N-9 may increase risk of HIV transmission during vaginal intercourse and can damage the rectal lining. N-9 never should be used for anal intercourse.

For patients who complain about lack of sensitivity with condom use, the following techniques may help:

- Apply a drop of lubricant inside the condom (not more, because it increases the risk that the condom will come off).
- Use polyurethane condoms instead of latex because they conduct heat and may feel more natural.
- Use insertive (female) condoms, which are not as restrictive to the penis.
- Use specially designed condoms that do not restrict the top of the penis (e.g., Inspiral, Xtra Pleasure).

For patients who are unable or unwilling to use condoms, the following suggestions may help reduce HIV transmission risk:

- Use plenty of lubricant to reduce friction and microtrauma, which create portals of entry for the virus.
- Avoid spermicides that damage the vaginal or anorectal linings.
- Avoid douching products.
- Avoid recreational drugs, especially methamphetamine, that impair the ability to maintain “safer” sexual behaviors.
- Avoid the use of drugs such as nitrates (poppers) that enhance blood flow to the genitals.

Insertive (Female) Condom Use

The insertive “female” condom may be used for vaginal or anal intercourse. It is a thin polyurethane pouch with a flexible ring at the opening, and another unattached flexible ring that sits inside the pouch to keep it in position in the vagina (for use in the anus, the inner ring must be removed and discarded). The female condom may be an option for women whose male partners will not use male condoms or for couples who do not like standard condoms. Female condoms are more expensive than male condoms, but may be procured at a lower cost at some health departments or Planned Parenthood clinics. They generally are less well known to patients and may be unacceptable to some women whose culture or religion prohibits or discourages touching one’s own genitals. Note that the female condom cannot be used at the same time as a male condom.

Be sure the patient knows how to use the insertive condom before she or he needs it; after teaching, encourage practice when alone at home and unhurried. Women who have used the diaphragm, cervical cap, or contraceptive sponge may find it easy to use the female condom. Illustrated directions are included in each box of insertive condoms. Instructions on the use of insertive condoms are provided in Table 3, in the Appendix.

Oral Sex

Although there is evidence that some people have become infected through receptive oral sex, the risk of HIV transmission via oral sex, in general, is much lower than the risk of transmission by vaginal or anal sex. Thus, most public health and prevention specialists focus their attention on riskier sexual and drug-use behaviors. However, because HIV transmission can occur with oral sex, clinicians should address this issue with patients and help them make informed decisions about risk reduction. Sores or lesions

in or around the mouth or on the genitals may increase the risk of HIV transmission, as may a concurrent STD. Patients (and their partners) should avoid oral-genital contact if they have these conditions. Similarly, patients and partners can further reduce risk by not brushing or flossing teeth before oral sex. Individuals who wish to further reduce the risk of HIV transmission during oral sex may use barriers such as condoms, dental dams, and flexible plastic nonporous kitchen wrap.

Individuals who smoke crack cocaine often develop open burns, cracked lips, or damaged mucous membranes inside the mouth and thus may be at elevated risk of HIV transmission via oral sex. HIV-infected crack users should be counseled about the risk of transmitting HIV to uninfected partners through those portals of entry during oral sex and should receive risk-reduction counseling. In addition, they (or their partners) may benefit from techniques such as insulating the end of the crack pipe to reduce burns while smoking (e.g., with a rubber band or spark plug cap) and avoiding the brittle or sharp-edged copper scrubbing pads used as screens in the crack pipe.

Influence of Substance Use on Sexual Behavior

Alcohol and drug use can contribute significantly to the risk of sexual transmission of HIV, because of behavioral disinhibition. While intoxicated, substance users may, for example, forgo condom use, practice riskier sexual behaviors, have multiple partners, or use erectile dysfunction agents to sustain sexual activity. Addressing substance use issues is an important aspect of PWP. Patients should be assessed for HIV transmission risks associated with alcohol and injection or noninjection drug use, including crystal methamphetamine, in the context of their sexual behaviors (for injection drug use, see below). As always, it is important to approach the patient in a nonjudgmental manner. If

alcohol or other drugs are posing barriers to practicing safer behaviors, the provider should counsel the patient to reduce or avoid substance use before engaging in sex, or refer the patient to prevention case management for more specialized risk reduction. Often, the provider can help the patient identify methods for reducing HIV transmission risk, including means that do not require abstaining from alcohol and drug use.

Injection Drug Use and Prevention of HIV

Clinicians should discuss substance use, including steroid use, and reinforce the patient's understanding of the adverse effects that these drugs can have on the body and the immune system. Assess whether referral for treatment is appropriate, and be knowledgeable about referral resources and mechanisms. If the patient is using injection drugs (including steroids and other hormones), emphasize the fact that HIV is readily transmitted by sharing needles and other injection equipment and that reusing or sharing needles and syringes can cause additional infections (e.g., endocarditis, hepatitis C). Assess the patient's readiness to change his or her drug injection practices, and refer to drug treatment programs as appropriate. Refer to an addiction counselor for motivational interviewing or other interventions, if available. After completion of substance abuse treatment, relapse prevention programs and ongoing support will be needed. If the patient continues to use needles, discuss safer needle-use practices (Table 1) and consider referral to a syringe service (needle exchange) program, if one is available, so that syringes and needles are not reused. A partial listing of needle exchange sites may be found on the North American Syringe Exchange Network website at www.nasen.org, although many states either do not have facilities or are prohibited from listing them. Local harm-reduction activists may be

aware of specific programs for obtaining clean needles and syringes. Patient-education flyers on safer injection practices, safer stimulant use, overdose prevention, and other topics are available on the Midwest AIDS Education and Training Center website (www.uic.edu/depts/matec/resource.html).

Noninjection Drug Use and Prevention of HIV Transmission

Exposure to HIV through contaminated blood may occur with the use of noninjection drugs; for example, by sharing cocaine straws or sniffers through which cocaine is inhaled. These straws easily can penetrate fragile nasal mucosa and become contaminated with blood from one user before being used by another individual, who may then experience mucous membrane exposure or even a cut or break in the mucous membrane from the bloody object. Straws or sniffers should not be shared.

Tattoo, Piercing, and Acupuncture Equipment

Patients should be aware of the risk of contamination of tattoo equipment, inks, and piercing equipment, and they should avoid situations wherein they might either transmit HIV or pick up other bloodborne pathogens. Acupuncturists generally use sterile needles, but clients should verify that before using their services.

Perinatal HIV Transmission

HIV-infected women can have healthy pregnancies, with good health outcomes for both mother and baby. For this to occur, women must know their HIV status as early as possible, preferably before becoming pregnant, and must receive effective ART. Although intervention to reduce the risk of perinatal infection is most effective if begun early in pregnancy, or preferably before pregnancy, it may be beneficial at any point

in the pregnancy, even as late as during labor. For further information, see chapter *Reducing Perinatal HIV Transmission*.

Preexposure Prophylaxis (PrEP)

Preexposure prophylaxis (PrEP) refers to the use of oral or topical ARVs before HIV exposure with the goal of preventing HIV infection. Studies have evaluated PrEP strategies using either oral tenofovir + emtricitabine (Truvada), oral tenofovir, or vaginal tenofovir to prevent sexual acquisition of HIV in MSM and high-risk heterosexually active women and men. Most have shown efficacy (ranging from about 40% to 75%) in reducing infection risk, but two others have not demonstrated protective benefit. A study of PrEP using tenofovir in injection-drug users also showed a reduction in HIV infections in the tenofovir group (a 49% reduction in incidence). In all studies, the effectiveness of PrEP has been strongly related to the study participants' adherence to the PrEP medication. It should be noted that, in these PrEP studies, the ARV prophylaxis was given in conjunction with other risk-reduction interventions, including counseling, condom provision, and STD testing and treatment.

The CDC has issued interim guidelines on the use of oral tenofovir-emtricitabine as PrEP in MSM, heterosexually active adults, and injection-drug users (see "References," below); these guidelines offer recommendations for PrEP screening and use, as well as ongoing monitoring for adherence, safety, and HIV infection. They emphasize that PrEP should be delivered in the context of a comprehensive package of health and prevention services. In 2012, the FDA approved the fixed-dose combination tenofovir/emtricitabine (Truvada) to reduce the risk of sexually acquired HIV-1 in adults at high risk; it has not yet approved an indication for PrEP in injection-drug users.

U.S. Public Health Service (PHS) guidelines for PrEP use are currently in development.

Postexposure Prophylaxis for Nonoccupational HIV Exposure

Postexposure prophylaxis (PEP) may be considered for certain sexual exposures, sexual assaults, and other nonoccupational exposures to HIV. As with occupational PEP, a risk assessment must be completed and PEP medications, if indicated, must be started as soon after exposure as possible. The risks and toxicities of ARV drugs must be weighed against potential benefits, and the client's informed consent must be obtained. For further information, see chapter *Nonoccupational Postexposure Prophylaxis*.

Appendix

Table 2. Instructions for Use of Standard Condoms

- Use a new latex or polyurethane condom with each act of sex (oral, anal, or vaginal). Make sure that the condom is undamaged, and that its expiration date has not passed.
- Carefully handle the condom to avoid damage (e.g., from fingernails, teeth).
- Being sure that the condom roll faces out, unroll the condom onto the erect penis before any genital contact with partner.
- Ensure that the tip of the condom is pinched when applying it to the top of the penis, to eliminate air in the tip that could cause breakage during ejaculation.
- Use only water-based lubricants with latex condoms. Oil-based lubricants (such as mineral oil, cooking oil, massage oil, body lotion, and petroleum jelly) can weaken latex or cause it to break, although they are fine with the use of polyurethane condoms. Adequate lubrication during intercourse helps reduce the risk of condom breakage.

Table 3. Instructions for Use of Insertive (Female) Condoms

Vaginal Intercourse
• Open the pouch by tearing at notched edge of packet, and take out the female condom. Be sure that the lubricant is evenly distributed on the inside by rubbing the outsides together. • Find a comfortable position, such as standing with one foot on a chair, sitting with knees apart, or squatting. Be sure the inner ring is inside, at the closed end of the pouch. • Hold the pouch with the open end hanging down. While holding the outside of the pouch, squeeze the inner ring with your thumb and middle finger. Still squeezing, spread the labia with your other hand and insert the closed end of the pouch into the vagina. • Now, put your fingers into the pouch itself, which should be inside the vagina, and push the inner ring and the pouch the rest of the way up into the vagina with your index finger. Check to see that the front side of the inner ring is just past the pubic bone. The back part of the inner ring should be up behind the cervix. The outer ring and about an inch of the pouch will be hanging outside the vagina. • Until you and your partner become comfortable using the female condom, use your hand to guide the penis into the vagina, keeping it inside the pouch. If, during intercourse, the outer ring is pushed inside the vagina, stop, remove the female condom, and start over with a new one. Extra lubricant on the penis or the inside of the female condom may help keep this from happening. • After intercourse, take out the condom by squeezing and twisting the outer ring to keep the semen inside the pouch. Throw away in a trash can; do not flush. Do not reuse. • More information is available on the Planned Parenthood website (www.plannedparenthood.org).
Anal Intercourse
• Remove the inner ring and discard it. Put the female condom on the penis of the insertive partner and insert the condom with the penis, being careful not to push the outer ring into the rectum. The outer ring remains outside the anus, for ease of removal after ejaculation.

Immunizations for HIV-Infected Adults and Adolescents

Background

Immunocompromised individuals are at higher risk of acquiring many types of infections compared with immunocompetent people. Although HIV-infected persons could benefit greatly from immunization against preventable infections, little specific research on the effectiveness of immunizations in this population has been completed. In general, vaccines have better efficacy in HIV-infected patients when immune function is relatively well preserved, notably when the CD4 count is >200 cells/ μ L. Persons with advanced immunodeficiency may have an impaired humoral response, and may not respond to vaccines, or they may require supplemental doses to develop serologic evidence of protection. If possible, vaccines should be administered before the CD4 count decreases to <200 cells/ μ L; if given when the CD4 count is <200 cells/ μ L, consideration should be given to repeating the vaccination when the CD4 count increases to >200 - 300 cells/ μ L (unless there is evidence of immunity).

Live vaccines generally should not be administered to individuals with HIV infection, particularly those with advanced immunodeficiency, unless the anticipated benefits of vaccination clearly outweigh the risks.

Administration of vaccines can be associated with a transient rise in plasma HIV RNA.

Recommendations about vaccination for patients with HIV infection are presented in Table 1.

HRSA HAB Performance Measures

Percentage of patients, aged 6 months and older seen for a visit between October 1 and March 31, who received an **influenza immunization** OR who reported previous receipt of an influenza immunization

(All-Age measure)

Percentage of patients with a diagnosis of HIV who completed the **vaccination series for hepatitis B**

(Adult and Adolescent measure)

Percentage of patients with a diagnosis of HIV who ever received **pneumococcal vaccine**

(Adult and Adolescent measure)

Table 1. Vaccine Recommendations

Vaccine Type	Recommendation
Pneumococcal Pneumococcal (polysaccharide) (PPV23) Pneumococcal 13-valent conjugate (PPV13)	• Recommended for all. • If CD4 count is <200 cells/μL, may be less effective; consider revaccination when CD4 count increases in response to ART. • Two types of pneumococcal vaccine; both should be given, as follows. • 1 dose as soon as possible after HIV diagnosis (or PCV13 may be given first, see below); revaccinate 5 years after initial vaccination. • For those who received 1-2 doses of PPV23 before age 65, repeat at age ≥ 65 if ≥ 5 years since their previous dose. • PPV23 should not be given <8 weeks after PPV13 (see below). • 1 dose recommended for all HIV-infected adults; timing varies according to whether PPV23 has been given: • No previous pneumococcal vaccination: • 1 dose PCV13 followed by PPV23 ≥ 8 weeks after PCV13. (If CD4 <200 cells/μL, PPV23 can be offered ≥ 8 weeks after PCV13 or can await increase of CD4 to >200 cells/μL.) • Previous PPV23 vaccination: • 1 dose of PCV13, given ≥ 1 year after last receipt of PPV23.
Hepatitis A Virus (HAV)	• Recommended, for persons with chronic liver disease, injection drug users, men who have sex with men, international travelers, and hemophiliacs. Consider for all, unless there is serologic evidence of previous disease. • Serologic response (HAV IgG Ab) should be checked 1 month after completion of series, and nonresponders should be revaccinated. • 2 doses (Havrix: 0, 6-12 months; Vaqta: 0, 6-18 months).
Hepatitis B Virus (HBV)	• Recommended for all, unless there is evidence of immunity (HBV surface Ab+) or active HBV infection (HBV surface Ag+, or HBV core Ab+ and evidence of HBV activity). • Many experts recommend giving a high dose of HBV vaccine (40 mcg), as is standard for hemodialysis patients; this may improve immunologic response in HIV-infected patients. • Most HIV-infected patients with isolated HBV core Ab+ (without HBV viremia) are not immune and should receive a complete series of HBV vaccine. • Anti-HBV surface Ab titers should be checked 1 month after completion of vaccine series. Patients whose titer level is ≤ 10 IU/mL should be revaccinated. • Standard dosing schedule is 3 doses (0, 1, and 6 months). If 40 mcg is given, the recommended schedule is 3 doses of Recombivax HB at 0, 1, and 6 months or 4 doses of Engerix-B at 0, 1, 2, and 6 months.
Influenza (inactivated vaccine)	• Recommended (yearly). • Vaccination is most effective among persons with CD4 counts of >100 cells/μL and HIV RNA of <30,000 copies/mL. • In patients with advanced disease and low CD4 cell counts, inactivated vaccine may not produce protective antibodies. A second dose of vaccine does not improve response in these patients. • Live, attenuated cold-adapted vaccine (LAIV, FluMist) is not recommended for use in patients with HIV infection as the efficacy of the vaccine in this population has not been evaluated. • Close contacts of severely immunocompromised persons (including household members and health care personnel) should not receive live, attenuated influenza vaccine.

Vaccine Type	Recommendation
Tetanus, Diphtheria (Td); Tetanus, Diphtheria, Pertussis (Tdap)	- Recommended (booster is recommended every 10 years in adults; or, if potential exposure [wound], after 5 years). - To protect against pertussis, substitute single dose of Tdap for Td booster in all patients aged 19-65 who have not received Tdap previously.
Measles, Mumps, Rubella (MMR)	- Live vaccine is contraindicated for use in patients with severe immunosuppression (CD4 count of <200 cells/μL). - Recommended for all nonimmune persons with CD4 counts of $\geq$200 cells/μL.
Varicella-Zoster (VZV) Varicella vaccine (primary immunization) Zoster vaccine	- Two doses (0, 3 months). - Live vaccine; contraindicated for use in patients with severe immunosuppression (CD4 count of <200 cells/μL). - Consider for HIV-infected, VZV-seronegative persons with CD4 counts of $\geq$200 cells/μL. - If vaccination results in infection with attenuated virus, treat with acyclovir. - Transmission of vaccine virus from vaccine recipients to susceptible individuals is possible; vaccine recipients should avoid close contact with high-risk susceptible individuals for 6 weeks after vaccination. - One dose. - Live vaccine; contraindicated in persons with AIDS or other clinical manifestations of HIV infection. - Consider for select patients aged >50 with CD4 counts of >200 cells/μL and with evidence of varicella immunity (if no evidence of varicella immunity, give primary varicella vaccination). Limited data show safety and immunogenicity in this group. - Transmission of vaccine virus to susceptible contacts is possible.
Human Papillomavirus (HPV)	- Two vaccines: - Gardasil includes HPV strains 16 and 18 (oncogenic) and 6 and 11 (wart causing); approved for use in women and men. - Cervarix: includes HPV strains 16 and 18; approved for use in women. - Gardasil or Cervarix recommended for females aged 9-26. - Gardasil vaccine recommended for males aged 9-26. - Not contraindicated for use in HIV-infected individuals; limited data on efficacy; may be less effective if CD4 count is <200 cells/μL.
Meningococcal	- Two doses (0, $\geq$8 weeks). - Recommended if risk factor is present (e.g., college freshmen living in dormitory, military recruits, asplenia, complement component deficiency, travel to or residence in area with outbreaks,* occupational exposure).

Abbreviations: Ab = antibody; Ag = antigen; ART = antiretroviral therapy

* In 2012, the New York City Department of Health and Mental Hygiene reported ongoing outbreak of meningococcal meningitis in men who have sex with men (MSM) and recommended vaccination for those with recent or future exposure risk. Many health departments in other areas have recommended vaccination of MSM, including HIV-infected MSM, who recently had or expect to have close contact with a man who is known to be, or could potentially be, from New York City.

Immunizations for HIV-Infected Patients Traveling to Developing Countries

Routine vaccinations should be reviewed and updated before travel. All patients traveling to other countries should be evaluated for both routine and destination-specific immunizations and prophylaxes. Inactivated (killed) and recombinant vaccines (e.g., diphtheria-tetanus, rabies, hepatitis A, hepatitis B, Japanese encephalitis) should be used for HIV-infected persons just as they would be used for HIV-uninfected persons anticipating travel. For further information, see the U.S. Centers for Disease Control and Prevention (CDC) webpage (wwwnc.cdc.gov/travel). Recommendations specific to HIV-infected travelers are located in “The Immunocompromised Traveler” under the section called “Advising Travelers with Special Needs.” Select the “Traveler’s Health” option for regional travel documents and information on outbreaks.

Decision making about immunization for the HIV-infected traveler should take into consideration the traveler’s current CD4 cell count, history of AIDS-defining illness, and clinical manifestations of symptomatic HIV. In the CDC recommendations, asymptomatic HIV-infected persons with CD4 counts of 200-500 cells/ μ L are considered to have limited immune deficits, whereas patients with CD4 counts of >500 cells/ μ L are considered to have no immunologic compromise. For patients taking antiretroviral therapy, current CD4 counts rather than nadir counts should be used in deciding about immunizations. The CDC recommends that newly diagnosed, treatment-naïve patients with CD4 counts of <200 cells/ μ L delay travel until after immunologic reconstitution with antiretrovirals to minimize risk of infection and immune reconstitution illness during travel.

The following should be noted about specific vaccinations:

- Inactivated (killed), enhanced-potency polio and typhoid vaccines should be given instead of the live, attenuated forms. In adults aged >18 , vaccinate 8 weeks before travel to allow time for the initial 2 doses of polio vaccine.
- Measles or measles, mumps, and rubella (MMR; omit if patient has evidence of immunity) should not be given to severely immunocompromised patients. Instead, immune globulin should be given to measles-susceptible, severely immunocompromised persons traveling to measles-endemic countries.
- Yellow fever vaccine is a live-virus vaccine with uncertain safety and efficacy for HIV-infected persons, and it should be avoided if possible. Travelers with asymptomatic HIV infection and relatively high CD4 counts who cannot avoid potential exposure to yellow fever should be offered the choice of vaccination. If travel to a zone with yellow fever is necessary and vaccination is not administered, patients should be advised about the risk of yellow fever, instructed about avoiding the bites of vector mosquitoes, and provided with a vaccination waiver letter (though travelers should be warned that not all countries accept waiver letters).
- The influenza season in the Southern Hemisphere is April through September, but in the tropics, influenza is a year-round infection. Immunocompromised patients should be protected on the basis of influenza risk at the destination. HIV-infected patients should not be given live intranasal influenza vaccine.

Preventing Exposure to Opportunistic and Other Infections

Background

Persons with HIV infection are more susceptible than others to certain infections. HIV-infected persons may come into contact with opportunistic pathogens in the course of various aspects of their daily activities. Pets, children, personal and sexual contacts, and food and water, as well as involvement in occupational tasks, recreation, hobbies, and other activities all potentially can expose an HIV-infected person to opportunistic pathogens, some of which are ubiquitous and cannot be avoided. Among the ubiquitous pathogens are *Candida*, *Mycobacterium avium*, *Pneumocystis jiroveci*, and human herpesvirus 6 and 7. Exposure to other opportunistic pathogens may be minimized if patients are aware of the risks.

The following tables group opportunistic pathogens by type of exposure. Mechanisms of transmission and recommendations for avoidance are outlined. Note that a number of infections can be transmitted by several of these modes.

For information about vaccinations, see chapter *Immunizations for HIV-Infected Adults and Adolescents*; for opportunistic infection (OI) prophylaxis, see chapter *Opportunistic Infection Prophylaxis*.

Topics:

- | | |
|----------------------------------|---------------------------------|
| • Water related | • Injection drug use associated |
| • Food associated | • Other bloodborne related |
| • Environmental | • Pet and animal related |
| • Respiratory and bodily contact | • Contact with children |
| • Associated with sexual contact | • Travel related |

Water Related	
Pathogens	• Hepatitis A virus (HAV) • <i>Cryptosporidium</i> • <i>Shigella</i> • <i>Campylobacter</i> • <i>Amoeba</i> • <i>Giardia</i> • <i>Isospora</i> • Microsporidia
Transmission	• Infection occurs through drinking contaminated water or eating produce or other food that has been washed in contaminated water. • Water ingested accidentally during recreation also can make people sick.
Recommended avoidance measures	• To decrease exposure from water in developing countries, take the following precautions: • Do not drink tap water or use it to brush teeth. • Avoid ice that is not made from bottled water. • Avoid raw fruits or vegetables, as they may have been washed in tap water. • Bring tap water to a rolling boil for at least 1 minute before consuming. If this is not possible, treatment with iodine or chlorine, especially in conjunction with filtering, reduces risk of infection. • Additional recommendations, include the following: • Avoid drinking untreated water. • When choosing a home water filter, especially for filtering untreated water, be aware that not all filters remove the pathogens listed above. • Do not drink water from lakes or rivers. • Avoid swimming in water that may be contaminated with stool. • Avoid swallowing water during recreational activities (lakes, rivers, saltwater beaches, pools, hot tubs, and ornamental fountains may be contaminated with <i>Cryptosporidium</i>). • In the event of a cryptosporidiosis outbreak in the municipal water supply, boil tap water for at least 1 minute to eliminate risk of infection. • <i>Cryptosporidium</i> may be present in municipal water outside outbreak settings, though the magnitude of this risk is unknown. Some HIV-infected patients may choose to take precautions to decrease risk. • Be aware that bottled water may be contaminated with <i>Cryptosporidium</i>. • See the discussion of travel-related topics, below.

Food Associated	
Pathogens	• <i>Toxoplasma</i> • <i>Salmonella</i>, <i>Shigella</i>, <i>Campylobacter</i> (enteric infections) • <i>Listeria</i> • <i>Cryptosporidium</i> • Other enteric pathogens
Transmission	• Exposure may occur through eating or handling contaminated food.
Recommended avoidance measures	• Always wash hands before preparing and consuming food. • Wash hands, cutting boards, counters, and utensils thoroughly after contact with uncooked foods. • Do not allow raw meat or eggs to come into contact with other foods. • Wash produce thoroughly. • Cook meat and poultry to an internal temperature of 165-170°F. It is safest to confirm temperature with a thermometer. Meat that is no longer pink inside likely has reached a temperature of 165°F. • Avoid raw or unpasteurized milk, including goat milk, and foods that contain unpasteurized milk or milk products. • Avoid foods that might contain raw egg (e.g., Hollandaise sauce, Caesar salad dressing, some mayonnaises, uncooked cake and cookie batter, eggnog, homemade ice cream). Pasteurized eggs can be used safely in recipes that call for raw egg. • Avoid eating raw or lightly steamed shellfish. • Avoid eating raw seed sprouts, as these may be contaminated with enteric pathogens. • Avoid foods from street vendors, especially in developing countries. • Be aware that unpasteurized juices may be contaminated with <i>Cryptosporidium</i>. • Rates of infection with <i>Listeria</i> are low, but HIV-infected people who are severely immunocompromised are at increased risk. • HIV-infected persons who wish to decrease their risk of listeriosis should take the following precautions: • Avoid soft cheeses including feta, brie, camembert, blue-veined, and Mexican-style cheeses such as queso fresco unless they are clearly labeled as pasteurized. Hard cheeses, processed cheeses, cream cheese, cottage cheese, and yogurt generally are safe. • Before eating leftover foods or ready-to-eat foods, such as hot dogs, cook them until they are steaming hot. • Avoid foods from deli counters, such as prepared meats, salads, and cheeses, or heat these foods until steaming hot before eating them. • Avoid refrigerated pâté, or heat until steaming hot. Canned or shelf-stable pâté generally is safe. • Avoid refrigerated smoked seafood, unless it is part of a cooked dish. Canned or shelf-stable smoked seafood generally is safe. • Also see information on travel-related infections, below.

Environmental	
Pathogens	• <i>Toxoplasma gondii</i> • <i>Cryptosporidium</i> • <i>Coccidioides</i> • <i>Histoplasma capsulatum</i> • <i>Cryptococcus neoformans</i> • <i>Aspergillus</i>
Transmission	• <i>Cryptosporidium</i> and <i>Toxoplasma</i> may be present in soil and sands, and infection can occur through handling soil during gardening or playing in or cleaning sandboxes. • Infection with <i>Coccidioides</i> and <i>Histoplasma</i> occurs with inhalation of fungal spores that become airborne owing to disturbance of contaminated soil.

Environmental	
Recommended avoidance measures	• Wash hands thoroughly after contact with soil or sand. • Endemic fungi cannot be completely avoided in certain geographic areas; however, avoiding high-risk activities can decrease risk of infection. • In endemic coccidioidomycosis areas, avoid exposure to soil disturbance such as that which occurs during dust storms and at excavation and construction sites. • Risk of <i>Aspergillus</i> infection also may be decreased by avoidance of dusty environments. • Patients with CD4 counts of <150 cells/μL should avoid activities that put them at increased risk of exposure to <i>Histoplasma</i> in endemic areas, such as: • Cleaning, remodeling, or demolishing old buildings • Disturbing soil beneath bird roosting sites • Cave exploration • Other contact with bird or bat droppings • Limiting exposure to bird droppings may decrease risk of infection with <i>C. neoformans</i>.

Respiratory and Bodily Contact	
Pathogens	• <i>Mycobacterium tuberculosis</i> • Enteric pathogens • Influenza • Varicella-zoster virus (VZV)
Transmission	• Tuberculosis (TB) is transmitted when a person with pulmonary or laryngeal TB coughs, sneezes, shouts, or sings, generating infected droplets that are inhaled by a susceptible person. • HIV-infected persons working or residing in certain environments, such as hospitals, nursing homes, homeless shelters, and correctional institutions, may become exposed to TB. • Influenza virus is spread by exposure to infected respiratory droplets or contaminated surfaces. • VZV is transmitted through contact with aerosolized respiratory droplets or by contact with skin lesions. • Many respiratory and enteric pathogens may be spread by contact with contaminated fomites.
Recommended avoidance measures	• HIV-infected persons should be aware of the increased risk of TB infection associated with certain environments. The following measures decrease risk of infection: • In settings with a high risk of TB transmission, patients with known or suspected TB should be physically separated from others. • All HIV-infected persons should be tested for latent TB infection. • All HIV-infected patients with latent TB infection (LTBI) should receive a complete course of LTBI treatment. • HIV-infected persons with a history of significant TB exposure should be treated presumptively for LTBI regardless of the results of LTBI testing, once active infection has been ruled out. • Bacillus Calmette-Guérin (BCG) vaccination is not recommended in the United States, and it is contraindicated for HIV-infected persons. • People susceptible to VZV should avoid persons with active chickenpox or herpes zoster (shingles). • VZV-susceptible, HIV-negative household contacts should be vaccinated against VZV, so that they will not transmit VZV to their HIV-infected contact. • Frequent handwashing can reduce risk of diarrhea in HIV-infected persons.

Associated with Sexual Contact	
Pathogens	• HIV • Hepatitis B virus (HBV) • Hepatitis C virus (HCV) • Hepatitis A virus (HAV) • Human papillomavirus (HPV) • Cytomegalovirus (CMV) • Herpes simplex virus (HSV) • Syphilis • <i>Chlamydia</i> • <i>Gonorrhea</i> • <i>Trichomonas</i> • Lymphogranuloma venereum (LGV) serovars of <i>Chlamydia trachomatis</i> • <i>Cryptosporidium</i> • <i>Shigella</i> • <i>Campylobacter</i> • <i>Amoeba</i> • <i>Giardia</i> • <i>Isospora</i> • Microsporidia
Transmission	• Depending on the pathogen, infection may be transmitted by exchange of body fluids, by skin-skin contact, or by oral-fecal contact. • Sexually transmitted diseases (STDs) can occur at genitals, rectum, or mouth, depending on sexual practices. • A number of enteric pathogens can be transmitted during sex (by oral-fecal contact).
Recommended avoidance measures	• Male latex condoms, when used consistently and correctly: • Are highly effective in preventing sexual transmission of HIV and many other STDs, including syphilis, chlamydia, gonorrhea, and trichomoniasis. • Decrease risk of acquiring HSV-2, HPV, CMV, HBV, and HCV. • Do not prevent enteric pathogen exposure (which is via fecal-oral contact). • HIV-infected persons should be screened for STDs at least annually. Those with multiple partners or high-risk partners or sexual practices should be screened more frequently. • To avoid infection with HSV, HIV-infected persons should avoid sexual contact when a partner has an overt herpetic lesion (genital or oral-labial), though HSV transmission also can occur during asymptomatic shedding. Consistent use of male condoms also has been shown to reduce HSV transmission risk in heterosexual couples. • The use of suppressive antiviral therapy by persons with genital herpes reduces HSV-2 transmission to susceptible partners, though the effectiveness of this approach in HIV-infected patients has not been evaluated. • Patients who are CMV seronegative should be advised that CMV can be sexually transmitted. • To decrease risk of exposure to enteric pathogens during sex, patients can: • Use barriers such as dental dams during oral-anal contact. • Change condoms after anal sex. • Wear latex gloves during digital-anal contact. • Wash hands after sex.

Injection Drug Use Associated	
Pathogens	• HIV • HCV • HBV • CMV • <i>Staphylococcus aureus</i>, including MRSA • <i>Pseudomonas aeruginosa</i> • <i>Streptococcus</i> • <i>Clostridium</i> • Enteric bacteria and oral anaerobes • <i>Leishmania</i> • Fungi
Transmission	• Injection drug users are at risk of a host of infections, including viral hepatitis, skin and soft-tissue infections, infective endocarditis, and pulmonary infections. • Injection drug use also may put users at risk of acquiring TB and STDs. • Infection may occur from contaminated drug-injection equipment (needles, syringes, water, and other preparation equipment). • Infection also may occur from the user's own skin or mouth bacteria, which can enter the bloodstream. • The drug itself, or an adulterating substance, may be contaminated.
Recommended avoidance measures	• Injection drug users should be advised not to share needles or drug preparation equipment, and should be educated about needle exchange programs. • If receptive, injection drug users should be referred to substance abuse treatment programs. • Injection drug users should be educated about methods of reducing risk, including the following: • If equipment is being reused, clean with bleach and water. • Avoid dangerous injection sites such as groin and neck. • Do not crush capsules or tablets in the mouth prior to injecting, as this may introduce harmful oral bacteria into the bloodstream. • Do not lick injection needles or syringes. • Use boiled water for preparing drugs for injection; if not available, use tap water. • Boil the drug before injecting. • Use a new or disinfected "cooker," and a new filter to prepare drugs for injection. • Always clean injection sites with alcohol before injecting. • Be aware that black tar heroin may be contaminated with <i>Clostridium</i> spores, which are not killed by heating the drug prior to use.

Other Bloodborne Related	
Pathogens	• HIV • HCV • HBV • CMV
Transmission	• Tattooing and body piercing. • Reuse of medical equipment and transfusion of infected blood (primarily outside the United States). • Occupational exposures (e.g., needlesticks) of health care workers.
Recommended avoidance measures	• Persons considering tattooing or piercing should be educated about the potential risk of bloodborne pathogen transmission if proper infection control procedures are not followed. • When receiving a transfusion, HIV-infected patients who are seronegative for CMV should be administered only CMV antibody-negative or leukocyte-reduced cellular blood products in nonemergency situations. • Universal precautions always should be followed by health care workers.

Pet and Animal Related	
Pathogens	• <i>Toxoplasma</i> • <i>Cryptosporidium</i> • <i>Salmonella</i> • <i>Campylobacter</i> • Shiga toxin-producing <i>Escherichia coli</i> • <i>Bartonella</i> • <i>Leptospira</i> • <i>Brucella</i> • <i>Capnocytophaga</i> • <i>Cryptococcus</i> • <i>Mycobacterium avium</i> and <i>marinum</i> • <i>H. capsulatum</i>
Transmission	• For the most part, people with HIV infection can and should keep their pets. • HIV-infected persons should be made aware of the potential risks posed by animals and of the avoidance measures for decreasing risks of infection. • Exposure may occur though a lick, a bite, or a scratch, or through contact with a pet's stool. Some infections may be spread though contact with an animal's coat or skin. • Fleas may spread some infections to pet owners. • Patients also may be exposed while performing occupational tasks that bring them into contact with animals (e.g., in pet stores, veterinary clinics, farms, and slaughterhouses).
Recommended avoidance measures	• Always wash hands after handling animals, and after cleaning cages or aquariums. • When acquiring a new pet, avoid animals <6 months of age (cats younger than 1 year) and those with diarrhea. • Stray animals may carry many infections and should be avoided. • Avoid contact with animal stool. • Avoid animals with diarrhea. • Pets with diarrhea should be examined by a veterinarian and should have stool checked for <i>Cryptosporidium</i>, <i>Salmonella</i>, <i>Campylobacter</i>, and Shiga toxin-producing <i>E. coli</i>. • Wash any bites or scratches with soap and water, and seek medical attention. • Animals should not be allowed to lick people in the mouth, or on any open cuts or wounds. • Cats may increase risk of <i>Toxoplasma</i> and <i>Bartonella</i> infection. • To minimize risk of <i>Toxoplasma</i> exposure: • Litter boxes should be cleaned daily, preferably by someone who is not HIV infected or pregnant. • If an HIV-infected person is cleaning a litter box, gloves should be used, and hands should be washed afterward. • Keep cats indoors and do not allow them to hunt. • Do not feed cats raw or undercooked meat. • In areas where histoplasmosis is endemic, avoid contact with bird droppings, including soil under bird roosting sites. • Always use gloves when cleaning aquariums to avoid contact with <i>Mycobacterium marinum</i>. • Avoid contact with reptiles (such as lizards, snakes, and turtles), as well as chicks and ducklings, as these may carry <i>Salmonella</i>. • Avoid exotic pets such as monkeys, ferrets, and other wild animals.

Contact with Children	
Pathogens	• CMV • <i>Cryptosporidium</i> • <i>Giardia</i> • HAV • Influenza • VZV • Enteric pathogens
Transmission	• HIV-infected persons who work as childcare providers, or who have children in daycare, may be exposed to opportunistic pathogens. • The poor personal hygiene habits of children facilitate spread of infection. • Risks specific to the individual, given his/her immune status and medical history, should be discussed with a health care provider. • CMV infection may occur through contact with many body fluids, including stool, urine, and saliva. • Diapering may bring a person into contact with <i>Cryptosporidium</i> and other enteric pathogens. • In addition to opportunistic pathogens, childcare providers are exposed to other illnesses, carried by children, to which they may be more susceptible.
Recommended avoidance measures	• Wash hands thoroughly after contact with stool or urine. • Wash hands after diapering and disinfect changing station often. • Wash hands after contact with saliva or objects covered with saliva, such as cups or pacifiers. • Ensure that the immunization status of HIV-infected persons is up to date, as appropriate for their immune status. • HIV-infected persons who are susceptible to VZV should avoid exposure to people with chickenpox or shingles. • VZV-susceptible household contacts of HIV-infected persons should be vaccinated against VZV if they are HIV negative, so that they will not transmit VZV to their HIV-infected contact.

Travel Related	
Pathogens	• Enteric pathogens • <i>Plasmodium</i> species (malaria) • Yellow fever virus • Dengue virus • Other geographically specific infections
Transmission	• Travelers to developing countries are at risk of foodborne and waterborne infections. • Malaria is transmitted by the bite of an infected female <i>Anopheles</i> mosquito. • HIV-infected patients are at higher risk of severe malaria. • Yellow fever and dengue fever are spread by mosquito bites.

Travel Related	
Recommended avoidance measures	• Plan the travel itinerary, vaccinations, and prophylaxis in consultation with a health care provider experienced in travel medicine. • Discuss area-specific risks and avoidance measures with the health care provider. • The U.S. Centers for Disease Control and Prevention (CDC) Traveler's Health website has detailed information on most issues pertaining to infections in travelers (wwwnc.cdc.gov/travel). • Review and update routine vaccination history prior to travel. • Generally, live vaccines for HIV-infected persons should be avoided, with some exceptions: • Measles vaccination is recommended for all nonimmune persons with CD4 counts of ≥ 200 cells/μL. Measles immune globulin should be considered for those with CD4 counts of < 200 cells/μL who are traveling in measles-endemic areas. • Varicella vaccination can be considered for VZV-seronegative persons with CD4 counts of ≥ 200 cells/μL. • Yellow fever vaccination may be considered, see below. • Inactivated (killed) enhanced-potency polio and typhoid vaccines should be given instead of the live, attenuated forms. • Killed and recombinant vaccines including influenza, diphtheria-tetanus, rabies, HAV, HBV, Japanese encephalitis, and meningococcal vaccines should be administered as they would be for HIV-uninfected persons preparing for travel. • The oral cholera vaccine (not available in the United States) is not recommended for most travelers by the CDC. Traveler's diarrhea: • See sections on foodborne and waterborne infections (above) for risk-reduction strategies. • Antimicrobial prophylaxis is not routinely recommended for HIV-infected persons traveling in developing countries. • Prophylaxis may be appropriate in select situations (for example, high risk of infection and short length of travel). • For those to whom prophylaxis is given, fluoroquinolones (such as ciprofloxacin 500 mg PO QD) may be considered for nonpregnant patients. • HIV-infected patients traveling in developing countries should bring antibiotics to be used empirically in the event of developing diarrhea. • Appropriate regimens include: • Ciprofloxacin 500 mg PO BID for 3-7 days • Azithromycin 500 mg PO QD as an alternative, and for pregnant women • Antiperistaltic agents such as loperamide or diphenoxylate can be useful in the treatment of traveler's diarrhea. • Do not use antiperistaltic agents if high fever or blood in the stool is present. Stop use if symptoms persist > 48 hours. • Seek medical care if diarrhea is severe, bloody, accompanied by fever and chills, leads to dehydration, or does not respond to empiric therapy.

Travel Related	
Recommended avoidance measures	Malaria: • HIV-infected patients should be advised to avoid travel in malarious areas. • If travel to a malarious area cannot be avoided, effective chemoprophylaxis should be given. Consult the CDC Traveler's Health website (wwwnc.cdc.gov/travel) for specific information. • Be aware that some malaria prophylaxis medications may have drug-drug interactions with antiretrovirals. • Personal protection measures should be followed, including avoidance of peak biting times and use of insect repellants, protective clothing, and permethrin-soaked bed netting. Yellow fever: • HIV-infected patients should be discouraged from visiting areas where yellow fever infection is a risk. • Vaccination may be considered in some HIV-infected persons with high CD4 counts who cannot avoid potential exposure, after discussion of risks and benefits. • Vaccine response may be poor, and serologic testing can be considered. • If vaccination is not administered, patients should be advised about the risk of yellow fever, instructed about avoiding the bites of vector mosquitoes, and provided with a vaccination waiver letter. • Personal protection measures should be followed, including avoidance of peak biting times and use of insect repellants, protective clothing, and permethrin-soaked bed netting. Other geographically specific opportunistic infections include visceral leishmaniasis, <i>Penicillium marneffe</i> infection, coccidiomycosis, histoplasmosis, and TB.

Opportunistic Infection Prophylaxis

Background

Prophylaxis against an opportunistic infection (OI) is treatment given to HIV-infected individuals to prevent either a first episode of an OI (primary prophylaxis) or the recurrence of an OI (secondary prophylaxis). Prophylaxis is recommended to prevent three important OIs: *Pneumocystis jiroveci* pneumonia (PCP), *Mycobacterium avium* complex (MAC), and toxoplasmosis. Prophylaxis also is recommended to prevent tuberculosis (TB) in patients with latent *Mycobacterium tuberculosis* infection (see chapter *Latent Tuberculosis Infection*). In endemic regions, prophylaxis against *Histoplasma capsulatum* and *Coccidioides* species is advised. And in some situations, prophylaxis against other OIs may be reasonable; see the OI prevention recommendations of the U.S. Centers for Disease Control and Prevention, the National Institutes of Health, and the HIV Medicine Association (reference below) for additional information.

HRSA HAB Performance Measures

Percentage of patients, aged 6 weeks or older with a diagnosis of HIV/AIDS, who were prescribed *Pneumocystis jiroveci* pneumonia prophylaxis
(Core measure)

Pneumocystis jiroveci Pneumonia

Background

PCP remains the most common life-threatening infection among U.S. residents with advanced HIV disease.

Primary Prophylaxis: Indications

- Prophylaxis should be administered to all HIV-infected patients with a CD4 count of <200 cells/ μ L, a history of an AIDS-defining illness, or a history of oral thrush. PCP prophylaxis also is indicated for patients with CD4 counts of >200 cells/ μ L in the presence of a CD4 percentage <14%.
- For patients whose CD4 counts are declining toward 200 cells/ μ L, the CD4 count should be monitored closely. PCP prophylaxis should be considered for patients with a CD4 count of 200-250 cells/ μ L if laboratory monitoring will not be possible within 3 months.

Prophylaxis Options: Recommended Regimens

- Trimethoprim-sulfamethoxazole (TMP-SMX) (also known as cotrimoxazole, Bactrim, and Septra) 1 double-strength (DS) tablet PO QD (Note: This regimen also is effective in preventing toxoplasmosis.)
- TMP-SMX 1 single-strength tablet PO QD (this lower-dose regimen may be better tolerated) (Note: This also is likely to be effective in preventing toxoplasmosis.)
- **Warning:** Many patients have adverse reactions to sulfa medications. Severe reactions may include persistent neutropenia, rash (including severe erythroderma), and Stevens-Johnson syndrome (bullae and desquamation of the skin). For patients with milder reactions, chemoprophylaxis with TMP-SMX should be continued if clinically possible. Some patients with a history of serious adverse reaction may undergo desensitization, but this must be done cautiously and it requires diligence from the patient and careful management by the provider (see chapter *Sulfa Desensitization*).

Prophylaxis Options: Alternative Regimens

Other options for prophylaxis include the following:

- TMP-SMX DS, 1 tablet TIW (e.g., Monday, Wednesday, and Friday) (Note: This regimen also is likely to be effective in preventing toxoplasmosis.)
- Dapsone 100 mg PO QD or 50 mg PO BID (Note: These regimens do not prevent toxoplasmosis.)
- Dapsone 50 mg PO QD + pyrimethamine 50 mg PO once weekly + leucovorin 25 mg PO once weekly (Note: This regimen also is effective in reducing the risk of toxoplasmosis.)
 - **Warning:** Glucose-6-phosphate dehydrogenase (G6PD) deficiency can increase the risk of hemolytic anemia or methemoglobinemia in patients receiving dapsone. Screen for G6PD deficiency before starting dapsone. (G6PD deficiency is found in approximately 10% of African-American males, and in 1-2% of males of Mediterranean, Indian, and Asian descent.)
- Dapsone 200 mg PO once weekly + pyrimethamine 75 mg PO once weekly + leucovorin 25 mg PO once weekly
- Aerosolized pentamidine 300 mg once per month, via Respigard II nebulizer (Note: This regimen does not prevent toxoplasmosis.)
 - **Warning:** Aerosolized pentamidine may increase the risk of extrapulmonary pneumocystosis, pneumothorax, and bronchospasm. It increases the risk of TB transmission to others if the patient has active pulmonary tubercular disease, unless ventilation (negative-pressurized facility with outside venting) is adequate. Do not use for patients in whom TB is suspected. The availability of treatment facilities offering aerosolized pentamidine may be limited.

- Atovaquone 1,500 mg QD (Note: This also is effective in reducing the risk of toxoplasmosis.) Atovaquone is more expensive than dapsone. It should be taken with high-fat meals for optimal absorption.
- Atovaquone 1,500 mg + pyrimethamine 25 mg + folinic acid 10 mg, all taken PO QD (Note: This regimen also is effective in reducing the risk of toxoplasmosis.)

Secondary Prophylaxis Indications

Prophylaxis should be given to all patients with a history of PCP.

Discontinuing Prophylaxis

Primary or secondary prophylaxis can be discontinued if the CD4 count has increased to ≥ 200 cells/ μ L for at least 3 months in response to effective antiretroviral therapy (ART), with the following cautions:

- If the patient had PCP in the past and the episode of PCP occurred at a CD4 count of >200 cells/ μ L, it may be prudent to continue PCP prophylaxis for life, regardless of how high the CD4 count rises as a consequence of ART.
- PCP prophylaxis should be reinitiated if the CD4 count decreases to <200 cells/ μ L or the patient meets other criteria as indicated above.

Prophylaxis During Pregnancy

TMP-SMX is the recommended agent for use during pregnancy; dapsone may be used as an alternative. Some experts recommend high-dose folate supplementation (e.g., 4 mg daily) for pregnant women receiving TMP-SMX, because TMP-SMX may worsen folate deficiency; however, this may increase risk of TMP-SMX failure; if high-dose folate supplementation is given, it should be limited to the first trimester. Prophylaxis that includes pyrimethamine generally should be deferred until after pregnancy. During the first trimester, aerosolized

pentamidine (which is not systemically absorbed) can be used if the potential teratogenicity of oral agents is a concern.

***Mycobacterium avium* Complex**

Background

MAC is common among patients with advanced HIV disease and it generally occurs in people with CD4 counts of <50 cells/ μ L.

Primary Prophylaxis: Indications

Prophylaxis should be administered to all HIV-infected patients with CD4 counts of <50 cells/ μ L. Before starting prophylaxis, rule out active MAC infection by clinical assessment and, if warranted, by acid-fast bacilli (AFB) blood cultures (see chapter *Mycobacterium avium Complex Disease*). Also rule out active TB prior to starting any rifabutin-containing regimen for MAC prophylaxis. Review the current drug regimen for medications that may interact with MAC prophylaxis.

Prophylaxis Options: Recommended Regimens

- Azithromycin 1,200 mg PO weekly
- Clarithromycin 500 mg PO BID (Note: Clarithromycin is not recommended for use during pregnancy, and it can have significant interactions with efavirenz, atazanavir, and other drugs; see chapter *Drug-Drug Interactions with HIV-Related Medications*.)
- Azithromycin 600 mg PO BIW

Prophylaxis Options: Alternative Regimens

Rifabutin 300 mg QD (Note: Rifabutin has significant interactions with many drugs; certain nonnucleoside reverse transcriptase inhibitors and protease inhibitors should be avoided or dosage adjustment of rifabutin

may be required. See chapter *Drug-Drug Interactions with HIV-Related Medications*.)

Secondary Prophylaxis

Patients should receive lifelong chronic maintenance therapy, unless immune reconstitution occurs in response to ART. See chapter *Mycobacterium avium Complex Disease*.

Discontinuing Prophylaxis

Primary prophylaxis for MAC can be discontinued in persons who have responded to effective ART with sustained increases in CD4 counts to >100 cells/ μ L for at least 3 months. Careful observation and monitoring are required, and prophylaxis should be restarted if the patient's CD4 count decreases to <50 cells/ μ L.

Secondary prophylaxis can be discontinued in patients who received at least 12 months of treatment for MAC, are asymptomatic, and have sustained (for at least 6 months) CD4 counts of >100 cells/ μ L on ART. Secondary prophylaxis should be reintroduced if the CD4 count decreases to <100 cells/ μ L.

Prophylaxis During Pregnancy

Azithromycin is the prophylactic drug of choice during pregnancy, although evidence for its safety in the first trimester is limited. Clarithromycin is teratogenic in animals.

Toxoplasmosis

Background

Toxoplasmic encephalitis (TE) usually is caused by reactivation of latent *Toxoplasma gondii* infection in patients with advanced immunosuppression (especially those with CD4 counts of <100 cells/ μ L). The CDC/NIH recommendations state that all HIV-infected patients should be tested for *Toxoplasma* immunoglobulin G (IgG) antibody soon after the diagnosis of HIV infection. *Toxoplasma* IgG-negative patients should be counseled

to avoid sources of infection (see chapter *Preventing Exposure to Opportunistic and Other Infections*), and should be retested for *Toxoplasma* IgG if CD4 counts fall to <100 cells/ μ L to determine whether they have seroconverted and are therefore at risk of TE. (See chapter *Toxoplasmosis* for more information on active disease and secondary prophylaxis.)

Primary Prophylaxis: Indications

Prophylaxis should be administered to all HIV-infected patients with CD4 counts of <100 cells/ μ L who are seropositive for *Toxoplasma*. IgG-negative patients should avoid exposure to *Toxoplasma*; see “Patient Education,” below, and chapter *Preventing Exposure to Opportunistic and Other Infections*.

Prophylaxis Options: Recommended Regimens

- TMP-SMX DS, 1 tablet QD (Note: This option also is effective in preventing PCP.)

Prophylaxis Options: Alternative Regimens

(Note: The following options also are effective in preventing PCP.)

- TMP-SMX DS, 1 tablet PO TIW
- TMP-SMX single strength, 1 tablet PO QD
- Dapsone 50 mg PO QD + pyrimethamine 50 mg PO weekly + folinic acid 25 mg PO weekly
- Dapsone 200 mg PO weekly + pyrimethamine 75 mg PO weekly + folinic acid 25 mg PO weekly
 - **Warning:** G6PD deficiency can increase the risk of hemolytic anemia or methemoglobinemia in patients receiving dapsone. Screen for G6PD deficiency before starting dapsone. (G6PD deficiency is found in approximately 10% of African-

American males, and in 1-2% of males of Mediterranean, Indian, and Asian descent.)

- Atovaquone 1,500 mg PO QD, with or without pyrimethamine 25 mg PO QD + folinic acid 10 mg PO QD (This alternative is quite expensive.)
- Neither aerosolized pentamidine nor dapsone alone provides protection against TE.

Secondary Prophylaxis

Patients should receive lifelong chronic maintenance therapy, unless immune reconstitution occurs in response to ART (see chapter *Toxoplasmosis*).

Discontinuing Prophylaxis

Primary prophylaxis for TE can be discontinued in patients who have responded to effective ART with sustained CD4 counts of >200 cells/ μ L for at least 3 months. CD4 counts should be monitored carefully, and prophylaxis should be restarted in patients whose CD4 counts decrease to <100-200 cells/ μ L.

Secondary prophylaxis may be discontinued if TE signs and symptoms have resolved with treatment and if patients have sustained (for at least 6 months) CD4 counts of >200 cells/ μ L on ART. Secondary prophylaxis should be reintroduced if CD4 counts drop to <200 cells/ μ L.

Prophylaxis During Pregnancy

TMP-SMX may be used as primary prophylaxis during pregnancy. Risks of TMP-SMX in the first trimester must be balanced against the risks of reactivated toxoplasmosis. Some experts recommend high-dose folate supplementation (e.g., 4 mg QD) for pregnant women receiving TMP-SMX, because TMP-SMX may worsen folate deficiency; however, this may increase risk of TMP-SMX failure; if high-dose folate supplementation is given,

it should be limited to the first trimester. Pyrimethamine has been associated with birth defects in animal studies, but limited data in human studies have not shown an increased risk; guidelines support its use after the first trimester. Secondary prophylaxis generally should be provided using the same guidelines as for nonpregnant women.

Histoplasmosis

Background

Infection with *Histoplasma capsulatum* is common in several geographic areas, including the Ohio and Mississippi River Valleys as well as parts of Central and South America, Asia, and Africa. Symptomatic disease can occur via primary infection or reactivation of previously silent infection in the setting of waning cellular immunity. CD4 counts of ≤ 150 cells/ μL , along with positive *Histoplasma* serology and environmental exposure, are associated with increased risk of symptomatic disease. Histoplasmosis can cause a range of clinical manifestations including respiratory, gastrointestinal, central nervous system (CNS), and cutaneous disease.

Primary Prophylaxis: Indications

Prophylaxis can be considered for HIV-infected patients with CD4 counts of ≤ 150 cells/ μL who are at high risk because of occupational exposure and for those who live in an area where histoplasmosis is highly endemic. HIV-infected patients with CD4 counts of ≤ 150 cells/ μL should be educated to avoid exposure.

Prophylaxis Options: Recommended Regimens

- Itraconazole 200 mg PO QD (Note: Itraconazole has significant interactions with many drugs, including nonnucleoside reverse transcriptase inhibitors, protease inhibitors, and maraviroc. Dosage adjustments may be required, and some combinations may be contraindicated; consult with a pharmacist or other specialist.)

Secondary Prophylaxis

Patients with a history of severe disseminated disease or CNS infection and those who have relapsed despite receiving appropriate therapy should receive long-term suppressive therapy.

Discontinuing Prophylaxis

Primary prophylaxis can be discontinued once CD4 counts are ≥ 150 cells/ μL for at least 6 months. CD4 counts should be monitored carefully, and prophylaxis should be restarted for patients whose CD4 counts decrease to < 150 cells/ μL .

Secondary prophylaxis may be discontinued if patients have received at least 1 year of itraconazole, have negative blood cultures, have had CD4 counts of ≥ 150 cells/ μL for at least 6 months on ART, and have serum *Histoplasma* antigen < 2 units. Suppressive therapy should be restarted for patients whose CD4 counts decrease to < 150 cells/ μL .

Prophylaxis During Pregnancy

Azoles should be avoided during pregnancy, especially during the first trimester, because of teratogenicity concerns.

Coccidiomycosis

Background

The *Coccidioides* species fungus is endemic to many arid regions. In the United States, it is found primarily in the Sonoran Desert in Arizona and the San Joaquin “Central” Valley in California, but also in areas of New Mexico, western Texas, Nevada, and Utah. It also is endemic to many arid regions in Central and South America. Immune response to *Coccidioides* species declines as CD4 counts decrease, and risk of developing symptomatic disease in endemic areas is increased when the CD4 count is <250 cells/ μ L. In HIV-infected patients, six syndromes have been described: focal pneumonia, diffuse pneumonia, cutaneous involvement, meningitis, liver or lymph node involvement, and positive serology without localized infection.

Primary Prophylaxis: Indications

- Primary prophylaxis is not beneficial and is not recommended. Patients in endemic areas cannot avoid *Coccidioides* but should be educated to avoid extensive exposure (e.g., through disturbed soil and dust storms). Annual monitoring for seroconversion of HIV-infected patients in endemic areas is reasonable; in patients with CD4 counts of <250 cells/ μ L who develop a new positive IgM or IgG, antifungal therapy is recommended to preempt active disease (fluconazole 400 mg PO QD).

Secondary Prophylaxis

Patients who have completed initial treatment for coccidiomycosis should receive lifelong suppressive therapy.

Discontinuing Prophylaxis

Patients with a history of meningeal disease should be treated with suppressive therapy for life, as they are at high risk of relapse. Patients with a history of diffuse pulmonary disease or nonmeningeal disseminated infection also are at high risk of relapse; consult with experts. Patients with focal coccidioidal pneumonia who have had good clinical response to antifungals can discontinue secondary prophylaxis once they have received 12 months of therapy, and have CD4 counts of >250 cells/ μ L on ART. These patients should undergo close radiologic and serologic monitoring for recurrence.

Prophylaxis During Pregnancy

Women who acquire coccidiomycosis in the second or third trimester of pregnancy are at increased risk of dissemination. Azoles should be avoided during the first trimester of pregnancy because of teratogenicity concerns.

Patient Education

- Discuss adverse effects of the selected medication(s) and how the patient should respond in the event of rashes, diarrhea, and other complications.
- Explain the purpose of each medication, and be sure that patients understand the dosage and frequency of administration.
- Reinforce the need to continue taking the medication indefinitely (potentially for life) to reduce the risk of the OI.
- OIs can occur despite prophylaxis. Instruct patients to contact their health care provider if they become ill.
- Counsel patients who are *Toxoplasma* IgG negative to avoid exposure to *Toxoplasma*. Specifically, they should avoid eating raw or undercooked meat, especially pork, lamb, game, and venison. Patients should wash hands after handling raw meat and after gardening or contact with soil. Encourage patients not to adopt or handle stray cats, and, if they own cats, to wash hands thoroughly after cleaning litter boxes. (See chapter *Preventing Exposure to Opportunistic and Other Infections*.)
- For women of childbearing potential who are taking clarithromycin, emphasize the need for effective contraception to avoid potential teratogenic effects of clarithromycin.
- Educate patients in *Histoplasma*- and *Coccidioides*-endemic areas regarding measures to decrease exposure. (See chapter *Preventing Exposure to Opportunistic and Other Infections*.)

Latent Tuberculosis Infection

Background

Latent (or inactive) tuberculosis (TB) infection occurs when an individual has dormant *Mycobacterium tuberculosis* organisms and no active disease. It can be diagnosed by a tuberculin skin test (TST) or by a blood test called an interferon-gamma release assay (IGRA); both are described below. HIV-infected persons with latent TB infection (LTBI) have a much higher risk of developing active TB (estimated at 3-16% per year) than the general population (estimated at <10% in a lifetime). Whereas treatment of HIV infection with antiretroviral therapy (ART) reduces the risk of active TB, this risk remains higher than that for HIV-uninfected persons. The risk of an HIV-infected individual with LTBI developing active TB can be reduced 60% with treatment of LTBI. Hence, identifying and treating HIV-infected persons with LTBI is a high priority. Treatment of LTBI not only reduces the risk of disease to the individual but also reduces the risk of further TB transmission within the community. Standard treatment with isoniazid (INH) is effective and safe.

Issues of concern regarding treatment of LTBI among HIV-infected persons include the following:

- Excluding active pulmonary or extrapulmonary TB disease before treatment with INH alone
- Assessing the risk of latent infection with drug-resistant TB
- Avoiding or managing drug interactions if rifamycin-containing regimens are used (rifampin, rifabutin, rifapentine)

S: Subjective

Ask about symptoms of active TB, including fever, cough, and weight loss; see chapter *Mycobacterium tuberculosis*. Patients with symptoms that could represent active TB must be evaluated for active TB and ruled out by appropriate diagnostic methods before initiating treatment (see “Assessment,” below). HIV-infected persons are eligible for LTBI treatment if they have positive LTBI screening results, no symptoms of active TB, and have not been treated previously for active or latent TB (re-treatment of LTBI should be considered if a patient is a close contact to an active TB case).

Persons who have had bacillus Calmette-Guérin (BCG) vaccine can be evaluated by an IGRA (preferably) or by a TST with correct interpretation. Immigrants from many countries

will have had childhood BCG vaccination.

Health care providers should ask about a history of potential exposure to TB. Close contact with an active TB case is an indication for LTBI treatment, after active TB has been excluded, regardless of the screening results on TST or IGRA.

O: Objective

Diagnostic Evaluation

Current U.S. Centers for Disease Control and Prevention (CDC) and U.S. Department of Health and Human Services (HHS) guidelines strongly recommend LTBI testing for all newly diagnosed HIV-infected persons. Repeat testing is recommended for patients whose CD4 lymphocyte count increases

HRSA HAB Performance Measures

Percentage of patients aged 3 months and older with a diagnosis of HIV/AIDS, for whom there was **documentation that a tuberculosis screening test was performed** and results interpreted (for tuberculin skin tests) at least once since the diagnosis of HIV infection

(All-Age measure)

from low numbers to counts of >200 cells/ μ L, and annual testing is suggested for patients whose initial test result is negative and who are considered at high risk of repeated or ongoing exposure to TB (risk factors include incarceration, residence in a congregate setting, active drug use, and residence in or travel to a TB-endemic setting).

CDC and HHS guidelines recommend use of either the TST or one of the three currently available IGRAs (QuantiFERON-TB Gold, QuantiFERON-TB Gold In-Tube [QFT-GIT], or TSPOT-TB). The TST evaluates delayed hypersensitivity to antigens from a number of *Mycobacterium* species (including non-tuberculosis species). The IGRAs are in vitro tests of lymphocyte recognition and response to antigens more specific to *M. tuberculosis*, but they still may cross-react with *M. kansasii*, *M. marinum*, or *M. szulgai*. Because the IGRAs use antigens more specific to *M. tuberculosis*, they generally are thought to have greater specificity and a lower false-positive rate. A positive TST or IGRA result suggests previous contact with *M. tuberculosis*, and it implies latent or active TB infection. Neither TST nor IGRA screening can distinguish between LTBI and active TB infection.

Use of an IGRA is preferred for persons with previous BCG exposure and for patient groups at risk of not returning for TST readings. The TST is preferred for children under 5 years of age. The cost of an IGRA is higher than the cost of a TST, and individual clinics should compare the total costs of both testing approaches, including the costs involved in TST protocols of recalling patients who miss visits, repeating TSTs, and treating persons with previous BCG exposure who may have false-positive TST results. Both IGRAs and TST testing have increased rates of anergic test results in HIV-infected patients with advanced immunosuppression (particularly those with CD4 counts of <100 cells/ μ L).

Tuberculin skin test

The TST is administered as an intradermal injection of 0.1 mL (5 tuberculin units) of purified protein derivative (PPD), which raises a wheal in the skin. This is sometimes referred to as the Mantoux test. Multiple-puncture tests such as tine tests and the use of other strengths of PPD are considered unreliable. Anergy testing with *Candida* and mumps antigens is not routinely recommended because a randomized controlled study of HIV-infected patients in the United States did not show an advantage to treating anergic, tuberculin-negative persons.

PPD tests are not designed for reading by the patient; a trained health care worker must measure the area of induration (not erythema) 48-72 hours after the test is administered. Induration of 5 mm or more is considered a positive result for HIV-infected persons, other immunosuppressed persons, anyone with recent TB exposure, and anyone with fibrosis on chest X-ray that is consistent with previous TB. For HIV-uninfected health care workers, 10 mm of induration is a positive result; in various other populations, either 10 mm or 15 mm of induration may be considered positive. Care providers at many large HIV clinics find it challenging to ensure that their patients return for the PPD reading. One randomized study found that offering incentives (e.g., a fast-food coupon) plus counseling was more effective than counseling alone in obtaining return visits for PPD readings.

Interferon-gamma release assay

IGRA tests performed on peripheral blood samples are available in the United States from two manufacturers. Although the tests are expensive, results are obtained without the patient having to make a return visit to the clinic, and false-positive readings following BCG vaccination do not occur. In addition, IGRAs do not appear to be boosted by prior TST testing and two-step testing is not required. Three test results

are possible with IGRA testing: positive, negative, and indeterminate. Unlike the TST, interpretation of IGRA test results does not vary by the risk category of the person tested. An indeterminate test indicates either a high background IFN-gamma level or failure of the mitogen to respond, and should be interpreted as “no test result” (not as “partially positive”). Repeating the IGRA once may yield interpretable test results. However, if the subsequent IGRA result is indeterminate, no further testing is recommended until there is a change in the patient’s immune status, such as reconstitution with ART.

Limited data suggest that the QFT-GIT is the most specific test (lowest rate of false-positive results) and the T-SPOT is the most sensitive test (with the lowest rate of false-negative results). However, few studies have compared the IGRA assays, and there is no reliable “gold standard” for sensitivity or specificity for latent TB infection. Although these tests do not detect previous BCG exposure, they will yield positive results in all three TB-causing species of the *M. tuberculosis* complex – *M. tuberculosis*, *M. bovis*, and *M. africanum* – and may yield positive results in persons with exposure to certain mycobacteria other than *M. tuberculosis* (*M. kansasii*, *M. marinum*, and *M. szulgai*).

There are accumulating data to support the use of IGRA testing in HIV infection. Data suggest that IGRAs are more specific than the TST and correlate more closely with risk factors for TB infection. As with TST, false-negative and indeterminate test results are more likely with advanced immunosuppression. One case series suggests that a significant number of QTF tests may be falsely positive on initial testing but negative on retesting, particularly in patients who were not born in TB-endemic settings. Accordingly, for patients with a positive IGRA result but no risk factors for TB other than HIV infection, it may be reasonable to repeat the IGRA and confirm positivity before treatment.

A: Assessment

After screening for symptoms (see “Subjective”), a chest X-ray should be obtained for all HIV-infected persons with positive TST or IGRA test results. Asymptomatic patients with negative chest X-ray results should be offered treatment for LTBI. (As above, it may be reasonable to repeat the IGRA for HIV-infected patients in non-TB-endemic settings who have no other risk factors for TB prior to LTBI treatment.) Persons with symptoms consistent with pulmonary or extrapulmonary TB, and those with abnormal chest radiography, require further assessment before LTBI treatment. This assessment may include sending two to three separate sputum specimens for acid-fast bacilli (AFB) stain, nucleic acid amplification testing if available, and culture, or obtaining other specimens depending on the suspected site of extrapulmonary TB. If suspicion of TB is low, patients with negative sputum smears (or other biopsy or tissue samples) can begin LTBI treatment. If suspicion of active disease is high, treatment for active disease should be started while the culture results are pending (see chapter *Mycobacterium tuberculosis*). HIV-infected persons with significant exposure (close contact) to someone with infectious TB should receive a full course of TB prophylaxis regardless of TST or IGRA results. Health departments can assist clinicians in assessing the degree of exposure for an HIV-infected patient and in determining whether there is a need for a full course of treatment.

An HIV-infected person with fibrosis on a chest X-ray that is consistent with previous TB and with no history of TB treatment (or a history of inadequate treatment) should be evaluated for active TB regardless of TST or IGRA results. If found not to have active TB, the patient should be treated for LTBI. If the patient is strongly suspected to have active TB, standard treatment for active TB should be given while culture analysis is under way. If

cultures are negative, patients may be switched to LTBI treatment. Highly suspect but culture-negative patients may be given a 4-month total course of treatment for active TB. (See chapter *Mycobacterium tuberculosis*.)

P: Plan

As with any treatment of TB, adherence to the regimen is required for success. Treatment regimens for LTBI in the United States and other low-prevalence TB countries are presented in Table 1. Treatment should be offered to all HIV-infected persons with evidence of LTBI or close contact with an active TB case, regardless of age.

In some highly TB-endemic settings outside the United States, LTBI treatment given to TST-negative patients or patients of unknown TB status has led to reduction of active TB, although TST- or IGRA-positive patients appear to benefit most from LTBI treatment.

INH is preferred for treatment of LTBI because of extensive data supporting its efficacy and

because it has no significant interactions with ARV medications. Treatment with INH for 9 months is recommended. Rifampin-based LTBI treatment is an alternative and is given for 4 months. However, rifampin has substantial drug interactions with a number of ARVs (see “Potential ARV Interactions,” below). Rifabutin is an alternative for patients on PI-based regimens, although there are limited data for use in LTBI. Rifapentine, in combination with INH, has been approved as part of a 12-week treatment course for LTBI; however, it is not recommended for ART-treated patients outside clinical trials because of possible interactions with ARV medications. Rifampin + pyrazinamide is not recommended for LTBI treatment owing to unacceptable rates of hepatotoxicity.

For treatment of LTBI in persons exposed to drug-resistant TB, there are limited data on efficacy of various regimens in preventing progression to disease; consult with experts.

ART is indicated for all persons with LTBI.

Table 1. Treatment Regimens for Latent Tuberculosis

Drug	Dosage (taken orally)	Frequency	Duration (minimum number of doses for completion)
Preferred therapies			
INH*	Adults: 300 mg Children: 5 mg/kg	Daily	9 months or 270 doses within 12 months
INH*	Adults: 900 mg Children: 10-20 mg/kg	Twice weekly (DOT)**	9 months or 76 supervised doses within 12 months
Alternative therapies			
Rifampin [#]	Adults: 600 mg Children: 10-20 mg/kg	Daily	4 months or 120 doses in 6 months; if used in children, 6 months is recommended
Rifabutin [#]	Dose according to ARV medications	Daily	4 months or 120 doses in 6 months
Exposure to Multidrug-Resistant TB			
Treatment options depend on sensitivity of the organism.	Seek expert advice from public health authorities and those experienced in treatment of multidrug-resistant TB. Treatment may be postponed until sensitivity test results are available or may be based on resistance pattern of index case, if known.		

* 25 mg of pyridoxine (vitamin B6) should be given with each INH dose to reduce the risk of INH-induced peripheral neuropathy.

** DOT = directly observed treatment

[#] Rifampin and rifabutin have significant interactions with a number of ARV and other medications. See text and “Potential ARV Interactions,” below, about contraindicated combinations and dosage adjustments.

Length of LTBI Treatment

LTBI treatment is recommended for 9 months with INH (4 months with rifampin/rifabutin) in low-prevalence TB settings such as the United States. Accumulating data suggest that 36 months or indefinite LTBI treatment may be of benefit in some highly TB-endemic settings where TB reinfection may be common.

Monitoring on therapy

INH may cause liver toxicity and it should be used cautiously in patients with active alcohol consumption, liver disease, or chronic hepatitis B or C infection. INH is contraindicated for use in patients with acute hepatitis or decompensated liver disease. Baseline liver function tests are recommended for all HIV-infected persons prior to starting LTBI treatment. Monthly assessment to screen for signs and symptoms of hepatotoxicity (e.g., abdominal pain, jaundice, nausea, vomiting, and fatigue) and neuropathy is recommended. Patients with abnormal hepatic enzymes at baseline or liver disease such as viral hepatitis should receive regular checks of transaminases. If patients develop abnormalities in liver transaminases while taking INH (ALT or AST >3 times the upper limit of normal [ULN] with symptoms, or >5 times above the ULN in the absence of symptoms), the INH should be withheld. Obtain expert consultation before treating patients with abnormal liver function or advanced liver disease. All patients should receive pyridoxine (vitamin B6) 25 mg QD during INH treatment to reduce the risk of peripheral neuropathy.

Rifampin and rifabutin may cause liver and bone marrow toxicity. Before use, obtain baseline liver and renal function tests and a complete blood count. Given the potential for interaction with ARV and other drugs, a careful review of current medications should be done to assess for possible drug interactions. Follow-up is the same as for INH use.

Potential ARV Interactions

Rifampin and rifabutin have important interactions with certain antiretroviral drugs, and dosage adjustments or treatment modifications may be required. Rifampin reduces the blood levels of nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors, and the CCR5 antagonist maraviroc; it also may decrease elvitegravir/cobicistat levels. Rifampin can be used by persons taking efavirenz or the integrase inhibitors raltegravir or dolutegravir, though dosage adjustments may be required. Coadministration of rifampin and maraviroc is not recommended, but may be possible with appropriate dosage adjustment of maraviroc; consult with an expert. Rifampin should not be used with nevirapine, etravirine, or rilpivirine, or with PIs or elvitegravir/cobicistat. (In some cases, the adverse pharmacokinetic effect of rifampin on PIs may be overcome with large doses of ritonavir, but consultation with a specialist should be obtained before this approach is undertaken; rifampin should not be used in combination with ritonavir-boosted saquinavir because of high rates of hepatic toxicity.)

No data are available on the use of rifabutin for treatment of LTBI. Nevertheless, rifabutin may be considered in place of rifampin for patients taking antiretroviral combinations that include certain NNRTIs (other than efavirenz) or PIs (other than ritonavir alone), and the integrase inhibitor raltegravir. In these cases, the dosages of both rifabutin and the antiretroviral agent usually require adjustment.

See Table 3 in chapter *Mycobacterium tuberculosis* for details on dosage adjustments.

Other Drug Interactions

Rifampin decreases the blood concentrations of estrogens, anticonvulsants, hypoglycemic agents, and many other drugs. Review all medications a patient is taking before initiating rifampin and make adjustments as necessary. (See Table 12, “Clinically Significant Drug-Drug Interactions Involving the Rifamycins,” at www.cdc.gov/mmwr/preview/mmwrhtml/rr5211a1.htm#tab12.)

Pregnancy

HIV-infected pregnant women with positive LTBI test results and no evidence of active TB should be evaluated for prophylaxis. The potential risks of INH should be evaluated in light of the potential risks of active TB. Consult with an expert. All pregnant women should receive ART for prevention of perinatal HIV transmission; ART also serves to reduce risk of LTBI progression.

Patient Education

- Patients should know that TB bacteria in their bodies cannot be passed to others while the TB is latent. However, because they have HIV infection, the TB bacteria is more likely to make them sick at some point in the future.
- Treatment for LTBI will help kill the TB bacteria and reduce patients' chances of becoming sick with active TB.
- Patients must take all of their medicine, every day, to prevent the TB from spreading and making them sick.
- Advise patients to contact their health care provider immediately if they have adverse effects to the medication, such as rash or itching. Occasionally, INH can cause tingling or numbness in the hands or feet. The pyridoxine (vitamin B6) they are taking should help prevent that, but they should let their provider know if it occurs.

- Advise patients to avoid the consumption of alcohol while taking INH. The medicines for TB are processed by the liver and, when combined with alcohol, they easily can overload the liver. Acetaminophen (Tylenol) also is processed by the liver, so patients should keep their intake to a minimum. (Patients with hepatitis C, liver disease, or chronic alcohol consumption should be cautioned to strictly limit their use of acetaminophen.)
- Tell patients that blood tests may be done regularly to make sure the liver is working well, so it is important to keep follow-up appointments. They should take all their medications, vitamins, and supplements with them to the clinic so that their health care provider can review them and make sure there are no drug interactions.
- If patients experience nausea, vomiting, poor appetite, or abdominal pain; if they notice their urine darkening or becoming “cola” colored; or if they notice their eyes or skin yellowing, they should contact the clinic immediately. These problems may indicate that the liver is being overwhelmed, and it is important to find out before permanent damage is done.
- Rifampin and rifabutin will cause sweat, tears, urine, and plastic contact lenses to turn orange; this is not harmful.
- Rifampin and rifabutin can make birth control pills ineffective. Patients should use a backup method of contraception until treatment is complete. Condoms can help prevent HIV transmission and reduce the likelihood of pregnancy.

Smoking Cessation

Jeffery Kwong, MS, MPH, ANP

Background

According to the U.S. Centers for Disease Control and Prevention, smoking prevalence among the general adult population in the United States is approximately 20%. Among HIV-infected persons, the prevalence of cigarette smoking appears to be two to three times greater than in the general population, with estimates ranging from 50% to 70%.

The health effects of cigarette smoking are extensive and have been well documented. There are approximately 400,000 smoking-related deaths annually in the United States. HIV-infected smokers appear to be at higher risk of a variety of tobacco-related conditions than HIV-uninfected smokers. These include lung cancer, head and neck cancers, cervical and anal cancers, oral candidiasis, and oral hairy leukoplakia. HIV-infected smokers who smoke are more likely to develop the conditions listed above, as well as bacterial pneumonia, *Pneumocystis jiroveci* pneumonia, other pulmonary conditions, and cardiovascular disease. Additionally, HIV-infected smokers have been shown to have a decreased immunologic and virologic response to antiretroviral therapy.

Thus, for HIV-infected persons, even more so than for HIV-uninfected persons, clinicians should consider smoking cessation a health care priority. Although many care providers may feel that they can do little to affect the smoking behaviors of patients, evidence suggests that brief interventions by physicians are quite effective. Studies indicate that smoking cessation interventions as brief as 3 minutes in duration, when delivered by a provider, have a positive impact on abstinence rates of current smokers. Furthermore, studies have found that more than half of current HIV-infected smokers have expressed interest in, or have thought about, smoking cessation.

Cigarettes are highly addictive; the U.S. Surgeon General has equated the addictive potential of cigarettes to that of heroin and cocaine. This is in part because nicotine stimulates the release of several neurotransmitters in the brain, including dopamine. Over time, chronic exposure to nicotine causes physiologic changes in the brain that contribute to the addictive potential of cigarettes.

Cigarette smoking involves dependence on more than a single chemical compound, however. It is a multidimensional behavior that has both physiologic and psychological components. Therefore, smoking cessation efforts often require a combined approach to be successful.

HRSA HAB Performance Measures

Percentage of patients aged 18 years and older who were **screened for tobacco use** one or more times within 24 months AND who **received cessation counseling intervention** if identified as a tobacco user

(Adult and Adolescent measure)

Behavioral Model for Smoking Cessation

Several behavioral models present a psychological framework for understanding individuals who are attempting to change behaviors. The transtheoretical model of health

behavior change is one of the more frequently cited frameworks for understanding the stages of behavior change of smokers. According to this model, there are five phases of behavior change: precontemplation, contemplation, preparation, action, and maintenance. Using this framework, clinicians can devise

interventions that are most appropriate for the patient's current stage on the continuum.

- **Precontemplation:** The individual does not expect to make any change in behavior within the next 6 months. At this stage, the individual is resistant to hearing or learning about health behavior change.
- **Contemplation:** The individual plans to make a behavior change within the next 6 months. This stage is characterized by ambivalence about smoking.
- **Preparation:** The individual anticipates making a behavior change within the next month. Individuals in this phase have made plans for taking action and intend to make a change.
- **Action:** The individual has made a significant change; in the case of smoking cessation, this means that the individual

has quit completely.

- **Maintenance:** The individual attempts to prevent relapse.

Patients may move back and forth among these stages at various points during the process of smoking cessation.

Cessation interventions in the clinic

As suggested above, brief smoking cessation interventions delivered by clinicians can significantly increase abstinence rates of current smokers. The U.S. Surgeon General has developed guidelines for clinicians to use during clinic visits to help patients who are interested in smoking cessation. These include use of the Five A's model, which provides a brief and structured framework for addressing smoking cessation in clinical settings (see Table 1).

Table 1. The Five A's Model for Treating Tobacco Use and Dependence

Component	Action	Example
ASK every patient about tobacco use	Identify and document tobacco use at every visit .	Incorporate questions about tobacco use when obtaining vital signs or when reviewing a patient's history. • "Do you currently use tobacco?" • "Do you currently smoke cigarettes?"
ADVISE to quit	Using a clear, strong, and personalized message , urge every tobacco user to quit.	• "It is important for you to quit smoking now." • "Quitting is the most important thing you can do to protect your health." • "I can help you quit." Also link smoking with something specific to the patient, such as secondhand exposure to children or partners, his/her own lung, cardiovascular, or cancer risk, or the expense of cigarettes.
ASSESS readiness to make a quit attempt	Determine whether the tobacco user is willing and ready to make a quit attempt within 30 days.	• "Are you willing to give quitting cigarettes a try?"
ASSIST in the quit attempt	For the patient willing to quit, assist in developing a quit plan . Provide practical counseling, support, and supplementary materials.	• Have patient set a quit date and enlist the support of his/her family and friends. • Offer pharmacotherapy, as appropriate, including nicotine replacement. • Provide counseling that includes problem solving and skills building.

Component	Action	Example
ARRANGE for follow-up	Arrange for follow-up contacts beginning within the first week after the quit date.	• Contact patient via telephone or in person soon after the quit date. This can be done by the primary clinician or other trained staff members. • During the follow-up encounter, assess and identify any problems, review medication use and side effects, provide reminders about additional resources. • Congratulate patients on their successes. • Help those with relapses assess problems with and barriers to quitting, and offer additional or different assistance. • For patients who report a relapse, help them identify the circumstances that led the relapse and assist them with recommitting to smoking abstinence.

Adapted from Fiore MC, Jaén CR, Baker TB, et al. *Treating Tobacco Use and Dependence: 2008 Update. Clinical Practice Guideline*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service; May 2008. Available at www.ncbi.nlm.nih.gov/books/NBK63952. Accessed December 1, 2013.

For patients who are not ready to quit, techniques such motivational interviewing (MI) can be used in conjunction with the stages-of-change model to explore the smokers' beliefs, feelings, and barriers to successful cessation efforts. Components of MI include: a) expressing empathy; b) developing discrepancy; c) rolling with resistance; and d) supporting self-efficacy. Effective use of MI involves specialized training. Partnering with clinic staff or outside agencies that are familiar with MI techniques can help improve behavior change outcomes, such as smoking cessation. (For further information, see "References," below.)

Pharmacologic interventions

In addition to counseling, the use of pharmacologic interventions such as nicotine replacement therapy and other adjuvant therapies should be considered. These therapies were developed for the general population, but current clinical guidelines suggest that they should be efficacious for HIV-infected smokers.

Clinicians should be aware of potential medication adverse effects (see Table 2).

S: Subjective

- Ask all patients about their smoking status at every visit. This can be easily incorporated as part the initial intake when vital signs are obtained.
- Document smoking history, including the number of cigarettes smoked per day.
- If the patient is not ready to quit, use MI techniques to identify beliefs and barriers and to create ambivalence about smoking.
- For the smoker interested in quitting:
 - Help identify triggers to smoking, and develop a quit plan.
 - Assess for potential complications of or considerations related to pharmacologic smoking cessation treatments such as history of seizure disorders, sleep disturbances, mood disorders, and pregnancy.
- For patients who recently quit, congratulate them on their accomplishments and reinforce the benefits of continued cessation.
- For patients who recently relapsed, help them identify what led to the relapse and how to avoid relapses in the future. Assist them in getting back on track with a cessation program.

O: Objective

During the physical examination, assess for evidence of smoking-related illnesses and the comorbid conditions that may be affected by smoking. At a minimum, measure blood pressure and oxygen saturation and examine for oral lesions, abnormal breath sounds, and decreased peripheral perfusion.

A/P: Assessment and Plan

Determine the smoker's readiness to change (see behavioral model for smoking cessation, above). For those smokers in the preparation or action stage, assist with implementing a quit plan. For those who are in the relapse stage, reinforce self-efficacy and encourage them to recommit to cessation. For those in the maintenance stage, congratulate them and reinforce the benefits of smoking cessation.

For patients willing to quit, offer resources and information that will help them to be successful in their quit attempt. Evidence suggests that the combination of counseling and medication is more effective than either intervention alone. Therefore, every effort should be made to combine counseling sessions with pharmacotherapy for patients who are motivated and ready to quit smoking.

Components of effective counseling include problem solving, skills training, and social support. Problem solving and skills training should focus on how to deal with triggers or urges that may lead to relapse. Examples

include recognition of situations or events that may prompt a person to smoke (e.g., drinking alcohol, being around other cigarette smokers, situational stress) and means of reducing or coping with these situations. Social support interventions include providing reassurance that the patient has the ability to succeed with smoking cessation, communicating caring and concern, and encouraging the patient to talk about the quit process.

Offer medications, if there are no contraindications to pharmacologic interventions (see Table 2). All currently available over-the-counter and prescription medications have been shown to be effective. However, studies have shown that combination therapy may be more efficacious than monotherapy. The current tobacco cessation guidelines recommend the following combinations, all of which include nicotine preparations: long-term nicotine patch (>14 weeks) with ad lib use of nicotine gum or spray, nicotine patch with nicotine inhaler, and nicotine patch with sustained-release (SR) bupropion.

Both bupropion SR and varenicline may cause sleep disturbance, and varenicline may cause exacerbation of neuropsychiatric symptoms. For HIV-infected patients who take efavirenz as part of their antiretroviral therapy, concomitant use of either bupropion SR or varenicline may increase the possibility of these side effects. Additional research in this area is needed.

Table 2. Pharmacologic Options for Smoking Cessation

Drug Recommended	Dosing	Common Side Effects	Comments
Nicotine Formulations*			
Nicotine Patch (available OTC) <i>Dosage varies by brand:</i> Nicoderm or Habitrol: • 21 mg/24 hours • 14 mg/24 hours • 7 mg/24 hours Nicotrol: • 15 mg/24 hours • 10 mg/24 hours • 5 mg/24 hours	Dosing recommendations vary based on the number of cigarettes smoked. Individualize treatment. Sample treatment recommendation for smokers who smoke ≥ 10 cigarettes per day: • High-dose patch for 4-6 weeks, then • Medium-dose patch for 2 weeks, then • Low-dose patch for 2 weeks For smokers who smoke < 10 cigarettes per day: • Medium-dose patch for 6-8 weeks, then • Low-dose patch for 2 weeks	Local skin reaction, insomnia or vivid dreams	• Apply upon awakening. • Place patch on a relatively hairless location, rotating sites to avoid irritation. • If experiencing sleep disturbance, remove patch prior to bedtime or use the 16-hour patch.
Nicotine Lozenge (available OTC) • 2 mg and 4 mg	• For patients who smoke their first cigarette > 30 minutes after waking, start with 2 mg dose. For patients who smoke their first cigarette within the first 30 minutes after waking, start with 4 mg. • Most patients should use 1 lozenge Q1-2H during the first 6 weeks. • Allow lozenges to dissolve, do not chew or swallow. Most individuals use 9 lozenges per day; maximum is 20 per day. • Lozenges should be used for up to 12 weeks, decreasing dosing from 1 lozenge Q1-2H for the first 6 weeks, to 1 lozenge Q2-4H during weeks 7-9, and 1 lozenge Q4-8H during weeks 9-12.	Nausea, hiccups, heartburn, headache, cough	• Do not eat or drink anything except water for 15 minutes before using a lozenge.

Drug	Recommended Dosing	Common Side Effects	Comments
Nicotine Formulations*			
Nicotine Inhaler (prescription only) 4 mg per inhalation 10 mg cartridge	Recommended dosage: 6-16 cartridges per day. Duration of therapy: up to 6 months, taper dosage in last 3 months.	Local irritation in the mouth and throat, cough, rhinitis; may cause bronchospasm (<1%)	Use caution in persons with severe reactive airway disease.
Nicotine Nasal Spray (prescription only) 0.5 mg per spray	- Patient should use 1-2 sprays each nostril per hour (total 1-2 mg per hour), increasing as needed for symptom relief. - Minimum recommended treatment is 16 sprays (8 mg) per day, with a maximum limit of 80 sprays per day (10 sprays per hour). - Recommended duration of therapy: 3-6 months. - Do not sniff, swallow, or inhale through the nose while administering doses. Tilt head slightly back when dosing.	Nasal irritation, transient changes in sense of smell and taste; may cause bronchospasm (<1%)	- Use caution in persons with severe reactive airway disease. - Nicotine nasal spray has highest dependence potential of the nicotine replacement therapies.
Non-Nicotine Medications, First Line			
Bupropion SR 150 mg	Begin 1-2 weeks before quit date. - Start at 150 mg daily for 3 days, then increase to 150 mg BID for 7-12 weeks. - May consider longer-term therapy.	Insomnia, dry mouth	- May lower seizure threshold in certain patients. - Levels increased in patients on P450 3A4 inhibitors. - Use with caution in patients with history of seizures or eating disorders, and those who have used a monoamine oxidase (MAO) inhibitor in the past 14 days.

Drug	Recommended Dosing	Common Side Effects	Comments
Varenicline 0.5 mg and 1 mg	Begin 1 week before quit date. - Start with 0.5 mg daily for 3 days, increase to 0.5 mg BID for 4 days, then 1 mg BID for duration of therapy. - Typical duration: 12 weeks. - Varenicline is approved for maintenance therapy for up to 6 months.	Nausea; flatulence; headache; sleep disturbance; abnormal, vivid, or strange dreams; depression; agitation; suicidal ideation; and suicide FDA Black Box warning regarding neuropsychiatric adverse effects	- Use with caution in patients with history of psychiatric illness. Monitor closely for mood and behavior changes. - Dosage reduction recommended for patients who have creatinine clearance (CrCl) of <30 mL/min or are on dialysis. - To reduce nausea, should be taken with food. To reduce insomnia, second pill can be taken at dinner rather than at bedtime. - Dosage may be reduced for patients with adverse effects.
Non-Nicotine Medications, Second Line			
Clonidine 0.1 mg tablet 0.1 mg transdermal patch	0.1 mg tablet PO BID OR 0.1 mg transdermal patch per day. Can increase by 0.1 mg/day per week if needed. - Duration of treatment: 3-10 weeks. - Do not discontinue therapy abruptly.	Dry mouth, drowsiness, dizziness, sedation, and constipation Rebound hypertension if discontinued abruptly	- Monitor blood pressure when using this medication. If discontinuing, taper medication to avoid rebound hypertension. - If using patch, place on relatively hairless location between the neck and waist. - Avoid in elderly patients
Nortriptyline	- Begin 10-28 days before quit date. - Start at 25 mg QD and increase to target dosage of 75-100 mg QD if tolerated. - Treatment duration: approximately 12 weeks; some may consider extending treatment up to 6 months.	Sedation, dry mouth, blurred vision, urinary retention, lightheadedness, tremor, cardiac conduction abnormalities	- Use with caution in patients with cardiac conduction abnormalities disease. - Do not coadminister with MAO inhibitors. - Overdose may produce life-threatening cardiovascular toxicity, as well as seizures and coma. - Avoid in elderly patients

* Use with caution for patients with cardiovascular disease (particularly those within 2 weeks of myocardial infarction), those with serious arrhythmias, and those with unstable angina pectoris (however, note that, for many patients, continued smoking may be more dangerous than nicotine replacement).

The adverse effects of cigarette smoking during pregnancy are well established, and smoking generally is more harmful than the use of nicotine replacements. Smoking cessation aids may help motivated patients quit during pregnancy.

All patients who are actively quitting should have close follow-up, and they should be offered support. Research has shown that ongoing support during the quit phase results in higher abstinence rates.

Follow-up can include telephone calls or in-person evaluation.

For patients who recently quit or relapsed, continue to provide support and encouragement. Assist individuals who relapsed with the opportunity to continue with cessation plans.

Refer patients to smoking cessation groups, classes, and other resources.

Patient Education

- For patients who have decided on pharmacologic interventions and for whom there are no contraindications, provide education regarding medication side effects, anticipated withdrawal symptoms, and strategies for managing withdrawal.
- Review and reinforce strategies in the event of relapse.
- For those who are not ready to quit, inform them of the consequences of continued smoking and remind them about the available resources.

Nutrition

Background

Maintaining good nutritional status is important to support overall health and immune system function for people with HIV/AIDS. Many HIV-related conditions affect and are affected by the body's nutritional status. These include conditions related to HIV itself (e.g., opportunistic infections and other illnesses), comorbid conditions, and adverse effects of therapies.

Inadequate nutrition in people with HIV infection may result from many factors, including conditions such as nausea, vomiting, and anorexia (see chapter *Nausea and Vomiting*) that may prevent adequate intake of nutrients and medications; diarrheal infections (see chapter *Diarrhea*) that prevent absorption of nutrients and medications; poor oral health conditions that interfere with chewing or tasting food (see chapter *Oral Health*); systemic illnesses (including HIV itself) that create a catabolic state; and psychological conditions (such as depression) that impair patients' ability to nourish themselves. In addition, financial constraints may limit patients' access to nutritious food.

Evaluation and enhancement of patients' nutritional status may help correct or compensate for deficiencies (e.g., in the case of weight loss or nutrient deficits), may be a key treatment modality for certain conditions (e.g., dyslipidemia, hyperglycemia), and may help to maintain good health and immune function. This chapter focuses on the evaluation of patients with nutritional deficiencies, particularly weight loss, and on simple strategies for maintaining good nutrition in individuals with barriers to maintaining adequate weight.

It should be noted that obesity and overweight conditions are increasingly common in HIV-infected individuals; many of the principles described here also may be applied to the evaluation of overweight patients. Recommendations for weight reduction for HIV-infected patients are the same as for the general population and will not be discussed in detail; for overweight patients with lipohypertrophy, diabetes, dyslipidemia, or coronary artery disease, see the respective chapters on these conditions.

Ideally, HIV-infected individuals will receive the services of HIV-experienced nutrition specialists, who may contribute to the patient care team in the following ways:

- Conducting routine screening to identify and treat nutritional problems
- Preparing a tailored nutritional plan to optimize patients' nutritional status, immune status, and overall well-being
- Screening and developing interventions for growth problems in children
- Developing strategies to prevent loss of weight and lean body mass
- Adapting dietary recommendations to help reduce the risk of comorbid conditions such as diabetes and heart disease, or treating these complications
- Educating patients about how to modify their dietary habits to maximize the effectiveness of medical and pharmacologic treatments
- Tailoring nutritional recommendations to fit patients' lifestyles and financial resources
- Counseling patients to promote nutrition self-care using available resources

- Providing nutritional support to patients may help to do the following:
 - Address common problems associated with HIV disease and its treatment (e.g., weight loss, wasting, fatigue, loss of appetite, adverse changes in taste, dental problems, gastrointestinal complaints)
 - Treat chronic comorbid conditions (e.g., cardiovascular disease, hypertension, diabetes, cirrhosis)
 - Improve quality of life
 - Enhance immune responses, slow disease progression, and prolong life

S: Subjective

History

Identify nutrition risk factors at the start of care through interview, questionnaire, or both. Update the history at least annually.

The history should elicit signs and symptoms related to nutrition issues, indications regarding dietary habits, and symptoms that suggest nutritional deficiencies.

Nutrition-Related Questions		
Factor	Areas to Explore	
Signs, Symptoms, and Comorbid Conditions	• Poor or sporadic appetite • Early satiety • Weight gain or loss • Trouble chewing or swallowing • Dental problems including poor dental hygiene • Gastrointestinal complaints, including nausea, diarrhea, constipation, heartburn, gas	• Changes in body contours with fat gain in abdomen, back of neck, and breasts (lipodystrophy) or fat loss in extremities and face (lipoatrophy) • Depression, stress • Fatigue • Chronic pain • Other diseases affecting diet and nutrition • Medications, including over-the-counter and herbal products
Medication-Related Factors	• Medication side effects • Difficulty coordinating meals with medicines	• Use of nutritional supplements
Social and Behavioral Factors	• Frequent eating out • Smoking • Alcohol or substance abuse • Erratic meal patterns • Unbalanced diet (e.g., high intake of low-nutrient foods; deficiency in key nutrients)	• Resources to ensure secure, continued food access • Availability of food storage and preparation facilities • Housing (stable, homeless, marginally housed, or in transition) • Nutrition literacy

To develop a specific dietary history, ask about the following:

Dietary History	
Usual Dietary Intake	Factors That May Affect or Limit Intake
• Frequency of intake of foods providing key nutrients (e.g., dairy products, fortified or whole grains, fruits and vegetables, eggs, beans, fluids, meat) as well as those that perhaps should be limited (fast-food items, highly processed or salted products) • Usual meal patterns (number of times per day, snacks) and whether meals are prepared and eaten at home or eaten at restaurants or fast-food establishments • Specific information about nutritional supplements (e.g., vitamins, minerals, herbs, protein), including contents, amounts, formulation (pills, powders, drinks), cost, and overlap among products	• Amount of money available for food, or participation in food assistance programs (e.g., food stamps, food pantries) • Appetite, general well-being (e.g., fatigue, pain, depression) • Food allergies, intolerances • Problems with dentition, swallowing, heartburn, diarrhea, constipation • Coordination of foods and supplements with medications (HIV or other)

Elicit symptoms that may be related to nutritional deficiencies.

Symptoms with Possible Relationship to Nutritional Deficiencies	
• General symptoms (e.g., fatigue, decreased cognitive function, headache) • Behavioral changes (e.g., irritability, apathy, decreased responsiveness, anxiety, attention deficit) • Body habitus changes (e.g., loss or gain of fat)	• Gastrointestinal symptoms (e.g., diarrhea, constipation, bloating) • Changes in skin, nails, hair (e.g., dryness, breaking, thinning) • Muscle loss • Neurologic symptoms (e.g., weakness, sensory changes, gait abnormalities)

O: Objective

Physical Examination

Perform a careful physical examination, if possible with anthropometric and body composition testing as described below (Table 1). Compare current findings with past assessments and review at least every 6 months.

The physical examination should include the following:

- Vital signs, with orthostatic vital signs if dehydration is suspected
- Weight (compare with previous values) and body mass index (BMI)
- General appearance and gross nutritional status (e.g., obesity, cachexia, wasting)
- Body habitus: loss of subcutaneous fat in face, buttocks, arms and legs and/or

increased fat in abdomen, breasts, neck, and upper back (“buffalo hump”)

- Muscle mass
- Mouth: breakdown in oral mucosa, cheilosis, angular stomatitis, glossitis, papillar atrophy
- Abdomen: hepatomegaly (may be caused by fatty infiltration)
- Skin: dryness, peeling, breakdown, pallor, hypopigmentation or hyperpigmentation
- Nails: pale nail beds, fissures or ridges
- Neurologic system, including strength, sensation, coordination, gait, deep tendon reflexes

Anthropometric and body composition tests are usually performed by registered dietitians. They can provide important information about patients’ nutritional status.

Table 1. Anthropometric Measurements for Adults and Children

	Height	Weight	Assessment for Changes over Time
Adults	Measure at baseline (self-report is not accurate).	- Measure at least quarterly and consider intervention when small changes are observed. Do not wait until major amounts of weight have been lost or gained. - Record sequentially at the front of the patient's chart and monitor for trends.	Use healthy, premorbid weight to assess change, not the first clinic weight or the ideal weight. (Use the patient's weight at a time when the patient is healthy, feels well, and can easily maintain that weight.)*
Children	Measure at least quarterly using length board (0-2 years) or wall-mounted stadiometer (≥2 years).	- Measure at least quarterly and consider intervention when small changes are observed. Do not wait until the patient has dropped significantly on the growth chart. - Calculate age and plot the measurements on growth charts specific for age, sex, and country.#	Assessment of optimal growth is based on the observed pattern over time. General goals include a weight relatively "matched" for length or height (about the same percentile) and relative stability of percentile tracking over time.* #

* BMI (body mass index) is useful as an evaluative index. See chapter *Initial Physical Examination*, and the U.S. Centers for Disease Control and Prevention (CDC) online calculator at www.cdc.gov/healthyweight/assessing/bmi. Accessed December 1, 2013.

Growth charts for children in the United States are available online from the CDC at www.cdc.gov/growthcharts. A variety of growth charts are available for children from specific ethnic groups (e.g., Chinese, Vietnamese, Thai), children with selected conditions affecting growth (e.g., Down syndrome), or those who are born prematurely. Percentiles for both height and weight should be recorded sequentially.

Body Composition Testing

Body composition commonly is tested by bioelectrical impedance analysis (BIA) (Table 2) or skinfold thickness and circumference (Table 3).

Table 2. Bioelectrical Impedance Analysis

BIA testing is the standard of care for adults but has not been well validated for children:

- BIA is useful for assessing disease progression or health maintenance, documenting response to treatment, and justifying the cost of nutritional supplements and AIDS-wasting medications.
- The test is simple, noninvasive, and quick (<5 minutes). However, staff training and specialized software are required to interpret the results.
- Perform BIA at baseline, if possible. Update every 6-12 months or more frequently if the patient is ill, has a decline in immune status, or has a weight change of 5-10%.
- The BIA test reports the following:
 - Body cell mass (BCM):** the target component, reflecting cells in muscles, organs, and the circulation; losses may indicate AIDS wasting. BCM is recorded in pounds. Monitor for trends.
 - Fat:** an index of energy stores; recorded in pounds and percentage.
 - Phase angle:** a measure of cellular integrity, an independent indicator of morbidity and mortality in HIV-infected patients.

Table 3. Skinfold Thickness and Circumference Measures

Skinfold thickness and circumference measures can be used for adults and children in resource-limited settings, and for situations in which bioelectrical impedance analysis is not available. Circumference measures also can be used to monitor changes over time associated with lipodystrophy in adults. • Skinfold thickness is measured with calipers. • Circumference measures are taken at specific anatomical landmarks with nonstretchable tape. • Techniques and protocols for taking anthropometric measurements can be found at the CDC website (www.cdc.gov/nchs/data/nhanes/nhanes_03_04/BM.pdf).

Laboratory Testing

Perform basic laboratory (blood) tests, including the following:

- Hemoglobin and/or hematocrit
- Total protein, albumin
- Fasting blood glucose
- Fasting lipids (triglycerides, total cholesterol, low-density lipoprotein cholesterol [LDL], high-density lipoprotein cholesterol [HDL])
- CD4 cell count and HIV viral load, if no recent values are available
- Specific vitamin and nutrient tests as indicated by symptoms (e.g., iron studies in case of anemia, vitamin B12 in case of peripheral neuropathy)
- Others tests, such as testosterone and thyroid hormone levels as appropriate, to rule out other causes of symptoms

A: Assessment

Assess subjective information and objective findings to evaluate nutritional status.

Identify Nutrition Concerns

Several factors may influence nutrition, including the following:

- Barriers to good nutrition (e.g., lack of knowledge or motivation for self-care, poor appetite, lack of money for food, lack of facilities for food storage and preparation)
- Lifestyle factors (e.g., smoking, substance abuse, frequent eating out, erratic eating patterns, hectic schedule, high stress)

- Physical problems affecting food and nutrient intake (e.g., poor appetite, nausea, fatigue, pain, weakness, mouth or throat pain, acid reflux, missing or decayed teeth, poorly fitting dentures, poor eyesight, constipation)
- Nutrient losses (e.g., owing to diarrhea, vomiting)
- Potential confounding factors (e.g., use of multiple overlapping or questionable supplements, eating disorders)

Evaluate Dietary Intake

Assess the following diet-related issues:

- Expected excesses or deficiencies from dietary history or interview
- Rating of food security, including access to cooking and refrigeration
- Food intolerances, aversions, or allergies likely to affect adequacy of intake
- Special needs related to other conditions (e.g., documented cardiovascular disease, diabetes, hypertension)

Evaluate Weight, Body Composition, and Weight Distribution

Assess physical findings of malnutrition and confirm with nutrition history, laboratory tests, and anthropometric evidence. Normal and abnormal findings of anthropometric tests and recommendations for monitoring changes over time are presented in Table 4.

Table 4. Evaluating the Findings of Anthropometric Tests	
Monitoring Trends and Recommendations	
Adults - Chart trends over time relative to previous measurements and the following population norms: BMI (healthy range: 19-25) BIA: BCM (percentage of weight): women 30-35%; men 40-45% Fat (percentage of weight): women 20-30%; men 15-25% Phase angle: women >5; men >6 Skinfold thicknesses and circumferences: Chart changes in absolute measures and percentiles Changes in body contours: Evaluate lipodystrophy (excess accumulation of fat in abdomen, breasts, dorsocervical area) and lipoatrophy (loss of subcutaneous fat in face, extremities, buttocks)	Children Plot measurements on growth charts and track percentiles over time (the consistency of percentiles rather than the absolute percentile is important) Skinfold thicknesses and circumferences: Chart changes in absolute measures and percentiles

Abbreviations: BCM = body cell mass; BIA = bioelectrical impedance analysis; BMI = body mass index

Evaluate Laboratory Findings

- Evidence of malnutrition (e.g., low iron or protein stores)
- Evidence of disease or risk of disease for which dietary treatment is indicated (e.g., high fasting glucose, hypertension, hyperlipidemia)

Develop a Problem List

The following suggests a useful format for a nutrition-related problem list.

Nutrition-Related Problem List

Problem Number	Description of Problem (circle/describe)
	Nutrition barriers: insufficient knowledge, poor appetite, food insecurity, no food preparation or storage facilities, homelessness
	Lifestyle: substance abuse, smoking, erratic eating, frequent fast-food intake, high stress
	Weight or body composition: undesirable weight gain or loss (adult), changes in growth trajectory (children), loss of lean body mass (wasting), gain of excess fat (obesity), lipoatrophy or lipodystrophy
	Physical problems: fatigue, pain, early satiety, poor dentition, clinical signs of malnutrition
	Laboratory findings: low hematocrit or hemoglobin, low protein or albumin, low or high fasting glucose, high total cholesterol, high LDL, high triglycerides, low HDL, low testosterone
	Gastrointestinal: diarrhea, vomiting, reflux, constipation
	Poor diet: poor food choices, bingeing, skipping meals, high sugar intake, high alcohol consumption, high intake of refined foods, low fruit and vegetable intake, insufficient protein, insufficient calcium, food allergies or intolerances that limit intake
	Comorbid conditions: diabetes, hypertension, cardiovascular disease, cancer, gastroesophageal reflux disease (GERD)
	Medications: drug-drug or drug-nutrient interactions or difficulty coordinating medicines with meals
	Supplements: insufficient or excessive intakes, cost of supplements unaffordable, supplements with potential or unknown risks

P: Plan

Develop a nutritional plan and provide practical nutrition education for common problems (see “Resources,” below).

Evaluate and treat concurrent medical problems (e.g., diarrhea, nausea, infections, malignancies, depression, pain). For severe or persistent nutritional problems, or for

specific needs, refer to a nutrition specialist for evaluation and treatment.

Common nutrition-related problems are presented in Table 5, along with simple management suggestions that may help resolve them and help patients maintain adequate nutrition.

Table 5. Practical Interventions for Common Nutrition-Related Problems

Problem	Suggestions
Weight Loss (decrease in both body cell mass and fat)	• Early identification and ongoing monitoring are key. • Identify and treat underlying risk factors. • Try to add calories without adding “bulk”: • Fat (9 calories/gram): butter, margarine, avocado, cream, mayonnaise, salad dressing • Carbohydrate (4 calories/gram): jam, jelly, sugar, icing, gum drops • Protein (4 calories/gram): protein powders, cheese, nut butters, trail mix, powdered breakfast drinks, nonfat dry milk • Eat more frequently. • Maximize good days. • Use canned supplements (e.g., Ensure, Boost). • For wasting or substantial weight loss, consider referral for therapies such as appetite stimulants or human growth hormone.
Diarrhea	• Increase soluble fiber; decrease insoluble fiber. • Replenish beneficial bacteria (e.g., with lactobacilli or other probiotic preparations). • Avoid intestinal irritants and stimulants. • Decrease dietary fat. • Decrease or eliminate lactose. • Increase fluids and provide electrolytes (sodium, potassium). • Treat with pancreatic enzymes.
Early Fullness	• Take small, frequent meals. • Concentrate on solid foods, with liquids between meals. • Eat lower-fat, lower-fiber foods. • Wear loose-fitting clothing. • Sit up while eating. • Eat, walk, and eat again.
Nausea	• Take small, frequent meals. • Try dry snack foods. • Avoid fried foods, very sweet foods, spicy foods, and foods with strong odors. • Try cool, clear beverages, popsicles. • Try ginger-containing foods and drinks. • Keep liquids to a minimum at meals.

Problem	Suggestions
Changes in Taste	• Eat a variety of foods, not only favorite foods. • Try protein sources other than red meat. • Marinate foods, use sauces. • Use more and stronger seasonings. • Try tart foods. • Use sugar or salt to tone down the flavor of foods. • Try a mouth rinse of 1 teaspoon of baking soda in 1 cup of warm water before eating.
Loss of Appetite	• Rely on favorite foods. • Ask family members and friends to prepare meals. • Eat small, frequent meals. • Keep snacks handy for nibbling. • Eat before bedtime. • Eat in a pleasant place, with other people. • Make the most of good days. • Try light exercise to stimulate appetite. • Add extra calories without adding bulk. • Consider appetite stimulants (e.g., megestrol, dronabinol).
Difficulty Chewing or Swallowing or Sore Mouth and Throat	• Choose soft, nutritious foods. • Blend or puree foods (e.g., soup or stew, smoothies). • Add cream sauces, butter, or gravy for lubrication. • Sip liquids with foods. • Use a straw or drink foods from a cup. • Choose bland, low-acid foods. • If hot foods cause pain, serve foods cold or at room temperature. • Avoid alcohol and tobacco. • Soothing lozenges or sprays may help.
Food Insecurity	• Refer to social services for assistance with accessing resources such as food stamps, community meals, or a food pantry program. • Refer to a dietitian for assistance with low-cost food ideas. • Use materials provided by CheapCooking.com (www.cheapcooking.com/index.htm).
Unbalanced Diet and Other Conditions Requiring Dietary Modification	• Refer to a dietitian for counseling and education.

Nutrition Specialists

Whenever possible, nutritional services should be provided by a registered dietitian (RD) who is a qualified HIV care provider. In the United States, holding this status requires a nutrition degree from an accredited college, graduation from an approved internship or master's degree program, and maintenance with 75 continuing-education units every 5 years, including specific and ongoing HIV training. An RD with HIV/AIDS expertise in the United States can be located by going to www.eatright.org, clicking on "Find a Registered Dietitian," entering the patient's zip code or city, and selecting "HIV/AIDS" under areas of specialty. Membership in the Infectious Diseases Nutrition Dietetic Practice Group (idndpg.org) also may indicate HIV experience.

Resources

The following online resources provide information, guidelines, and tools for providers and patients in managing issues related to nutrition and HIV:

- **2000 CDC Growth Charts: United States**
Center for Disease Control and Prevention, National Health and Nutrition Examination Survey. Available at www.cdc.gov/growthcharts.
- **Center for Disease Control and Prevention National Center for Health Statistics**
Available at www.cdc.gov/nchs/products/series.htm.
- **CheapCooking.com**
Website with recipes using low-cost ingredients and tips for frugal meal planning. Available at www.cheapcooking.com.

- **Infectious Diseases Nutrition Dietetic Practice Group**

Affiliate of the American Dietetic Association. Website includes screening tool (Nutrition Screen and Referral Criteria for Adults with HIV/AIDS). Formerly HIV/AIDS Dietetic Nutrition Practice Group. Available at idndpg.org.

- **ChooseMyPlate.gov**

A U.S. Department of Agriculture website with dietary guidelines, tips, resources, and consumer-oriented information. Available at www.choosemyplate.gov.

- **Health Care and HIV: Nutritional Guide for Providers and Clients**

Manual from HRSA. Available at aidsetc.org/aidsetc?page=etres-display&resource=etres-193

Antiretroviral Therapy

Susa Coffey, MD

Background

Potent combination antiretroviral therapy (ART), typically consisting of three or more antiretroviral (ARV) drugs, has greatly improved the health and survival rates of HIV-infected patients in areas of the world with access to ARVs. More than 20 individual ARVs in six classes are available in the United States, in addition to several fixed-dose combination preparations. These can be combined to construct a number of effective regimens for initial and subsequent therapy. Although ART has its limitations (see below), it saves lives and improves immune system function, reduces the risk of many HIV-related and “non-AIDS” complications, and reduces the risk of HIV transmission. Increasingly, several lines of evidence point to the benefit of ART even for patients with high CD4 counts.

Mortality and morbidity benefits of ART are particularly obvious in patients with relatively advanced immune suppression or with symptoms related to HIV infection. For asymptomatic patients with higher CD4 counts (particularly >500 cells/μL), the question of when to initiate ART remains an area of research and debate. It is clear there is a spectrum of risk for adverse outcomes that increases as the CD4 count declines. In persons with CD4 counts of <200 cells/μL, effective ART dramatically decreases morbidity and mortality. For persons with CD4 counts of 200-350 cells/μL, data from randomized controlled studies as well as cohort studies also demonstrate a reduction in both AIDS and non-AIDS events among those who start ART. For patients with higher pretreatment CD4 levels, randomized and cohort studies also have found decreased rates of complications and death in those who initiated ART with CD4 counts of >350 cells/μL rather than <350 cells/μL, and some (though not all) observational evidence suggests a mortality benefit of ART among persons with CD4 counts of >500 cells/μL. For patients with CD4 counts of >500 cells/μL, the limited data that are currently available (from cohort studies) are inconsistent on the question of whether initiation of ART results in better outcomes. A randomized clinical trial of earlier (>500 cells/μL) versus deferred (<350 cells/μL) treatment is under way, and the results of that study along with those from the cohort studies may help define an optimal threshold at which to initiate ART.

Meanwhile, in recent years, a growing body of evidence has demonstrated ongoing and adverse effects of untreated HIV on many organ systems and aspects of functioning, even in persons with high or relatively high CD4 counts (>350-500 cells/μL). These include the following:

- Cardiovascular disease
- Kidney disease, specifically HIV-associated nephropathy (HIVAN)
- Liver disease, particularly among patients with chronic hepatitis B virus (HBV) or hepatitis C virus (HCV)
- Neurocognitive deficits, including dementia
- Cancers, both AIDS-malignancies and non-AIDS malignancies

HRSA HAB Performance Measures

Percentage of clients, regardless of age, with a diagnosis of HIV who were **prescribed antiretroviral therapy** for the treatment of HIV infection during the measurement year

(Core measure)

Percentage of patients, regardless of age, with a diagnosis of HIV with an **HIV viral load of <200 copies/mL** at last HIV viral load test during the measurement year

(Core measure)

Many of these effects appear to be mediated through persistent immune system activation and ongoing inflammation in various organ systems. ART with virologic suppression appears to reduce immune activation and protect against many of these morbidities, but it may not restore immune system function to normal and may not fully reverse disease processes. The beneficial effects of ART may be attenuated for patients who start ART with lower CD4 cell counts. Additionally, the risk of certain ARV-related adverse events may be greater for those who start ART at lower CD4 levels.

Although ART can confer substantial health benefits, it has significant limitations. ART does not cure HIV infection and it requires that multiple medications be taken for life (i.e., potentially many decades). It may cause a variety of adverse effects (some severe), is expensive, requires close adherence to be effective and to prevent the emergence of resistance, and it sometimes fails (because of the patient's imperfect adherence or other factors). The failure of an ARV regimen when accompanied by drug resistance may mean that subsequent regimens are less likely to succeed, despite the availability of second-line ARV combinations.

In past years, many of the available ARVs presented challenges in the realms of adverse effects, pill quantity, dosing frequency, and durability. Given these limitations of ART, much attention was devoted to estimating the point at which the potential benefits of ART outweighed the potential risks of ART. Today, the newer ARV regimens, specifically those currently recommended by the U.S. Department of Health and Human Services (HHS) for initial therapy, are for most patients, simple, tolerable, and effective. As a result of both the availability of ARV regimens that are less toxic and easier to administer, and the increasing appreciation of the adverse impacts of untreated HIV, the balance between the potential benefit and the potential risk of ART has shifted strongly toward treatment for all willing individuals regardless of CD4 count, unless there are compelling reasons not to treat (see “When to Initiate Therapy: HHS ARV Guidelines,” below; also see the *HHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents* for a full discussion of these issues).

Recent data also demonstrate that ART very substantially reduces the risk of transmission of HIV between serodiscordant heterosexual partners. The prevention effect of ART in men who have sex with men (MSM) and other risk groups has not yet been established in randomized controlled trials, but other lines of evidence suggest that ART strongly protects against HIV transmission in all risk groups. Thus, an additional benefit of earlier treatment with ART is a reduction in the risk of HIV transmission.

Of course, in deciding when to start ART for the individual patient, practitioners must weigh the expected benefits of ART for that person (e.g., improvements in health, reduction in HIV transmission) against the possible risks of ART (e.g., toxicity, drug resistance, adverse drug interactions). Patients must be willing to start and to continue on treatment, with an understanding that high levels of adherence are needed for treatment success.

Although implementing and monitoring ART is complex, a number of guidelines from expert panels are available to help clinicians select effective regimens for particular patients. HHS keeps a repository of frequently updated recommendations on the use of ARV medications for adults and adolescents, pregnant women, and children. All clinicians who treat HIV-infected patients should be familiar with the most current versions of these treatment guidelines. They are available on the Internet at the AIDSinfo website (www.aidsinfo.nih.gov/guidelines). The HHS *Guidelines* are referenced frequently in this chapter.

HHS Guidelines: When to Start Therapy

The following recommendations have been adapted from the HHS *Guidelines*.

HHS guidelines recommend ART for all HIV-infected individuals, both for their own health and to prevent transmission:

“ART is recommended for all HIV-infected individuals to reduce the risk of disease progression. The strength and evidence for this recommendation vary by pretreatment CD4 cell count:”

• CD4 count <350 cells/μL:	Strongly recommended
• CD4 count 350-500 cells/μL	Strongly recommended
• CD4 count >500 cells/μL	Moderately recommended

“ART also is recommended for HIV-infected individuals for the prevention of transmission of HIV. The strength and evidence for this recommendation vary by transmission risks:”

• Perinatal transmission:	Strongly recommended
• Heterosexual transmission:	Strongly recommended
• Other transmission risk groups:	Strongly recommended

Note that these recommendations assume that resources are available for universal ART provision. In settings with limited resources, persons with lower CD4 counts or coexisting conditions (as below) may be prioritized.

ART also is strongly recommended for persons with certain conditions, regardless of CD4 count. These conditions include the following:

- Pregnancy (see chapters *Reducing Perinatal HIV Transmission* and *Care of HIV-Infected Pregnant Women*)

- History of AIDS-defining illness (including HIV-associated dementia)
- HIVAN (see chapter *Renal Disease*)
- HBV coinfection (see chapter *Hepatitis B Infection*)
- Acute HIV infection (see chapter *Early HIV Infection*)

In some situations, ART may be needed relatively urgently. These include the following:

- Pregnancy
- Acute/recent HIV infection
- AIDS-defining conditions
- Acute opportunistic infections
- HIVAN
- HBV coinfection
- HCV coinfection
- Lower CD4 counts (e.g., <200 cells/μL)
- Rapidly declining CD4 counts (e.g., >100 cells/μL/year)
- Higher viral loads (e.g., >100,000 copies/mL)

S: Subjective

Obtain the patient’s history and review of systems, including the following (see chapter *Initial History*):

- CD4 cell count history, including nadir
- HIV RNA (viral load) history, including pretreatment values if the patient is currently taking ARVs
- History of HIV-related conditions
- Previous and current ARV regimens, including start and stop dates, regimen efficacy, toxicity, resistance
- Current medications, including herbal preparations, supplements, and over-the-counter medications
- Medication allergies, intolerances, or prominent adverse effects

- Comorbid conditions (e.g., HBV, HCV, depression)
- Current and previous substance use, including alcohol and recreational drugs
- Self-assessment of adherence to previous regimens
- Desire to start or continue an ARV regimen
- Commitment to adherence (see chapter *Adherence*)
- Occupation and daily schedule
- Willingness and indicators of ability to adhere to various types of regimens (e.g., QD, BID, with or without food) given current life situation
- For women of childbearing potential: last menstrual period, current method of birth control (if any), current pregnancy status, thoughts on whether or when to have children

O: Objective

Perform the following objective tests:

- Complete physical examination (see chapter *Initial Physical Examination*).
- Current CD4 count and HIV viral load: preferably two or more separate results approximately 1 month apart.
- Drug resistance test, as appropriate; to look for transmitted ARV resistance mutations, a genotype should be performed for all patients before initiating ART; this should be done as early in the course of infection as possible, because mutations may revert to wild-type. Review the results of previous resistance testing or obtain a baseline resistance test, if this was not done earlier; if a test was done in the past, consider retesting before ART is begun (see chapter *Resistance Testing*). Patients on ART whose viral loads are not suppressed also should undergo resistance testing.
- Complete blood count (CBC) and

platelet count, liver function tests (LFTs), renal function tests, fasting lipid panel, fasting glucose, rapid plasma reagin (RPR), tuberculin skin test, hepatitis serologies, *Toxoplasma* IgG, urinalysis, (see chapter *Initial and Interim Laboratory and Other Tests*).

A: Assessment

Make the following basic decisions:

- This is or is not an appropriate time to start ART (e.g., do potential benefits of starting at this time outweigh the risks at this time?). See the HHS *Guidelines* noted above, which thoroughly address the issue, and note that many experts are increasingly concerned about the potential harm of untreated HIV infection, even in individuals with high CD4 cell counts. See chapters *Risk of HIV Progression/Indications for ART* and *CD4 Monitoring and Viral Load Testing*.
- The patient is or is not willing to start ARVs at this time (the choice to accept or decline therapy ultimately lies with the patient). If not, work with the patient on readiness issues, with more urgency if the CD4 count is low or the patient has symptoms, comorbidities, or coexisting conditions that suggest treatment is needed.
- The patient is or is not likely to adhere to an ARV regimen (an adherence counselor, with or without a mental health clinician, may be able to assist with this assessment and should be called upon if available). No patient should be automatically excluded from consideration for ART; the likelihood of adherence must be discussed and determined individually (see chapter *Adherence*).

P: Plan

After educating the patient about the purpose and logistics of the proposed regimen and assessing the patient's potential for adherence, ART can be initiated, changed, or postponed accordingly.

The primary goals of therapy are to reduce HIV-related morbidity and mortality and to prevent HIV transmission; this includes improving the quality of life, maximally and durably suppressing HIV virus, and improving immune function and reducing HIV-associated inflammation.

Considerations Before Initiating ART

No “average patient” exists. Some patients will do better during treatment and some will do worse than clinical studies would predict. Health care providers must work with each patient to develop a treatment strategy that is both clinically sound and appropriate for that individual’s needs, priorities, and circumstances of daily life. Despite the fact that the regimens currently recommended by the HHS *Guidelines* are more compact and have fewer adverse effects than earlier regimens, not all patients will be able to take or tolerate all drugs, and the patient’s understanding, readiness to commit to the regimen, and history of adherence to previous regimens must be considered when choosing ARV combinations. Major considerations are as follows:

- Degree of immunodeficiency and risk of disease progression as reflected by the CD4 count and HIV RNA level. ART is more urgent for patients with lower or rapidly declining CD4 counts and also is less likely to be successful in those with low CD4 counts or very high HIV RNA levels (see “HHS Guidelines, When to Start Therapy.” above, and chapters *Risk of HIV Progression/Indications for ART* and *CD4 Monitoring and Viral Load Testing*)
- Comorbidities
- Potential benefits and risks of ARV drugs
- Resistance, if any, to ARV medications (obtain resistance testing prior to ARV initiation for ARV-naïve patients)

Of course, the patient’s willingness to begin ART is critical, as mentioned above. Patients have the right to decline or postpone ART. This

decision should not affect any other aspect of care, and ART should be offered again at each visit to patients for whom treatment is indicated. If mental health issues, addiction, or the patient’s social situation are barriers to adherence, initiate appropriate referrals and reassess adherence barriers at regular intervals.

Preparing the Patient for ART

Before starting ART, it is important to have a detailed discussion with patients about their readiness to commit to a medication regimen, the expected benefits and possible adverse effects, and required monitoring and follow-up visits. Patients must understand that the first treatment regimen offers the best opportunity for effective viral suppression and immune reconstitution, which are primary goals of ART.

Supporting Adherence

Numerous strategies have been tested for their effectiveness in supporting patients’ adherence to the ART regimen. Successful approaches include extensive patient education, telephone contact with office staff members who can answer questions about adverse effects or other difficulties, family meetings, and peer support. Trust and accessibility appear to be important predictors of adherence, and some practitioners see the patient for two or three appointments before starting ART.

Compact regimens consisting of fewer pills and once-daily dosing often encourage adherence. Advise patients about potential adverse effects and at the same time let them know that many adverse effects may be treated or that substitutions often can be made for problematic ARVs. The choice to accept or decline ART ultimately lies with the patient (see chapter *Adherence*).

Anticipating Difficulties

Choosing an initial regimen that fits the patient’s lifestyle and that is likely to be tolerable and easy to take will improve the likelihood of long-term success with that regimen. If patients develop toxicities to one

or more components of an initial regimen, substitutions typically can be made without limiting the success of the regimen. Close monitoring and “check-in” appointments allow these adjustments to be made under clinical supervision. Close monitoring also can help to identify medication toxicities that may limit treatment and to detect early signs of inadequate medication adherence; early intervention to treat adverse effects and to support adherence may increase the likelihood of treatment success.

Considerations in Regimen Selection

Regimens should be selected with consideration of both patient factors and medication factors. The patient’s schedule, adherence history, and self-defined goals of ART should be considered in selecting a regimen to which the patient will adhere closely. The patient’s comorbid conditions and potentially interacting medications should be evaluated for possible contraindications or synergism with ARVs. The ARV history and all resistance profiles should be reviewed carefully so that a regimen that will be likely to achieve durable viral suppression can be chosen. Other factors should be evaluated with regard to specific ARV medications. For example, the HLA-B*5701 status and viral tropism should be determined if abacavir or maraviroc, respectively, are being considered: the HIV RNA level and creatinine clearance (CrCl) should be reviewed if rilpivirine or elvitegravir/cobicistat is being considered, and creatinine and CrCl should be evaluated if tenofovir is being considered. The patient’s HBV status will influence selection of NRTIs (tenofovir + emtricitabine or lamivudine should be included in the ART regimen, for co-treatment of HIV and HBV, unless contraindicated). In women who are pregnant or likely to become pregnant, FDA pregnancy categories and teratogenicity potential for specific ARVs should be taken into account. Drug interactions among ARVs or between ARVs and other medications should be evaluated, as dosage adjustments may be required or certain combinations may be

contraindicated (see relevant tables in the HHS *Guidelines*).

The advantages and disadvantages of various drug classes and individual drugs recommended for use in initial therapy are reviewed in Table 6 of the HHS *Guidelines*.

Use of Multiple Classes of Drugs

For initial therapy in patients with wild-type HIV virus, the HHS *Guidelines* recommend the use of two nucleoside reverse transcriptase inhibitors (NRTIs) in combination with a nonnucleoside reverse transcriptase inhibitor (NNRTI), a ritonavir-boosted protease inhibitor (PI), or an integrase inhibitor (INSTI). Alternative types of combinations generally do not reduce virus levels as effectively as these recommended types. The question of whether to use an NNRTI, a PI, or an INSTI in initial therapy is a matter of debate. Some clinicians advocate using an NNRTI or INSTI initially to preserve use of the PI class for later and to avoid PI-related toxicities. Others are more concerned about the potential toxicities of NNRTIs or the low genetic barrier to resistance presented by NNRTIs and some INSTIs, and instead recommend starting with a PI-containing regimen. Each of the initial regimens proposed by the HHS *Guidelines* is highly effective if taken as directed, and each has specific advantages and disadvantages (see Table 6 of the HHS *Guidelines*). In the end, the regimen should be selected with the individual patient in mind because the only effective combination for that patient is the one that he or she is willing and able to take on a consistent basis. See the information on drug resistance and toxicities below as well as the full text of the HHS *Guidelines* for more complete discussions.

Salvage therapy for patients with ARV-resistant HIV often comprises agents from three or more ARV classes; consult with an expert.

Boosted Protease Inhibitors

Ritonavir is used at low doses in combination with most other PIs to enhance or “boost” the serum level and prolong the half-life of the PI. This strategy generally decreases the dosing

frequency and the number of pills required, and it improves the activity of some PIs. Several currently used PIs require boosting with ritonavir, and some require ritonavir boosting when used with certain other medications, in order to overcome drug-drug interactions (e.g., atazanavir must be boosted with ritonavir if tenofovir also is a component of the ARV regimen); see “Drug Interactions,” below, and appropriate tables in the HHS *Guidelines*.

Preferred Starting Regimens

More than 20 ARVs in six drug classes have been approved for use in the United States by the U.S. Food and Drug Administration (FDA) (see relevant tables in the HHS *Guidelines*). In recent years, an increasing number of fixed-dose combinations (FDCs) have become available to simplify dosing and reduce pill burden.

These include four NRTI combinations:

- Abacavir + lamivudine (Epzicom)
- Abacavir + lamivudine + zidovudine (Trizivir)
- Tenofovir + emtricitabine (Truvada)
- Zidovudine + lamivudine (Combivir)

One PI coformulation:

- Lopinavir + ritonavir (Kaletra)

And three one-pill-per-day formulations of two NRTIs + one NNRTI or one INSTI:

- Efavirenz + tenofovir + emtricitabine (Atripla)
- Rilpivirine + tenofovir + emtricitabine (Complera)
- Elvitegravir + cobicistat + tenofovir + emtricitabine (Stribild)

Other FDCs are in development and may become available in coming years.

The HHS *Guidelines* suggest “preferred” and “alternative” components for initial therapy (Table 1). Clinicians should note that these recommendations change over time as new data regarding efficacy or toxicity become

available and should refer to the most up-to-date HHS guidelines. Among regimens with adequate potency (taking into account possible ARV resistance), regimen selection should be guided by factors such as anticipated tolerability, pill burden, drug interactions, and the patient’s comorbid conditions.

Table 1. Recommended Regimens for Initial Antiretroviral Treatment

Preferred Regimens	
NNRTI based	Efavirenz ¹ /tenofovir/emtricitabine ²
PI based	Atazanavir/r + tenofovir/emtricitabine (TDF/FTC) ² Darunavir/r (QD) + TDF/FTC ²
INSTI based	Raltegravir + TDF/FTC ² Elvitegravir/cobicistat/TDF/FTC ^{2,3} Dolutegravir (QD) + abacavir/lamivudine (ABC/3TC) ^{2,4} Dolutegravir (QD) + TDF/FTC ²
Alternative Regimens	
NRTI based	Efavirenz ¹ + ABC/3TC ^{2,4} Rilpivirine ⁵ /TDF/FTC ² Rilpivirine ⁵ + ABC/3TC ^{2,4}
PI based	Atazanavir/r + ABC/3TC ^{2,4} Darunavir/r + ABC/3TC ^{2,4} Fosamprenavir/r (QD or BID) + ABC/3TC ^{2,4} or TDF/FTC ² Lopinavir/r (QD or BID) + ABC/3TC ^{2,4} or TDF/FTC ²
INSTI based	Raltegravir + ABC/3TC ⁴

¹ Efavirenz is teratogenic in nonhuman primates. Strongly consider alternative agent for women who plan to become pregnant or are not using effective and consistent contraception.

² 3TC can be used in place of FTC and vice versa.

³ Should be considered only for patients with estimated CrCl ≥70 mL/min.

⁴ Abacavir should not be used by patients who test positive for HLA-B*5701; use with caution if HIV RNA level is >100,000 copies/mL or if there is a high risk of cardiovascular disease.

⁵ Rilpivirine is not recommended if the pretreatment HIV RNA is >100,000 copies/mL; caution if the CD4 count is <200 cells/μL.

Abbreviations: /r = low-dose ritonavir; INSTI = integrase inhibitor; NNRTI = nonnucleoside reverse transcriptase inhibitor; NRTI = nucleoside/nucleotide analogue; PI = protease inhibitor

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents. *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. Department of Health and Human Services. Available at www.aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Note: Many other ART combinations are possible, and in some cases a different option may be most appropriate for the individual patient. The HHS *Guidelines* also list regimens that are “Acceptable,” those that “May be acceptable,” but are “less satisfactory” or lack definitive data, and several that “May be acceptable but should be used with caution”; see Table 5b in the HHS *Guidelines*.

Once-Daily Regimens

The use of convenient and simplified dosing is an obvious strategy for improving adherence, particularly with the availability of coformulations that reduce pill burden (see “Preferred Starting Regimens,” above). The HHS *Guidelines* emphasize the importance of simple regimens and currently include six once-daily combinations among “preferred” regimens for initial therapy, and list a number of other possibilities among “alternative” regimens.

Avoiding Drug Resistance

ARV medications never should be given as single agents, in two-drug regimens, in suboptimal regimens, or in lower dosages than recommended, because of the potential for development of resistance. High-level resistance to NNRTIs, as well as to emtricitabine and lamivudine, may develop quickly (i.e., within days to weeks) in these situations, and the same may be true for the INSTIs raltegravir and elvitegravir. It may take longer for high-level resistance to develop to other NRTIs and to ritonavir-boosted PIs, and perhaps also the INSTI dolutegravir. Patients must be instructed to take the full dosage of all medications on schedule and to avoid skipping doses or taking “days off” from their regimens. Careful medication dosing is important because resistance to one drug within a particular class may transfer to other drugs in the same class (cross-resistance). Cross-resistance can limit the options for future therapy significantly or necessitate the use of very complicated regimens in the future. Once resistant viral strains have developed, they may be transmitted to other people.

Acquired or “primary” resistance, in which a patient is infected with ARV-resistant virus, is common in parts of the United States. Because both multi- and single-class resistance has been found among ARV-naïve persons in many U.S. cities, it is recommended that individuals with newly diagnosed HIV infection and all others entering care should receive a baseline resistance test. This test should be obtained as early as possible, in order to maximize the likelihood of detecting transmitted mutations, and before initiation of ART (see chapter *Resistance Testing*).

Drug Interactions

Many of the ARVs interact with one another as well as with other common medications. When starting or changing an ARV regimen, review all the patient’s current medications carefully for possible drug interactions. See chapter *Drug-Drug Interactions with HIV-Related Medications* for a summary of this issue and for references and resources to review medication lists and combinations. For further information on drug interactions involving ARVs, see relevant tables in the HHS *Guidelines*.

Drugs and Drug Combinations That Should Not Be Used

Most clinicians in the United States avoid using the NRTIs zidovudine (except for pregnant women), stavudine, or didanosine if other options are available, because of the high rates of metabolic and other adverse effects associated with these agents. Stavudine, in particular, is likely to cause peripheral neuropathy and lipodystrophy. Drugs with additive or overlapping toxicities, such as stavudine and didanosine, should not be combined. Zidovudine and stavudine, which compete intracellularly and therefore cause antagonism, should not be used together.

Drugs with similar mechanisms of action and resistance mutations (e.g., lamivudine and emtricitabine, or efavirenz and nevirapine) offer no significant advantage when combined and may increase toxicities. Certain drug

combinations have suboptimal efficacy and are not recommended (e.g., tenofovir + didanosine as an NRTI backbone; three-NRTI regimens). Some ARVs require specific dosing intervals in particular patients. For example, once-daily dosing of lopinavir/ritonavir is not recommended for patients receiving concomitant efavirenz or nevirapine, and some once-daily PIs or combinations should not be used for treatment-experienced patients. For further information, see relevant tables in the *HHS Guidelines*.

Follow-Up of Patients Starting ART

Patients who start a new ARV regimen ideally should be seen at least twice within the first month to allow for an assessment of their adherence to therapy and the tolerability and adverse effects of the regimen.

When patients have been on a new regimen for 2-8 weeks, clinicians should check the following:

- HIV viral load, to monitor initial virologic response to therapy, then every 4-8 weeks until the viral load is below the level of detection
- CBC with platelets, for patients starting a zidovudine-containing regimen, to monitor for anemia
- LFTs, to monitor for hepatotoxicity (patients starting a nevirapine-containing regimen should be monitored closely for the first 18 weeks of treatment)
- Serum electrolytes, blood urea nitrogen, and creatinine (particularly for patients taking tenofovir)
- Fasting glucose and lipids (after 1-3 months)

CD4 cell count should be checked after about 3 months.

For further information, and for recommendations about monitoring stable patients, see chapter *Initial and Interim Laboratory and Other Tests*.

Regimen Failure

An ART regimen may fail for several reasons, including the following:

Incomplete virologic response

- Viral load is >200 copies/mL on consecutive tests after 24 weeks on therapy. (For some patients with multidrug resistance, it may not be possible to decrease plasma HIV viral load to undetectable levels, and stabilization of viral load below the previous baseline may be an appropriate goal of therapy.)

Virologic rebound

- Virus is repeatedly detected in plasma (>200 copies/mL) after suppression to undetectable levels. Confirmatory testing is required to rule out “blips” of virus (isolated elevations in viral load of less than several hundred copies/mL) that are not clinically significant and to ensure that the increase is not caused by infection, vaccination, or problems with test methodology. Note that some patients may have persistently detectable low-level viremia (<200 copies/mL); the clinical significance of this is not clear.

Immunologic failure

- Despite virologic suppression on ART, the CD4 cell count shows an inadequate response or a persistent decline.

Clinical progression

- Recurrent, persistent, or new HIV-related illness occurs after ≥ 3 months on ART. Note that new or recurrent symptoms of opportunistic illness occurring in the first weeks to months after starting ART, especially in patients with severe immunosuppression, may not reflect a failure of ART. Rather, these symptoms could be attributable to persistence of opportunistic infections that may require longer treatment, or they could be caused by an immune reconstitution inflammatory syndrome (see chapter *Immune Reconstitution Inflammatory Syndrome*).

Responding to Apparent Treatment Failure

- Carefully assess patient adherence, because inadequate adherence to ART is a common reason for regimen failure. In some cases, adherence support, treatment of adverse drug effects, substitution for poorly tolerated ARVs, or other measures to enhance adherence may result in virologic suppression (see chapter *Adherence*). In other cases, ARV resistance may have developed. Poor adherence may affect the decision to change therapy, and adherence issues should be addressed before a new regimen is initiated. If resistance is suspected, obtain an appropriate resistance test (or CCR5 tropism assay, if the patient is taking a CCR5 antagonist) while the patient is on the failing regimen; see below.
- The availability of effective alternative ARVs is a critical consideration in deciding whether or when to change therapies. The development of new ARVs and new ARV classes in recent years has made virologic suppression possible for most patients, even those with extensive resistance. For the few patients in whom treatment possibilities are limited or nonexistent, it may be necessary to weigh the value of partial virologic suppression with the current regimen against the likelihood of further resistance developing. Strongly consider consultation with an experienced HIV provider and the use of HIV resistance testing when considering changes in therapy. When no treatment options remain among currently approved drugs, refer the patient to an appropriate clinical trial, if possible.

Note that the optimal management of immunologic failure is uncertain and is an active area of research. Consult with an HIV expert and consider referral to a research study.

Resistance and Coreceptor Tropism Testing

If resistance is suspected, obtain an appropriate resistance test (see chapter *Resistance Testing*). Resistance testing is recommended, before changing regimens, in cases of virologic rebound during ARV therapy or suboptimal suppression of viral load on ARV therapy. Resistance testing often is crucial in identifying ARVs that are not likely to be effective against the patient's virus. It should be done while the patient is taking the failing regimen (or within 4 weeks of discontinuation) to maximize the likelihood that resistant viral populations will be present in detectable numbers. In virologic failure of a first regimen, it is fairly common to see resistance to only one or two drugs in a multidrug combination. The test results should be interpreted in the context of the patient's ARV history and the results of previous resistance tests.

Standard genotypes test give information about resistance that may affect NRTI, NNRTI, and PI agents. If INSTI (or fusion inhibitor) resistance is suspected, a specific genotype test must be ordered. For patients with virologic failure while taking a CCR5 antagonist, a coreceptor tropism assay should be obtained (though the result does not rule out the possibility of resistance to CCR5 antagonists).

Cross-resistance exists among ARVs, such that resistance to one drug in a class of agents often extends to other drugs in that class. For example, cross-resistance between efavirenz and nevirapine is almost complete, and resistance mutations to NRTIs, INSTIs, and PIs often decrease viral susceptibility to other drugs in those classes. As a result, selecting a new ARV regimen can be complicated because it requires knowledge of expected resistance patterns. The likelihood of sustained viral suppression is lower when resistant virus is present, unless three ARVs that are fully active against the patient's virus can be included in the subsequent regimen.

If treatment with a CCR5 antagonist is being considered, a tropism test must be obtained to verify that the patient has only CCR5-tropic virus (the currently available agent in this class is not effective in patients with any degree of CXCR4 virus). The standard test requires an HIV viral load of >1,000 copies/mL at the time of testing; a newer proviral DNA assay can identify coreceptor tropism in blood samples with HIV RNA levels below the limit of detection (this has not been clinically validated).

Suggestions for Changing an ARV Regimen for Suspected Drug Failure

The following recommendations are adapted from the HHS *Guidelines*.

Distinguish between the need to change a regimen because of drug intolerance or inability to adhere to the regimen and the failure to achieve the goal of sustained viral suppression. In the event of intolerance, single agents usually can be changed without resistance testing.

In general, do not change a single drug or add a single active drug to a failing regimen; it is important to use at least two or, preferably, three fully active ARVs (e.g., ARVs selected on the basis of resistance testing or because they are from a drug class to which the patient's virus has not been exposed). If resistance testing (performed while the patient is taking the failing regimen) shows resistance to only one agent in a regimen, it may be possible to replace only that drug; however, consultation with an expert is recommended.

In general, the goal of ART is to suppress HIV RNA to undetectable levels, in order to improve or maintain immune function. This usually is possible even for patients with resistance to multiple drugs as new ARV agents and new classes of ARVs have become available. Nevertheless, some patients have

limited options for new regimens that will achieve durable virologic suppression. In some of these cases, it may be reasonable to continue the same regimen if partial virologic suppression and clinical and immunologic stability are maintained. The risk of continuing patients on a partially suppressive regimen, however, is the emergence of additional resistance mutations.

Data on the value of restarting a drug that the patient has previously received are limited. Resistant virus can be archived and will reemerge for patients who are rechallenged with regimens on which they had previously developed resistance. As a result, resistance tests from previous regimens should be used with current resistance tests to determine what drugs might be active in a new regimen.

Making the decision to change therapy and choosing a new ARV regimen require that the clinician have considerable expertise in the care of people with HIV infection. Those less experienced in the care of persons with HIV are strongly encouraged to obtain assistance by consulting with or referring to an expert.

Follow-Up of Patients Not Started on ART

Patients who are not on ART

These patients should continue their regular visits for monitoring, prophylaxis, and other medical treatment (see section *Testing and Assessment* for chapters on physical examinations and laboratory tests). ART should be discussed again and offered at regular intervals to anyone who initially refuses treatment. Routine clinic visits present ongoing chances to discuss the benefits of ART and the risks of delayed treatment, and to educate patients about new medications and research findings. Decreases in patients' CD4 count or declines in their condition should be taken as opportunities to reassess their decisions about ARVs. If lack of readiness or

probable adherence difficulties are at issue, an adherence counselor (if available) or a mental health provider should be engaged to bolster the patients' support and coping mechanisms (see chapter *CD4 Monitoring and Viral Load Testing* and the HHS *Guidelines*).

Special Situations for ART

ART during acute or recent HIV infection

There are no definitive data that demonstrate long-term benefit if ART is started during early HIV infection, though emerging clinical data as well as theoretical considerations suggest early treatment may reduce the severity of immune system disruption and lessen both the short-term and the long-term impact of HIV infection. In addition early treatment may decrease the risk of HIV transmission during the highly infectious period of acute HIV. The HHS *Guidelines* recommend treatment of acute HIV (if identified during pregnancy, ART should be started as quickly as possible to reduce the risk of perinatal HIV transmission). Before starting an ARV regimen, patients must be counseled carefully about potential limitations, such as toxicity, pill burden, cost, and the possible development of drug resistance. Patients should be monitored with HIV viral load, CD4 counts, and other parameters, as with patients with established infection who are receiving ART. See chapter *Early HIV Infection*.

Pregnant women

Combination ARV regimens are recommended for all women during pregnancy, regardless of CD4 count or HIV RNA level. The goal of ART for pregnant women is to reduce the risk of transmission to the infant and to treat HIV infection in the mother, through maximal virologic suppression. Obviously, the decision of whether to start ART during pregnancy is the choice of the woman, and her choice must be respected. There are a number of

specific considerations about ART for pregnant women, including the timing of ART initiation (for those not already on treatment), specific ARVs that are recommended or that should be avoided (because of toxicity or teratogenicity concerns), pharmacokinetic variations and dosing requirements in pregnancy, and indications for resistance testing. See chapters *Reducing Perinatal HIV Transmission* and *Care of HIV-Infected Pregnant Women*; also refer to the HHS *Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*.

Older persons

Older persons with HIV infection may experience earlier development of a number of conditions that are associated with aging, such as cardiovascular disease and neurocognitive impairment. Additionally, older persons may have dampened immunologic responses to ART. For these reasons as well as others, ART initiation in older persons probably should not be delayed. Current HHS *Guidelines* recommend ART for all patients older than 50 years of age.

Acute opportunistic infections

The presence of opportunistic infections is a strong signal of the need for ART and effective immune reconstitution. For some of these infections, ART is the primary therapy, and for others it is adjunctive. Although ART sometimes causes immune reconstitution inflammatory syndromes if initiated in the setting of acute opportunistic infection, clinical data for many such infections (including *Pneumocystis jiroveci* pneumonia and tuberculosis in persons with very low CD4 counts) suggest improved outcomes, including better survival, if ART is started early. Exceptions to this recommendation include cryptococcal meningitis, for which most experts recommend a short period of antifungal treatment before ART is started.

For further information, see chapter *Immune Reconstitution Inflammatory Syndrome* and the *Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents: Recommendations from CDC, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America* (see “References,” below).

Hepatitis B coinfection

If treatment for either HIV or HBV is to be started, both infections generally should be treated simultaneously, by including in the ART regimen two NRTIs with activity against both viruses (tenofovir + emtricitabine or tenofovir + lamivudine), if possible. The use of a single NRTI with activity against both viruses (resulting in monotherapy for HBV) is not recommended. If tenofovir is contraindicated, another anti-HBV drug should be used in combination with lamivudine or emtricitabine. Flares of HBV may occur if tenofovir, emtricitabine, or lamivudine is discontinued; monitor closely or consider substitution of another anti-HBV drug. See chapter *Hepatitis B Infection* and the *HHS Guidelines* for additional information.

HIV-associated nephropathy

ART is a primary treatment for HIVAN and should be started urgently for patients with suspected HIVAN. See chapter *Renal Disease*.

Expert Consultation

The National HIV/AIDS Clinicians' Consultation Center is a valuable resource for any clinician seeking expert advice about ART, HIV clinical manifestations, laboratory evaluations, and other issues. Its National HIV Telephone Consultation Service (Warmline) is staffed by HIV-experienced physicians and pharmacists. The Warmline operates Monday through Friday, 9 a.m. to 8 p.m. eastern time and is available free of charge in the United States at 800-933-3413.

Patient Education

- Making the decision to start ART is rarely an emergency situation. Before starting patients on ART, health care providers must work with them to determine what goals of therapy are likely to be achieved, and which personal issues are pertinent for selecting the best regimen to fit their lifestyles,
- Providers should review the proposed drug regimen with their patients. Be sure patients understand the instructions about dosage, scheduling, food requirements or restrictions, drug storage, adverse effects, toxicities, and type of reactions that must be reported immediately, as well as remedies for common adverse effects.
- Providers should explain to patients that successful ART requires a commitment to taking the medications every day, as prescribed. If ARVs are taken incorrectly, HIV can quickly become resistant to the medications. This will mean even fewer choices and less-effective treatment in the future. It also may mean that patients could transmit resistant virus to a partner or, if they are pregnant, to an infant.
- Patients should know that HIV medications may reduce the risk of HIV transmission substantially but do not offer perfect protection against infecting others. Recommend prevention measures such as using latex barriers during sex (safer sex) and not sharing needles or other drug-using equipment, even with other HIV-infected persons (see chapter *Preventing HIV Transmission/Prevention with Positives* for more information).
- HCV, HBV, and other sexually transmitted diseases such as syphilis and gonorrhea can be transmitted between two HIV-infected partners.
- Patients should be advised to check with their provider before discontinuing ARVs.

If ARVs must be discontinued, it is usually best to stop all ARVs at once. The exception to this recommendation may be NNRTI-containing regimens. In this case, blood levels of the NNRTIs may be detectable for several weeks after discontinuation; if NRTIs are stopped, that may result in NNRTI monotherapy and the risk of NNRTI resistance. The optimal strategy for discontinuing NRTIs is not clear; some experts recommend continuing the NRTIs for a period of time after discontinuation of the NNRTI or switching from an NNRTI to a PI for some time before stopping all agents.

- Patients should be encouraged to advise their provider of all other medications that they take, including over-the-counter medications, herbal remedies, and nutritional supplements.
- Discuss contingencies in the event the client is unable to take ARVs for a day or more (e.g., illness, severe adverse effects, hospitalization, or other unexpected circumstances).

Reducing Perinatal HIV Transmission

Carolyn K. Burr, EdD, RN

Background

This chapter describes strategies for reducing the risk of perinatal HIV, based on the U.S. Department of Health and Human Services (HHS) *Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*. It is not intended to be a comprehensive discussion of these topics, and all HIV-infected pregnant women should be treated by an HIV-experienced obstetrician and an HIV specialist. For centers that do not have HIV specialists available, experts at the National Perinatal HIV Consultation and Referral Service are available for consultation through the Perinatal HIV Hotline (888-448-8765). For more information on other aspects of caring for HIV-infected pregnant women, see chapter *Care of HIV-Infected Pregnant Women*.

Unless otherwise referenced, the information in this chapter is based on the most recent HHS perinatal guidelines available at the time this chapter was published. Consult the AIDSinfo website (aidsinfo.nih.gov/guidelines) for the most current recommendations.

Overview of Prevention of Perinatal HIV Transmission

In the absence of antiretroviral (ARV) prophylaxis or other interventions, the rate of perinatal HIV transmission in the United States ranges from 16% to 25%. Antiretroviral therapy (ART) is highly effective in reducing the risk of perinatal transmission of HIV, to as low as <1%. It probably prevents HIV transmission in several ways, including by reducing the mother's viral load in blood and genital secretions and by providing pre- and postexposure prophylaxis for the infant. All pregnant women with HIV infection should be educated about the risks of perinatal HIV transmission and offered ART and other medical management to maintain or improve their own health and to reduce the risk of HIV transmission to their infants.

In 1994, the Pediatric AIDS Clinical Trial Group study 076 (PACTG 076) found that ARV treatment during pregnancy could significantly reduce the risk of HIV transmission to infants. The intervention, consisting of zidovudine (ZDV) given PO to the women during the last weeks of pregnancy and IV during labor

and delivery, as well as to the newborns for 6 weeks, reduced the rate of infant infection from 25.5% to 8.3%. The ZDV regimen quickly became the standard of care in the United States and other high-income countries. Subsequent studies showed that combination ARV regimens with suppression of maternal HIV viral load to undetectable levels further reduced the risk of perinatal infection.

Studies in resource-limited countries as well as in resource-abundant areas have examined various ARV strategies for reducing the risk of perinatal HIV transmission. The Petra study, a placebo-controlled trial in a breast-feeding population in Uganda, South Africa, and Tanzania, found a transmission rate of 8.9% among women who received PO ZDV plus lamivudine (3TC) intrapartum and for 1 week postpartum and whose infants also received 1 week of ZDV/3TC, compared with a rate of 15.3% in the placebo group. The HIV NET 012 trial in a breast-feeding population in Uganda compared the efficacy of a single dose of nevirapine (NVP) given to the mother at the onset of labor plus a single dose given to the newborn 48 hours postpartum with that of PO

ZDV given to the mother during labor and to the newborn. The transmission rate was 11.8% in the NVP arm, compared with 20.0% in the ZDV arm. The results of this study and the low cost of NVP prompted a number of resource-limited countries to institute NVP prophylaxis as the standard of care for preventing mother-to-child transmission of HIV. Numerous other trials have demonstrated the efficacy of various ARV strategies, combining different ARVs with different treatment durations and given to mothers, newborns, or both, in both breast-feeding and non-breast-feeding populations. Research has shown that ARV interventions even late in the peripartum or newborn periods may decrease the infant's risk of HIV infection. A retrospective study of subjects in New York found that the rate of perinatal HIV transmission was 9.3-10% if ZDV was given either to both the mothers intrapartum and their newborns or to the newborns only, compared with 26.6% if no ARV medication was given. This study underscores the importance of offering ARV interventions to pregnant women with HIV infection whenever they are identified during pregnancy or during labor and delivery, or as an intervention with the newborn.

In the United States, the PACTG 076 regimen remains an important component in the prevention of perinatal HIV transmission, and usually is incorporated into combination ART for pregnant women. For international settings, other guidelines have been developed by global agencies such as the World Health Organization (see "References," below) and by individual governments.

Mother-to-child transmission also can occur through breast-feeding. Recent studies have shown that ART given to the nursing mother and/or her infant decreases but does not eliminate the risk of HIV transmission to the infant. In the United States, because substitute feeding is safe, affordable, feasible, sustainable, and available, mothers in the United States should not breast-feed.

HIV Testing During Pregnancy

The success of interventions to reduce the risk of perinatal HIV transmission has been achieved through the routine HIV testing and counseling of all pregnant women.

Interventions to prevent transmission can be effective only if women know their HIV status and have access to treatment. HHS has recommended universal HIV counseling and testing for pregnant women since 1995. Many national professional and governmental organizations, including the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, and the U.S. Preventive Services Task Force, endorse those recommendations. Current recommendations from the U.S. Centers for Disease Control and Prevention (CDC) feature the following three approaches to HIV testing during pregnancy:

- Routine testing as part of first-trimester prenatal screening tests for all pregnant women, using an "opt-out" policy whereby a pregnant woman is tested unless she specifically declines testing
- Routine "opt-out" testing with a rapid HIV test for women who present in labor with unknown or undocumented HIV status, in order to offer ARV prophylaxis during labor for those who test positive for HIV
- Expedited HIV testing for newborns of mothers of unknown HIV status so that they can receive postexposure ARV prophylaxis, if indicated

The CDC also recommends repeat HIV testing in the third trimester for women who receive health care in jurisdictions with an elevated incidence of HIV or AIDS among women, as well as for women at high risk of acquiring HIV (e.g., a history of injection drug use, exchange of sex for money or drugs, multiple sex partners, or a partner known to be HIV infected). Jurisdictions in which repeat third-trimester testing is recommended include Alabama, Connecticut, Delaware,

District of Columbia, Florida, Georgia, Illinois, Louisiana, Maryland, Massachusetts, Mississippi, Nevada, New Jersey, New York, North Carolina, Pennsylvania, Puerto Rico, Rhode Island, South Carolina, Tennessee, Texas, and Virginia. A number of states mandate a third-trimester HIV test for all pregnant women.

Any pregnant woman with signs or symptoms of acute HIV infection should be evaluated (see *chapter Early HIV Infection*) and receive an HIV plasma RNA test as well as an antibody test.

State laws regarding HIV testing during pregnancy vary widely, and many are currently under review. A number of states have adopted the opt-out approach, whereas some still require written informed consent before an HIV test is done. Others require patient education and a chart note from the providers. Clinicians should be familiar with relevant state laws regarding HIV testing during pregnancy, opt-out or consent provisions, and regulations about rapid HIV testing during the intrapartum or newborn period. (Information on state laws regarding HIV testing during pregnancy can be found at the National HIV/AIDS Clinicians' Consultation Center's Compendium of State HIV Testing Laws at www.nccc.ucsf.edu.) Whatever the consent process, a woman should know that an HIV test is being done and should receive at least the information outlined below.

HIV Education and Counseling of Pregnant Women

Educating pregnant women about the importance of HIV testing is a critical element in preventing perinatal HIV transmission. However, extensive pretest counseling is not essential. A woman must be told that HIV testing is a standard component of prenatal care, that her clinician recommends the tests, and that all pregnant women should be tested for HIV because knowing about HIV infection is important for their health and the health of their babies. Research has

shown that a provider's strong endorsement of HIV testing is a major predictor of whether a woman receives an HIV test. Testing should be voluntary and free of coercion, and a woman should know that she can decline testing without the risk of being denied care. A woman's age, cultural background, educational level, and primary language may influence her knowledge about HIV transmission and her willingness to be tested; the clinician should consider these factors carefully when providing education and information.

The following minimum information should be provided through an educational session with a health care provider or through written or electronic media (e.g., brochures, videos):

- HIV is the virus that causes AIDS.
- Without treatment, approximately 25% of babies born to HIV-infected women will be infected, either during pregnancy, during labor and delivery, or by breast-feeding.
- A woman could be at risk of HIV infection and not know it.
- ART is highly effective in protecting the infant from being infected with HIV and can improve the mother's health.
- HIV testing is recommended for all pregnant women.
- Women who decline testing will not be denied care.

Women should be told that test results are confidential to the extent allowed by law and that medical and other services are available for women with HIV infection. Reporting requirements for the specific state should be explained.

HIV testing should be performed as early in pregnancy as possible to allow for interventions to prevent transmission and for effective management of a woman's HIV infection, if the woman is found to be HIV seropositive. The CDC recommends repeat HIV testing in the third trimester for women who have risk factors for HIV or who live in

areas with a high incidence of HIV in women; some states mandate third-trimester testing for all pregnant women.

If the client declines testing at any point, the clinician should inquire about her reasons and follow up at subsequent visits. If the provider is persistent, the woman may choose to have an HIV test at a later visit.

In the United States, the vast majority of pregnant women who are tested for HIV will be HIV seronegative. When giving test results to an HIV-negative woman, the clinician should take the opportunity to discuss risk-reduction strategies to help ensure that she remains uninfected by HIV. Women at risk of HIV infection should be referred for more extensive counseling because some research indicates that pregnancy may place them at greater risk of acquiring HIV infection, and acute HIV infection may confer greater risk of transmission to the fetus.

Counseling a pregnant woman with a positive HIV test result requires knowledge and sensitivity. The clinician should explain that, even though the woman may feel well, she is infected with the virus. The woman should be told about the importance of medical management of HIV for her own health and for the prevention of perinatal transmission, and she should be guided to the medical and social services available in her local community. She also should be referred to an HIV obstetric specialist who can work closely with her primary obstetric and HIV providers to manage her care during the pregnancy. The patient may be surprised or shocked upon receiving the HIV diagnosis, or she may have known her status but been reluctant to disclose it. The clinician should emphasize the importance of emotional and social support, assess the patient's social support resources, and offer her referrals as needed.

Expedited HIV Testing During Labor

As discussed earlier, beginning ART during pregnancy offers the greatest chance for preventing perinatal transmission of HIV, but interventions during the intrapartum and neonatal periods also offer opportunities to decrease the risk of HIV transmission. Expedited HIV testing for women who present in labor with unknown or undocumented HIV status can identify women who are infected with HIV so that interventions can be offered. Available rapid HIV antibody tests are both sensitive and specific and provide results in as little as 20 minutes. Fourth-generation antigen-antibody HIV tests also are becoming increasingly available through hospital laboratories using random access machines that deliver results in 30 minutes to 2 1/2 hours.

Women who should receive HIV testing during labor include the following:

- Those who have had little or no prenatal care
- Those who were not offered testing earlier in pregnancy
- Those who declined previously
- Those whose HIV test results are not available at the time of labor

Education and counseling for the woman in labor who needs an HIV test should incorporate the information for prenatal education discussed earlier, with consideration given to the special circumstances of labor. Special educational formats such as flip charts have been developed to help with patient education. Confidentiality should be assured for the information and consent process and for treatment. If an opt-out approach is used in the labor setting, a woman of unknown serostatus should be told that no HIV test is found on her chart, that HIV testing is part of routine care, and that she can decline if she wishes, but that experts recommend HIV testing because available interventions can

decrease her baby's risk of becoming infected with HIV if she is found to be seropositive.

Women who present in labor with unknown HIV serostatus should undergo expedited HIV antibody testing. If the results are positive, a confirmatory HIV test should be sent as soon as possible but maternal prophylaxis should be started immediately (intravenous ZDV).

This should be followed by combination ARV prophylaxis (ZDV + NVP) for the infant beginning as soon as possible after birth. ARV drugs should be initiated pending results of the confirmatory test. If the confirmatory HIV test result is positive, infant ARV drugs should be continued for 6 weeks. If the confirmatory test result is negative, the infant ARV drugs should be stopped.

Factors Influencing Perinatal HIV Transmission

Perinatal transmission is most likely to occur in the intrapartum period. Several factors influence the risk of transmission from mother to infant. One of these is the mother's HIV RNA level (viral load). Clinical trials and observational studies have shown a strong positive correlation between maternal HIV viral load during pregnancy or during delivery and the risk of perinatal HIV transmission, even among women receiving treatment with ARVs. However, HIV transmission may occur at any level of maternal HIV RNA, including (rarely) when the viral load is undetectable. HIV RNA levels in the blood and the genital tract generally correlate but discordance may occur. Low-level cervical-vaginal HIV shedding has been found even in women on ART with undetectable plasma HIV RNA, particularly in the presence of genital infections.

ARV prophylaxis is a critical factor in reducing HIV transmission. For women on effective combination ART with undetectable HIV RNA, the rate of perinatal HIV transmission is approximately 1%. Thus, ARV prophylaxis

with full suppression of HIV RNA is recommended for all pregnant women with HIV infection, regardless of HIV viral load. Note that ART may exert protective effects not only by lowering maternal HIV RNA but also (for ARVs with good transplacental passage) by providing pre- and postexposure prophylaxis for the infant.

Other maternal factors associated with increased risk of perinatal transmission include low CD4 cell count, sexually transmitted diseases, active genital herpes during labor, illicit drug use, cigarette smoking, and unprotected sex with multiple partners.

Obstetric factors also affect the risk of HIV transmission. Infection risk increases linearly with the increased duration of ruptured membranes, although the effect of ruptured membranes in women with low viral loads is not known. Invasive procedures performed at any time during pregnancy, such as amniocentesis, placement of scalp electrodes, artificial rupture of membranes, episiotomy, or operative (forceps) delivery may increase risk by exposing the fetus to maternal blood; these procedures should be avoided (though the risk of transmission in women on fully suppressive ART is not clear). In addition, the mode of delivery, whether vaginal or cesarean, can influence the risk of HIV transmission. Scheduled cesarean delivery decreases the rate of perinatal infection for women with an HIV RNA level of >1,000 copies/mL, but its efficacy is not clear for women whose labor has begun or for those whose membranes have ruptured; see "Intrapartum Management and Mode of Delivery," below, for further information.

Infant risk factors for HIV infection include premature birth, low birth weight, skin and mucous membrane lesions such as thrush, and breast-feeding. Breast-feeding increases the risk of HIV transmission by 5-20%. In the United States, where safe, affordable replacement feeding and clean water routinely are available, women with HIV should not breast-feed.

However, some women with HIV will be under tremendous cultural and familial pressure to breast-feed and will need the clinician's ongoing support to use substitute formula.

Because many factors that affect the risk of perinatal HIV transmission may be modified, clinicians should educate pregnant women carefully about the importance of ARV prophylaxis and other strategies to reduce the risk of maternal-fetal transmission of HIV.

Antiretroviral Therapy During Pregnancy

The goals of ART for the pregnant woman are the same as those for any person living with HIV:

- To suppress the level of HIV as low as possible for as long as possible
- To preserve and restore immune function
- To prolong life and improve quality of life
- To reduce risk of HIV transmission to sex partners

An additional, and crucial, goal of ART for pregnant women is to reduce the risk of perinatal HIV transmission through maximal HIV suppression.

The HHS recommendations discuss in detail the multiple issues that must be considered when balancing the woman's need for therapy for her own health and the need to decrease the risk of transmission to the infant. Combination ART is recommended for all HIV-infected pregnant women regardless of CD4 count or HIV viral load. Decisions about ART are complex and should be made by the woman and her health care provider after discussing the risks and benefits. Clinicians are urged to consult an HIV specialist and the most current HHS recommendations when making therapeutic decisions. The Perinatal HIV Hotline (888-448-8765) provides free clinical consultation on all aspects of perinatal HIV care. The following discussion addresses some of the issues in determining ART

strategies and is taken from the HHS *Perinatal ARV Guidelines*.

The HHS Perinatal HIV Guidelines Working Group recommends fully suppressive combination ART for all pregnant women, unless there are compelling reasons based on pregnancy-specific maternal and fetal safety issues to modify this approach. Key recommendations from the HHS *Perinatal ARV Guidelines* include the following:

- Assess the woman's HIV disease status and make recommendations about initiating or altering an ARV regimen, as part of the initial evaluation.
- Recommend ARV prophylaxis to all pregnant women regardless of HIV viral load or CD4 count.
- Discuss known benefits and potential risks of ART.
- If HIV RNA level is >500-1,000 copies/mL, perform drug-resistance testing prior to starting or changing ART.
- If HIV is diagnosed late in pregnancy, ART should be initiated promptly without waiting for results of resistance testing.
- Emphasize the importance of adherence to the regimen.
- Ensure that the woman has access to and coordination of services among perinatal, primary care, and HIV providers as well as mental health and drug abuse services and income support as needed.
- Considerations about continuing ART after pregnancy are the same as for nonpregnant individuals.

A fundamental principle of the *Guidelines* is that therapies of known benefit should not be withheld during pregnancy unless they may cause adverse effects to the woman, fetus, or infant, and these adverse effects outweigh the potential benefits. Thus, women should be advised of the potential risks and benefits of ART (to the woman, fetus, and infant) and of the limited long-term data on outcomes for

infants with in utero exposure to ARVs, but treatment decisions should be guided by the woman's clinical, virologic, and immunologic status and by the goal of preventing perinatal transmission. An additional benefit of ART is the reduction in risk of transmission to sex partners. Women should be educated and counseled on the importance of close adherence to the ART regimen (see chapter *Adherence*).

Drug-resistance testing should be conducted for all pregnant women before the initiation of therapy, and for women who are already on ART without fully suppressed HIV RNA.

All women receiving ARVs during pregnancy for prophylaxis or for treatment should receive a combination containing at least three agents, with the aim of viral suppression to undetectable levels (i.e., <20-75 copies/mL, depending on the assay). Monotherapy (e.g., with ZDV) and dual therapy are not as effective and generally are not recommended. Current *Guidelines* recommend that the regimen include two nucleoside reverse transcriptase inhibitors (NRTIs) and either a nonnucleoside reverse transcriptase inhibitor (NNRTI) or a protease inhibitor (PI). Regimen selection should be individualized on the basis of factors such as anticipated safety and efficacy, ARV history, results of resistance testing, and comorbidities (e.g., hepatitis B virus [HBV]) (see chapter *Antiretroviral Therapy* for considerations in selecting ARVs). It should be recognized that only limited information is available for many ARVs and ARV combinations regarding potential toxicities for the fetus or infant (see Table 5 of the *Guidelines*), and for dosage requirements with pregnant women.

The HHS *Perinatal ARV Guidelines* offer recommendations on the use of specific ARV agents during pregnancy. The table below shows "Preferred" and "Alternative" ARVs; others are classified as "Use in special circumstances" or "Insufficient data to recommend use." For more complete information, see Table 5 of the *Guidelines*).

Recommendations for ARV Use During Pregnancy

ARV Class	Preferred Agents	Alternative Agents
NRTI	- Lamivudine - Zidovudine	- Abacavir[#] - Emtricitabine - Tenofovir
NNRTI	Nevirapine*	
PI	- Atazanavir/ ritonavir - Lopinavir/ ritonavir (Kaletra)	- Darunavir/ ritonavir - Saquinavir/ ritonavir

* For women with CD4 counts of >250 cells/μL, NVP should be initiated only if benefit clearly outweighs risk, owing to the increased risk of potentially life-threatening hepatotoxicity in women with high CD4 counts. Women who are already taking NVP at the start of pregnancy and are tolerating it well may continue NVP, regardless of CD4 count.

[#] Risk of hypersensitivity reaction; should be given only to patients who test negative for HLA-B*5701. Test for HLA-B*5701 before starting abacavir.

Adapted from U.S. Department of Health and Human Services. *Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

The guidelines' preferred NRTI component is ZDV/3TC, because of data showing safety and efficacy in pregnancy. Alternative NRTIs listed above may be used for women with intolerance to ZDV (e.g., severe anemia) or documented resistance to ZDV (see "Safety and Toxicity of Antiretroviral Medications During Pregnancy," below). Tenofovir + 3TC or FTC is the preferred NRTI pair for women with hepatitis B coinfection (see "Special Circumstances," below).

Of the NNRTIs, NVP may be started for women with CD4 counts of ≤250 cells/μL or continued for women who are already on NVP-containing regimens. NVP generally should not be started for treatment-naïve women with CD4 counts of >250 cells/μL because of an increased risk of symptomatic and potentially fatal hepatic and rash toxicity. Efavirenz is not recommended for use during the first 5-6 weeks of pregnancy because of concern for potential teratogenicity, but it can be continued in pregnant women already

taking an effective efavirenz-based regimen who present for antenatal care in the first trimester, and it can be considered for other women (after the first 6 weeks of pregnancy) if other agents are not appropriate (see “Safety and Toxicity of Antiretroviral Medications During Pregnancy,” below). There are insufficient pharmacokinetic and safety data to recommend the use of etravirine or rilpivirine during pregnancy.

Atazanavir + ritonavir and lopinavir/ritonavir are recommended PIs based on efficacy studies in adults and experience in pregnant women. For both of these (and for darunavir), serum levels may be low in the second and third trimesters; see the *Guidelines* for recommendations about dosage adjustments. The alternative PIs are ritonavir-boosted darunavir and ritonavir-boosted saquinavir, although pharmacokinetic data during pregnancy are limited. Nelfinavir has been used widely for pregnant women but current guidelines recommend its use only in “special circumstances” because, in nonpregnant adults, it has shown inferior efficacy compared with first-line agents. Indinavir also may be considered when preferred and alternative agents are not available. Fosamprenavir and tipranavir are not recommended because of lack of data in pregnancy, but they may be considered if other agents are not tolerated or are not appropriate.

The integrase inhibitor raltegravir may be considered if preferred or alternative agents are not appropriate. Pharmacokinetic and safety data in pregnancy are not sufficient to recommend the use of maraviroc or enfuvirtide, and they do not consider the newer agents rilpivirine, etravirine/cobicistat, or dolutegravir; these may be considered for use by women for whom drugs in other classes have failed but they should be prescribed in consultation with HIV and obstetric specialists.

ART Recommendations by Clinical Scenario

Recommendations for ARV Use by Pregnant Women

The HHS *Perinatal ARV Guidelines* offer recommendations on ART for pregnant women based on four clinical scenarios; these are categorized by the woman’s ART status when she presents for care (see Table 6 of the *Guidelines*). Note that current adult and adolescent guidelines recommend ART for all, regardless of CD4 cell count (see chapter *Antiretroviral Therapy*).

HIV-infected pregnant women currently receiving ART

Women already receiving ART should, in general, continue to receive it during pregnancy if it is suppressing viral replication. If the woman has detectable virus (e.g., >500–1,000 copies/mL) on therapy, HIV drug-resistance testing should be performed, and the regimen should be optimized to maximize the likelihood of achieving virologic suppression. Women presenting in the first trimester should be counseled about the risks and benefits of ART during this period. Discontinuation of therapy could lead to increased viral load and potential for transmission to the fetus.

Pregnant women receiving NVP-containing regimens should continue them, regardless of CD4 count, if they are virologically suppressed and tolerating the regimen. For women who become pregnant while taking efavirenz, current *Guidelines* state that, because the risk of neural tube defects is limited to the first 5 to 6 weeks of pregnancy and pregnancy is rarely recognized before 4 to 6 weeks of pregnancy, efavirenz can be continued (assuming the regimen is maximally suppressive).

HIV-infected pregnant women who are ARV naive

All pregnant women should start potent combination ART. The drug regimen should be based on the recommendations of the *Perinatal ARV Guidelines* (see above and Table 5 of the *Guidelines*). As in other scenarios,

drug-resistance testing should guide ARV selection.

Starting ART early in pregnancy may be more effective in reducing perinatal HIV transmission but the potential benefits of early ART must be weighed against potential fetal effects of first-trimester exposure. Starting ART after the first trimester can be considered in women with high CD4 T-lymphocyte (CD4-cell) counts and low HIV RNA levels.

Inclusion of NRTIs with good placental passage (zidovudine, lamivudine, emtricitabine, tenofovir, or abacavir) is recommended.

ART should be continued intrapartum. ZDV should be administered to HIV-infected women by continuous IV infusion if they have HIV RNA levels of >400 copies/mL (or unknown HIV RNA levels) near delivery, regardless of ART regimen or mode of delivery.

After delivery, consider the indications for continuing ART and the woman's willingness and ability to do so (note that ART currently is recommended for all adults and adolescents); see "Postpartum Follow-Up of HIV-Infected Women," below, and chapter Antiretroviral Therapy.

HIV-infected pregnant women who previously have received ART or prophylaxis but are not currently receiving any ARV medications

In some instances, a pregnant woman has been on ART for her own treatment or for prophylaxis during a previous pregnancy and subsequently discontinued the medications. ARV drug-resistance testing should be conducted prior to initiating ART. The regimen should be chosen on the basis of previous ART experience and the reasons for stopping and results of past and current resistance testing, with avoidance of drugs and combinations with adverse maternal effects. The selection of an ART regimen for women with advanced HIV disease or a history of extensive prior therapy can be challenging, and consultation with an HIV specialist is

recommended. Principles of ARV selection are as described above.

For women who present late in pregnancy, ART should be started promptly, without waiting for results of resistance testing. The use of raltegravir during late pregnancy for women who have high viral loads has been suggested because of its ability to suppress viral load rapidly (an approximately 2-log₁₀ copies/mL decrease by week 2 of therapy). However, the efficacy and safety of this approach have not been evaluated and only anecdotal reports are available. Until more data become available on the safety of raltegravir use during pregnancy, this approach cannot be recommended for treatment-naïve women.

Intrapartum ZDV infusion should be given as described above if the HIV viral load is >400 copies/mL near the time of delivery.

HIV-infected women who have received no ARV before labor and their Infants

HIV-infected pregnant women who have not received ARV prior to labor should be given ZDV as a continuous infusion during labor. The mother's need for continuing ARV treatment postpartum should be evaluated. Infants born to women who had no ART during pregnancy should begin ARV prophylaxis as close to birth as possible. In addition to receiving ZDV for 6 weeks, the infant should also be given three doses of NVP in the first week of life (at birth, 48 hours later, and 96 hours after the second dose).

Pharmacokinetic Considerations During Pregnancy

Physiologic changes that occur during pregnancy (e.g., prolonged gastrointestinal transit time; increase in body fat and water; and changes in cardiac, circulatory, hepatic, and renal function) may affect the kinetics of drug absorption, distribution, and elimination. Few pharmacokinetic studies have been conducted on levels of ARVs during pregnancy, but available data suggest that altered dosing for some PIs (e.g., atazanavir/ritonavir,

darunavir/ritonavir, lopinavir/ritonavir) may be required (see Table 5 of the *Guidelines*).

Special Circumstances

Hepatitis B Coinfection

Screening for HBV infection with hepatitis B surface antigen (HBsAg), hepatitis B core antibody (anti-HBc), and hepatitis B surface antibody (anti-HBs) is recommended for all pregnant women who have not been screened during the current pregnancy. The HBV vaccine series should be administered to pregnant women who screen negative for hepatitis B.

For pregnant women coinfecting with HIV and HBV, providers should treat both infections at once, by including a two-NRTI combination that is active against both infections. The NRTI combination tenofovir + 3TC or FTC is preferred for pregnant women with HIV/HBV, in combination with an NNRTI or PI. Liver transaminases should be monitored for signs of hepatotoxicity or HBV flare. Treatment may be complicated, and consultation with an expert is recommended. Also see the relevant discussion in the HHS *Perinatal ARV Guidelines*, and chapter *Hepatitis B Infection* in this manual.

HBV-infected pregnant women who are not immune to hepatitis A should be vaccinated. Infants born to coinfecting women should receive HBV immune globulin and start the HBV vaccine series within 12 hours after birth (with subsequent vaccine doses per usual protocol).

Hepatitis C Coinfection

Treatment for hepatitis C virus (HCV) is not recommended during pregnancy. Recommendations for ART during pregnancy are the same for women who are HIV/HCV coinfecting as for those without HCV coinfection. Liver transaminases should be monitored for signs of hepatotoxicity.

Coinfecting pregnant women should be tested for immunity to hepatitis A and HBV; if not

immune, they should be vaccinated. Infants born to coinfecting women should be evaluated for HCV infection.

See the relevant discussion in the HHS *Perinatal ARV Guidelines*, and chapter *Hepatitis C Infection* in this manual.

Safety and Toxicity of Antiretroviral Medications During Pregnancy

Limited data are available on the safety of ARVs during pregnancy, particularly when ARVs are used in combination. The existing safety and toxicity information is derived from animal and human studies, clinical trials, registry data, and anecdotal experience.

Several drugs are of special concern when used during pregnancy (see HHS *Perinatal ARV Guidelines*; Table 5), including the following:

- Efavirenz:** Efavirenz is classified by the U.S. Food and Drug Administration (FDA) as a Pregnancy Class D drug because malformations have occurred in monkeys receiving efavirenz during the first trimester. Several cases of neural tube defects in humans after first-trimester exposure to efavirenz have been reported. As mentioned above, the *Guidelines* state that alternative ARVs should be strongly considered in women who are planning to become pregnant or are not using effective contraception with male partners. For pregnant women who present for antenatal care in the first trimester, discontinuation of efavirenz is not necessary, because the risk of neural tube defects is limited to the first 5–6 weeks of pregnancy and pregnancy is rarely recognized before 4–6 weeks.
- Nevirapine:** Women, including pregnant women, who begin NVP therapy when their CD4 count is >250 cells/μL have nearly a 10 times higher incidence of hepatotoxicity than women initiated on NVP at lower CD4 counts. Symptoms of hepatotoxicity include fatigue, malaise, anorexia, nausea, jaundice, liver tenderness, and hepatomegaly. NVP should be initiated as part of an ARV

regimen for pregnant women with CD4 counts of >250 cells/ μ L only if the benefits clearly outweigh the risks (see Table 5 of the *Guidelines*). Women with higher CD4 cell counts who are already taking and tolerating NVP may continue it.

- **Didanosine + stavudine:** The combination of didanosine and stavudine may cause fatal lactic acidosis and hepatic steatosis and should be avoided unless no alternative is available. Patients may present with symptoms 1-6 weeks in duration that include nausea, vomiting, abdominal pain, dyspnea, and weakness; clinicians should be alert for early signs and symptoms of lactic acidosis and evaluate them promptly.

In addition, PIs have been associated with an increased risk of new-onset diabetes, worsening diabetes, and diabetic ketoacidosis. Of course, pregnancy itself is a risk factor for hyperglycemia. Clinicians should monitor the glucose levels of pregnant women taking PIs and should educate them about the symptoms of hyperglycemia. The HHS *Perinatal ARV Guidelines* recommend that pregnant women on ART should be screened with a standard 50 g glucose loading test at 24-28 weeks (see chapter *Care of HIV-Infected Pregnant Women*).

Information on ARV toxicity during pregnancy should be consulted carefully before treatment choices are made. The HHS *Guidelines* provide information on each ARV drug, including preclinical and clinical data, pharmacokinetic and toxicity data, and recommendations regarding use during pregnancy. These guidelines are updated routinely as information is received (see Table 5 and Appendix A of the *Guidelines*). Numerous other medications also are contraindicated for use during pregnancy, and potential toxicity should be considered carefully before any medication is given to a pregnant woman.

Adverse Events Related to ARV Drugs During Pregnancy

A number of studies have identified an increased risk (up to double) of preterm delivery in women who take combination therapy during pregnancy (whether started before or during pregnancy), while other studies have not. Given the conflicting data, the *Guidelines* advise clinicians to be aware of a possible small increased risk of preterm birth among women who receive ART. However, the benefit of ART for the mother's health and for prevention of perinatal transmission is clear, and combination ART should not be withheld. Until more is known, pregnant women who are taking combination regimens should be monitored closely for complications and toxicities and should be educated about the signs of premature labor.

Antiretroviral Pregnancy Registry

The Antiretroviral Pregnancy Registry collects observational data on HIV-infected pregnant women taking ARV medications to determine whether patterns of fetal or neonatal abnormalities occur. This is a project initiated by the pharmaceutical industry and overseen by an advisory committee comprising representatives from the CDC, National Institutes of Health, FDA, pediatric and obstetric providers, and others. Providers who care for pregnant women taking ARVs are encouraged to enroll patients in the registry at the time of initial evaluation. Information is confidential and patients' names are not used. More information can be obtained by visiting the registry website (www.apregistry.com/) or by calling 800-258-4263, 8:30 a.m. to 5:30 p.m. eastern time.

Intrapartum Management and Mode of Delivery

In 2012, a significant change was made in the *Guidelines* recommendation regarding intrapartum management of the woman with HIV infection. For women on ART with HIV

RNA levels of <400 copies/mL near delivery, IV ZDV during labor can be considered but is not required (though they should continue their usual ARV medications). IV ZDV is recommended for HIV-infected women with HIV RNA levels of ≥ 400 copies/mL (or with unknown viral loads) near delivery, regardless of antepartum regimen or mode of delivery. IV ZDV should be given to the woman during labor as a 1-hour loading dose of 2 mg/kg followed by a continuous infusion of 1 mg/kg per hour until delivery. Women on ART should continue their regimen on schedule as much as possible during labor, except that women receiving ZDV or a ZDV-containing fixed-dose combination whose viral load is ≥ 400 copies/mL should be given IV ZDV, with other components continued orally. For women on a stavudine-containing regimen, the stavudine component should be discontinued while IV ZDV is being administered.

For women on ART who have detectable viral load at the time of delivery, the addition of the single-dose NVP protocol (single dose to the woman during labor, single dose to the neonate) is not recommended in the United States, because clinical trials have not shown benefit and there is a risk of NVP resistance. For the neonate, an expanded infant prophylaxis regimen may be indicated (see “Follow-Up of HIV-Exposed Infants,” below).

Studies conducted before the availability of viral load testing found that cesarean delivery performed before the onset of labor or rupture of membranes significantly reduced the risk of perinatal transmission. However, in the United States and other settings where HIV-infected pregnant women typically receive potent combination ART, rates of HIV transmission rates are very low (<1%, unadjusted for mode of delivery) and it is difficult to determine whether delivery by cesarean section further decreases the risk of peripartum transmission.

For a woman with a viral load of <1,000 copies/mL, cesarean delivery is not routinely recommended; decisions on mode of delivery

should be individualized and based on discussions between the woman and her obstetric clinician. The woman and her health care providers should decide about mode of delivery before the onset of labor, based on her current viral load, her health status, and the outcome of discussions about other concerns, which should include counseling about the risks and benefits of cesarean delivery. If cesarean delivery is planned for standard obstetrical indications it should be scheduled for 39 weeks' gestation.

For a woman with HIV RNA levels of >1,000 copies/mL at or near the time of delivery, the HHS *Perinatal ARV Guidelines* and the American College of Obstetricians and Gynecologists recommend delivery by scheduled cesarean section at 38 weeks' gestation.

IV ZDV should be started 3 hours before a scheduled cesarean delivery. Prophylactic antibiotics are recommended at the time of cesarean delivery for HIV-infected women to decrease the risk of maternal infection.

It is not clear whether cesarean delivery provides any benefits in preventing perinatal HIV transmission once labor has begun or membranes are ruptured. Management of a woman for whom a scheduled cesarean was planned but who presents in labor or with ruptured membranes should be individualized on the basis of her HIV viral load, current ART regimen, length of time since membrane rupture, duration of labor, and other clinical factors.

The HHS *Perinatal ARV Guidelines* outline several scenarios in which the clinician must decide whether cesarean delivery is needed; see Table 8 of the *Guidelines* for further information. The data on the benefits of cesarean delivery are complex and must be considered alongside the increased risk to the mother after surgery. The clinician should consult an obstetric/HIV specialist to discuss specific situations.

A woman who presents in labor without a documented HIV status should receive an expedited HIV antibody test and, if the result is positive, should be presumed to be infected until the confirmatory HIV test result is received. She should receive IV ZDV immediately to prevent perinatal transmission, and her infant should start infant prophylaxis pending the mother's confirmatory results (see "Follow-Up of HIV-Exposed Infants," below). She will need confirmation and staging of her HIV infection (e.g., CD4 cell count, HIV RNA viral load) as well as referral to care for her own health and ongoing psychological support.

Questions remain about the management of labor when a vaginal delivery is planned. Because the duration of ruptured membranes is a risk factor for perinatal transmission, pregnant women with HIV infection should be counseled to go to a hospital for care at the first signs of labor or rupture of membranes. If the membranes rupture spontaneously before labor occurs or early in labor, the clinician should consider interventions to decrease the interval to delivery, such as administration of oxytocin. Procedures that potentially increase the neonate's exposure to maternal blood, such as the use of scalp electrodes or artificial rupture of membranes, should be avoided. Operative interventions with forceps or vacuum extractor and episiotomy should be performed only in select circumstances.

For management of postpartum hemorrhage owing to uterine atony, note that Methergine has significant interactions with PIs and with NNRTIs, and may interact with the pharmacokinetic booster cobicistat. Methergine should not be administered to women taking PIs, if possible. If alternative treatments are not available and Methergine must be used, it should be given at the lowest possible dosage and for the shortest possible duration. If Methergine is given to women taking NNRTIs, its dosage may need to be increased or additional uterotonic medications may be needed.

Postpartum Follow-Up of HIV-Infected Women

Women with HIV infection who have recently delivered need access to a comprehensive array of services for themselves and their infants. The clinician should refer the postpartum woman not only to her primary obstetric and HIV providers for family planning and HIV management but also to a pediatric HIV specialist for care of her infant. She should be referred as needed for mental health, substance abuse, and social support services. The clinician should be alert for indications of postpartum depression and should offer treatment promptly, if indicated. Adherence to ARV regimens may be particularly difficult for a woman in the immediate postpartum period because of postpartum physical and psychological changes and the demands of caring for a newborn; accordingly, the woman may require new or continued support services.

Women who are diagnosed through preliminary rapid HIV testing in labor will need thorough evaluation and management including confirmatory HIV testing and immediate linkage for medical and social services. They should not breast-feed unless the results of the confirmatory tests are received as negative.

Women should be evaluated regarding their ongoing need and desire for ART postpartum. Long-term ART generally should be recommended for all women, regardless of nadir CD4 count, in accordance with current HHS adult and adolescent guidelines. If ART was given only or primarily to reduce the risk of perinatal transmission, a discussion about continuing ART should include factors such as the woman's health status, her CD4 counts, the HIV status of her partner(s), and adherence issues. If the woman elects to discontinue ART postpartum, her need for treatment and willingness to restart ART should be reevaluated on an ongoing basis.

If ART is being discontinued, all drugs should be stopped at the same time if they have

similar half-lives. NNRTIs have longer half-lives than other agents, so an NNRTI should be discontinued for a period of time (the duration of this time has not been defined) before other ARVs, in order to avoid a period of NNRTI monotherapy and the development of NNRTI resistance mutations. Alternatively, a PI may be substituted for the NNRTI several weeks before stopping all the ARV agents. Note that, for women with HBV coinfection, discontinuation of NRTIs with anti-HBV activity (e.g., 3TC, emtricitabine, tenofovir) may result in a flare of HBV; consult with an expert before discontinuing ART.

Contraceptive counseling is an important aspect of postpartum care. Women should be offered dual-method contraception if pregnancy is not desired in the short-term future or if the ART regimen contains potentially teratogenic drugs such as efavirenz. Note that there are significant interactions between some hormonal contraceptives and PIs, NNRTIs, and elvitegravir/cobicistat. (See chapters *Care of HIV-Infected Pregnant Women* and *Health Care of HIV-Infected Women Through the Life Cycle*.)

Breast-feeding is not recommended in the United States or other parts of the world where replacement feeding is affordable, feasible, acceptable, sustainable, and safe. Women may experience culture-based and family pressure to breast-feed and may need support to use replacement feeding.

Follow-Up of HIV-Exposed Infants

The HIV-exposed neonate born to a mother with HIV infection should receive ZDV syrup at a dose based on the infant's gestational age. Infants at ≥ 35 weeks' gestation infant should be given ZDV syrup at a 4 mg/kg/dose PO BID, beginning as soon as possible after birth, preferably within 6-12 hours, and continuing for 6 weeks. Dosing for premature infants is detailed in the *Guidelines*. In the United States, the use of ARV drugs other than ZDV and NVP

cannot be recommended for premature infants because of lack of dosing and safety data.

Newborns should be discharged home with a supply of PO ZDV syrup. The use of ZDV for the neonate is recommended regardless of whether the mother has a history of resistance to ZDV. Two-drug therapy – specifically, ZDV by standard protocol for 6 weeks plus 3 doses of NVP given at birth, 48 hours later, and 96 hours after the second dose – is recommended for infants of mothers who did not receive ART before delivery or received ZDV only intrapartum. Few data are available to guide use of other combination therapies for neonates; consult with a pediatric HIV expert. Every HIV-exposed infant should be referred to a pediatric HIV specialist for diagnostic testing and monitoring of health status.

For an infant born to a mother whose HIV status is unknown, expedited HIV testing of the mother or the infant should be done as soon as possible. If the result for either is positive, ZDV prophylaxis for the infant should be started immediately. A confirmatory HIV test (e.g., Western blot) should be done at the same time and prophylaxis should be discontinued if the result is negative. If positive, the infant should be tested with an HIV DNA polymerase chain reaction (PCR) assay or an HIV RNA assay. If the newborn's HIV viral load test result is positive, prophylaxis should be discontinued and the infant should be referred urgently to a pediatric HIV specialist for management of HIV infection using combination ART.

Traditional HIV antibody testing cannot be used with infants because maternal antibodies may persist for up to 18 months. Diagnosis of HIV infection in infants requires virologic testing (HIV DNA or HIV RNA). Virologic testing should be performed by age 14-21 days, then at 1-2 months, and at 4-6 months. HIV can be diagnosed in an infant on the basis of two positive results from virologic tests done on separate blood samples at any time.

HIV can be excluded presumptively in an infant with two or more negative results from virologic tests, with one done at ≥ 14 days of age and one done at ≥ 1 month of age, or one negative virologic test result at ≥ 2 months of age, or one negative HIV antibody test result at ≥ 6 months of age. HIV can be excluded definitively with two or more negative virologic test results, with one test done at age ≥ 1 month and one done at ≥ 4 months. However, these tests may not be accurate in infants who are receiving combination ART. Some experts recommend retesting, using an antibody test, at age 12-18 months as a confirmatory test.

Infants should have a baseline complete blood count and differential and should be monitored for anemia while they are taking ZDV. Monitoring for anemia should be based on the infant's gestational age, ZDV dose, clinical condition, and maternal ARV history. Infants on ZDV/3TC prophylaxis should have a hemoglobin and neutrophil count at 4 weeks after initiation of ARVs.

Pneumocystis jiroveci pneumonia (PCP) prophylaxis for HIV-exposed infants is recommended starting at 6 weeks when the ZDV prophylaxis regimen is completed and continued until they are determined presumptively or definitively to be HIV seronegative. Initiation of PCP prophylaxis should be stopped or avoided altogether when HIV has been presumptively excluded.

Parents and family caregivers must be taught how to monitor the infant for signs of illness until an HIV diagnosis is made or ruled out. They also need to know that the infant's exposure to ARV agents in utero is an important part of the infant's medical history and should be shared with future health care providers. Although no enduring consequences of ARV exposure have been confirmed, the child may be at risk of long-term problems.

Patient Education

- The clinician should provide the pregnant woman with the most current information on the risk of perinatal HIV transmission and the importance of ARV prophylaxis.
- The clinician and the patient should have a detailed discussion about ART, both for the patient's own health and for decreasing the risk of perinatal transmission.
- The clinician should review with the patient the critical importance of her adherence to ART regimens before prescribing a regimen.
- The clinician should review possible adverse effects of the ARVs and give the patient specific instructions about managing them if they are mild or seeking medical advice if they are more serious, such as ongoing fatigue, persistent nausea and vomiting, or signs of hyperglycemia.
- The clinician should explain the signs and symptoms of early labor to the patient and emphasize the importance of seeking medical care if she has signs and symptoms of early labor or premature rupture of membranes.
- Early in the third trimester, the clinician and the patient should discuss the risks and potential benefits of cesarean section based on her viral load and clinical status.
- Intrapartum management, including the possible need to use intrapartum ZDV, should be discussed with the patient so that she knows to tell the delivery team about her HIV status when she presents in labor.
- The clinician should discuss infant feeding plans with the mother and reinforce that she should not breast-feed. The clinician may need to provide ongoing support for formula feeding.
- The clinician should advise HIV-infected mothers against premastication of the infant's food and promote safer feeding options.

- The clinician should discuss follow-up plans and make referrals for the patient and her infant. If possible, the woman should meet the pediatric HIV team before delivery or in the postpartum period. The importance of ARV prophylaxis and follow-up for the newborn should be emphasized.

Care of HIV-Infected Pregnant Women

Background

This chapter describes the elements involved in caring for the pregnant woman with HIV infection, whether the woman was known to be HIV infected before conception or was found to be HIV infected during pregnancy. It is not intended to be a comprehensive discussion of this topic, and an HIV-experienced obstetrician and an HIV specialist should be involved in the management of all HIV-infected pregnant women. For centers that do not have HIV specialists available, experts at the National Perinatal HIV Consultation and Referral Service are available for consultation through the Perinatal HIV Hotline (888-448-8765).

The goals of HIV management during pregnancy are to maintain and support the woman's health, provide optimal antiretroviral treatment (ART) to preserve or restore her immune system and suppress viral replication, and to offer interventions that decrease the risk of perinatal HIV transmission. According to the U.S. Department of Health and Human Services perinatal guidelines, *Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*, all HIV-infected pregnant women should be given ART during pregnancy to prevent mother-to-child transmission of HIV, and ART also is recommended for all women for their own health, regardless of pregnancy status (see chapter *Reducing Perinatal HIV Transmission*).

The first task in caring for an HIV-infected woman who is pregnant or considering pregnancy is to provide counseling that will allow her to make informed reproductive choices. Taking a careful reproductive history and providing preconception counseling should be part of any woman's routine primary care. To make informed choices about pregnancy, the patient needs education and information about the risk of perinatal transmission of HIV, potential complications of pregnancy, continuation or modification (or possibly, initiation) of ART, and the support she will need to optimize maternal and fetal outcomes. See chapter *Health Care of HIV-Infected Women Through the Life Cycle* for a more detailed discussion of preconception evaluation.

An appropriate ART regimen should be started before pregnancy to attain a stable, maximally suppressed maternal viral load prior to conception. This will support the woman's own health and greatly reduce the risk of HIV transmission either to a fetus or to a sex partner. Antiretroviral (ARV) resistance testing should be performed before ART is initiated. For women who intend to conceive, particular ARVs should be avoided, including those with increased risk of causing teratogenicity (e.g., efavirenz) or metabolic complications such as lactic acidosis (e.g., didanosine and stavudine). See chapter *Reducing Perinatal HIV Transmission*. It should be noted that most fetal organogenesis occurs in the early weeks of pregnancy, before most women know that they are pregnant. Thus, any medication with potential teratogenicity or fetal toxicity, whether an ARV or another drug, should not be administered to women who intend to become pregnant or may become pregnant. Certain medications (e.g., ribavirin) also should be avoided by male partners of women who may become pregnant.

Folate supplementation to reduce the risk of neural tube defects in the developing fetus should be started at least 1 month before conception, if possible, because the neural tube forms in the early weeks of pregnancy (see below).

Evaluation and Counseling of Pregnant Women

All HIV-infected pregnant women should receive thorough education and counseling about perinatal transmission risks, strategies to reduce those risks, and potential effects of HIV infection or HIV treatment on the course or outcomes of pregnancy.

- The goals of therapy for pregnant women receiving ART, as for all persons being treated for HIV infection, are to suppress the HIV viral load maximally (preferably to undetectable levels) for as long as possible, to improve quality of life, to restore or preserve immune function, and to prevent transmission to sexual (or injection drug equipment-sharing) partners. For pregnant women, an additional, and critical, goal is to reduce the risk of perinatal transmission as much as possible.
- Therapy-associated adverse effects, including hyperglycemia, anemia, and hepatic toxicity, may have a negative effect on maternal and fetal health outcomes. Pregnant women should be advised about possible ARV-related adverse effects and should be monitored regularly for these events.
- HIV-infected women should receive evaluation and appropriate prophylaxis for opportunistic infections (OIs), as well as the vaccinations indicated for persons with HIV infection (see below).
- Some medications, both ARVs and other drugs, may cause fetal anomalies or toxicity when taken during pregnancy. These should be avoided in pregnant women, unless the anticipated benefit outweighs the risk. Consult with an HIV or obstetric specialist, a pharmacist, or the drug labeling information before prescribing medications for pregnant women.
- Options for mode of delivery should be discussed early. The benefits and risks of vaginal vs. cesarean delivery are outlined in the perinatal guidelines. If the HIV viral

load is >1,000 copies/mL at 36 weeks of pregnancy, a scheduled cesarean delivery at 38 weeks' gestation is recommended to further reduce the risk of transmission.

Other evaluation and support measures for pregnant women should include the following:

- Screening for other potential maternal health problems, such as diabetes and hypertension
- Maternal nutritional evaluation and support, including initiation of a prenatal multivitamin containing folate (0.4 mg PO QD) to reduce the risk of fetal neural tube defects; for women receiving trimethoprim-sulfamethoxazole, some experts recommend higher folate doses in the first trimester; consult with an HIV-experienced obstetric specialist.
- Screening for psychiatric and neurologic disease
- Counseling about the risks of tobacco smoking; smoking cessation support as indicated (see chapter *Smoking Cessation*)
- Counseling about the risks of alcohol or drug use and support for discontinuation of these activities as needed
- Intimate partner violence screening
- Review of medications, including over-the-counter and nutritional agents, and discontinuation of medications with the potential for fetal harm
- Immunizations (e.g., influenza, Tdap, hepatitis B) as indicated
- Institution of the standard measures for evaluation and management (e.g., assessment of reproductive and familial genetic history, screening for infectious diseases or sexually transmitted diseases [STDs])
- Planning for maternal-fetal medicine consultation, if desired or indicated
- Selection of effective and appropriate postpartum contraceptive methods, if desired

Comprehensive Care of Pregnant Women with HIV Infection

Comprehensive care is important for pregnant women with HIV infection to achieve a healthy pregnancy and delivery. A multidisciplinary approach is the most effective way to address the medical, psychological, social, and practical challenges. For example, while her medical care is being managed by her obstetrician and an HIV specialist, the pregnant woman may need help from a social worker to find appropriate social services for food, housing, child care, and parenting issues. The pregnant woman may need counseling and psychological support for herself and her partner, as well as referrals for substance abuse and detoxification programs. Peer counselors may be of particular assistance. Some patients may need legal or domestic violence services during and after pregnancy. Cooperation and communication between the obstetrician or nurse/midwife and the primary HIV provider are imperative throughout the pregnancy and early postpartum period. Referral to a maternal-fetal medicine specialist may be needed in complicated obstetric cases.

Prenatal Care

All pregnancy-related complications seen in HIV-uninfected women, such as hypertensive disorders, ectopic pregnancy, psychiatric illness, multiple gestation, preterm delivery, and STDs, also can occur in HIV-infected women. These problems must be recognized quickly and treated appropriately to avoid life-threatening complications. Ideally, HIV-infected pregnant women are managed by both an experienced obstetrician-gynecologist and an HIV specialist. Communication between these specialists about medications, expectations, and complications is vital for the health and well-being of both mother and baby. If complications occur or abnormalities are detected, they should be evaluated and treated as indicated by the condition, and referral should be made to a maternal-fetal medicine specialist, if possible. Antenatal fetal surveillance and testing to identify fetal abnormalities should be carried out using guidelines established by the American College of Obstetricians and Gynecologists.

The suggested testing and monitoring practices for pregnant women with HIV infection, from the first trimester to labor and delivery, are presented in Tables 1 and 2.

Table 1. Recommended Evaluation and Routine Monitoring of the Pregnant Woman with HIV Infection

Evaluation		Frequency
History		
HIV History	Date of diagnosis	Initial
	Signs and symptoms	Initial and at every visit
	Nadir CD4 and current CD4 cell count; HIV viral load	Initial
	ARV history, including regimen efficacy, toxicity, and ARV resistance	Initial
	Opportunistic infections and malignancies	Initial and at every visit
	History of STDs	Initial
	Adherence	Initial and at every visit
Obstetric History	Number of pregnancies; complications and outcomes (GPAL [gravida, para, abortion, living children]); mode of deliveries	Initial
	History of genetic disorders	Initial
	Use of ARV prophylaxis during previous pregnancies	Initial
	HIV status of children	Initial
Current Pregnancy	Last menstrual period (LMP)	Initial
	Pregnancy: intended or not	Initial
	Contraceptive methods used, if any	Initial
	Gestational age (can be calculated in a woman with regular menses by counting weeks from LMP)	Initial and at every visit
	Estimated date of delivery	Initial
	Signs or symptoms of maternal complications: elevated blood pressure, headache, significant edema, gastrointestinal or genitourinary symptoms, vaginal discharge or bleeding, decreased fetal movement (fetal movement is usually first detected at 18-24 weeks of pregnancy)	Initial and at every visit
	Screen for depression	Initial
	Screen for intimate-partner violence	Initial and at every visit

Evaluation		Frequency
Physical Examination		
General	Vital signs and weight	Initial and at every visit
	Funduscopy, breast examination	Initial and as indicated
Gynecologic/ Obstetric (usually performed by the obstetric provider)	Pelvic examination, STD screening, examination for perineal or vaginal lesions (discoloration, condyloma, ulcerative lesions, vaginal discharge), cervical lesions, discharge or bleeding	Initial and as indicated
	Fundal height, correlating with gestational age (concordant between 18 and 30 weeks)	Every visit starting the second trimester
	Fetal heart beat and rate: may be audible with Doppler devices as early as 12 weeks	Initial and at every visit
	Fetal movements and position in third trimester	Every visit starting at 24 weeks
Laboratory and Other Studies		
HIV	HIV antibody test (if not already documented)	Initial
	HIV viral load and CD4 count (total and percentage); results obtained at 35-36 weeks guide decisions on the mode of delivery	Viral load at initial visit, 2-4 weeks after starting or changing ART, every 4 weeks until undetectable, then at least every 3 months CD4 count at initial visit and at least every 3 months
	Genotype if ARV naive or detectable HIV RNA while on ART	Initial and as indicated
	Cytomegalovirus (CMV) immunoglobulin G (IgG)	Initial
	<i>Toxoplasma</i> IgG	Initial
	G6PD level in appropriate ethnic or racial groups if PCP prophylaxis with dapsone is anticipated	Initial
General	Complete blood count (CBC)	Initial and every 3 months or more frequently, based on ARV regimen or symptoms; check weeks 24-28
	Chemistries, liver enzymes (LFTs)	Initial and every 3 months or more frequently, based on ARV regimen or symptoms If on NRTIs, monitor electrolytes and hepatic enzymes monthly in third trimester
	Fasting lipids and glucose	Initial and as indicated
	Blood group	Indicated
	Rh antibody screen	Indicated

	Evaluation	Frequency
Pregnancy Specific	Ultrasound	First trimester: confirm gestational age and potential timing for cesarean delivery if necessary Second trimester: assess fetal anatomy for women on combination ART during first trimester
	Screening for chromosomal abnormalities	Screen for neural tube and abdominal wall defect, trisomy 21, and trisomy 18; first-trimester testing may include laboratory and ultrasound exam, whereas patients in their second trimester are evaluated by multiple marker screening Abnormal result requires further investigation – consider amniocentesis only if abnormality is detected on multiple marker screening or level-2 sonogram and the woman is on suppressive ART (to decrease risk of HIV transmission); voluntary and requires counseling
	Diabetes screening	Consider at 20 weeks; check glucose 1 hour after 50 g glucose load; perform 3-hour glucose tolerance test if screen is abnormal If 3-hour test result is abnormal, perform regular glucose monitoring, especially in women taking protease inhibitors (PIs)
	Rubella antibody	Initial
	Varicella IgG for those without history of chickenpox or shingles	Initial
	Screening for syphilis: rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL)	Initial and during weeks 32-36
	Consider bacterial vaginosis (BV) screening (BV increases risk of preterm labor)	Week 24-28
	Screening for streptococcus B (if result is positive, intrapartum chemoprophylaxis is indicated)	Week 32-36
	Screening with herpes simplex virus-2 serology in high-risk patients is recommended by some experts	Initial
	Urinalysis and clean-catch urine culture	Initial and as indicated
	Papanicolaou test	Initial and as indicated (colposcopy is done on pregnant women, but biopsy is avoided; management resumes postpartum, after the 6-week postpartum visit)

	Evaluation	Frequency
Hepatitis Serologies	Hepatitis A virus (HAV) antibody (IgG)	Initial
	Hepatitis B virus (HBV): HBsAg, HBcAb , HBsAb	Initial
	Hepatitis C virus (HCV) antibody	Initial
TB Screening	Tuberculin skin test (purified protein derivative [PPD]), more reliable if CD4 count is >200 cells/ μ L (induration >5 mm is positive); or interferon-gamma release assay (IGRA); note there is limited experience with IGRAs in pregnant women	Initial
Disease Specific	Consider hemoglobin electrophoresis, if anemic or at increased risk of hemoglobinopathies	Initial
	Serum screening for Tay-Sachs disease – both partners – if at increased risk	Initial
	Urine toxicology screen	Initial and as indicated

Table 2. Recommended Evaluation and Routine Monitoring of the Pregnant Woman with HIV Infection: Labor and Delivery

Test	Comment
Record Review	- Documentation of HIV serostatus, blood type and Rh, hepatitis serologies, RPR - Review of ART, if any, during pregnancy - Review of HIV viral load results during pregnancy
Physical Evaluation	- Vital signs and fetal heart rate - Frequency and intensity of contractions - Fetal lie, presentation, attitude, and position - Vaginal examination: rule out HSV lesions; detect ruptured membranes; determine cervical effacement, dilatation, and position - Avoid procedures that increase risk of perinatal HIV transmission (e.g., fetal scalp electrodes, scalp sampling, or assisted rupture of membranes)
Admission Laboratory Tests	- Complete blood count - Liver function tests - RPR or VDRL, if not done recently - Repeat hepatitis B and C testing, if at risk of acquisition of hepatitis B or C, to prevent perinatal transmission of these infections - Others, as required by specific state laws

Immunizations and Opportunistic Infection Prophylaxis

Immunizations During Pregnancy

Generally, immunizations should be given before pregnancy, if possible. However, immunizations should be considered during pregnancy when the risk of exposure to an infection is high, the risk of infection to the mother or fetus is high, and the vaccine is unlikely to cause harm. The inactivated influenza virus and Tdap vaccines both meet this criteria and are generally recommended during pregnancy, as are certain others (see Table 3). Some vaccinations (particularly live-

virus vaccines such as measles/mumps/rubella and varicella vaccines) are contraindicated, and others should be given only if the anticipated benefit of the vaccination outweighs the risk. Special considerations for immunizations in HIV-infected individuals are discussed in chapter *Immunizations for HIV-Infected Adults and Adolescents*.

Because vaccinations may cause a transient increase in the HIV viral load and theoretically may increase the risk of perinatal HIV transmission, vaccination should be given after pregnant women are on ART.

Table 3. Immunizations and Postexposure Prophylaxis in Pregnant Women with HIV Infection

Immunization	Comment
Hepatitis A virus (HAV)	Recommended for susceptible patients at risk of becoming infected, those with chronic HBV or HCV, those traveling to endemic areas, injection drug users, and those in the setting of a community outbreak.
Hepatitis B virus (HBV)	Generally recommended for susceptible patients at risk of HBV infection during pregnancy.
Human Papilloma Virus (HPV)	Not recommended during pregnancy.
Influenza	Inactivated influenza vaccine is recommended for all pregnant women, before or during flu season. Live attenuated vaccines should not be used.
Measles/Mumps/Rubella (MMR)	Contraindicated.
Pneumococcus	Generally recommended. Limited data on safety during pregnancy for both the PPSV23 and PCV13 vaccines: no reports of adverse effects with PPSV23; limited experience with PCV13.
Tetanus-diphtheria-pertussis (Tdap)	Recommended during each pregnancy. Can be given at any time in pregnancy, but optimally between 27 and 36 weeks' gestation (to maximize maternal antibody response and passive antibody transfer to the infant). In addition, family members and caregivers should receive Tdap vaccination.
Varicella • Primary vaccination • Zoster vaccination	Contraindicated

Immunization	Comment
Immune globulins (for postexposure prophylaxis in susceptible individuals)	
Measles	Recommended after measles exposure.
Hepatitis A	Recommended after exposure (close contact or sex partner), or in case of travel to endemic areas.
Varicella-zoster virus immune globulin (VariZIG)	Recommended for susceptible individuals after close contact with someone with varicella or herpes zoster (give as soon as possible, and within 10 days of exposure).
Hepatitis B immune globulin (HBIG)	Recommended for susceptible individuals after needlestick or sexual exposure to a person with hepatitis B infection.

Opportunistic Infection Prophylaxis

Some OIs can have an adverse effect on pregnancy. In turn, pregnancy can affect the natural history, presentation, treatment, and significance of some OIs. Women should be monitored carefully for OIs during pregnancy, with special attention given to nonspecific symptoms such as fatigue, back pain, and weight loss, which may be attributable to HIV-related illness rather than to pregnancy. Respiratory symptoms in particular merit rapid, aggressive investigation. Clinicians should follow the most current recommendations of the U.S. Centers for Disease Control and Prevention (CDC), National Institutes of Health, and Infectious Diseases Society of America, *Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents*, which give special consideration to pregnant women for each OI discussed. The indications and recommendations for OI prophylaxis generally should follow the guidelines for adults (see chapter *Opportunistic Infection Prophylaxis*). However, because of the risks of teratogenicity or harm to the developing fetus, some drugs routinely used for prophylaxis of OIs in nonpregnant adults are contraindicated during the first trimester of pregnancy, whereas others should not be used at any time during pregnancy.

Special Considerations for OI Prophylaxis During Pregnancy

Trimethoprim-sulfamethoxazole use

In pregnant women, folate deficiency increases the risk of neural tube defects in the developing fetus. Trimethoprim inhibits the synthesis of metabolically active folic acid and thus increases the risk of folate deficiency and congenital anomalies. Pregnant women, or women who may become pregnant, who are taking trimethoprim-sulfamethoxazole (TMP-SMX, Septra, Bactrim, cotrimoxazole) should be given folate supplementation to reduce the risk of neural tube defects. However, folate also counteracts the activity of TMP, and may compromise the therapeutic efficacy of TMP-SMX. The recommended dosage of folic acid usually is 0.4 mg/day, but the optimal dosage in women on TMP-SMX is not clear. Some experts recommend higher dosages during the first trimester, when the fetus is at greatest risk for teratogenic effect. TMP-SMX is the recommended drug for women who require prophylaxis against PCP during pregnancy; alternatives to TPM-SMX during first trimester include aerosolized pentamidine and atovaquone.

Genital herpes

Women with HIV infection are more likely than HIV-uninfected women to experience outbreaks of genital herpes. If HSV is transmitted to the infant, neonatal infection can be severe, even if it is detected and treated early. In addition, there is increased genital shedding of HIV in those with active genital HSV lesions though it is not known whether this remains true in women treated with effective ART. Some experts recommend obtaining HSV-2 serologies in a woman whose clinical history is unclear. Treatment for symptomatic HSV infections should be offered during pregnancy, and suppressive therapy should be given to women with frequent recurrences. Suppressive therapy with acyclovir or valacyclovir also should be offered to any woman with an HSV recurrence during pregnancy, starting at 36 weeks' gestation. If a woman has an active outbreak of genital HSV or experiences prodromal symptoms at the time of labor or membrane rupture, delivery by cesarean section is indicated. Prophylaxis for pregnant women who are seropositive for HSV-2 but who do not have a history of genital lesions is not recommended.

Tuberculosis

Prophylaxis is recommended for any woman with a positive PPD skin test result (≥ 5 mm induration), a positive IGRA result, or a history of exposure to someone with active tuberculosis, after active disease has been ruled out. Patients receiving isoniazid also should receive pyridoxine to reduce the risk of neurotoxicity.

Toxoplasmosis

All HIV-infected persons should be tested for IgG antibodies to *Toxoplasma* soon after HIV diagnosis, and this should be a part of antenatal testing for pregnant women with HIV infection. Women with a negative IgG titer should be counseled to avoid exposure to *Toxoplasma* (e.g., by avoiding raw or undercooked meats, unwashed or uncooked

vegetables, and cat feces). Women with previous exposure to *Toxoplasma* (positive IgG titer) should be given prophylaxis during pregnancy, if the CD4 count is <100 cells/ μ L. For women who require prophylaxis, TMP-SMX is the preferred agent (see considerations for TMP-SMX, above).

HIV-infected pregnant women who have evidence of primary or reactivated *Toxoplasma* infection should be managed by a specialist.

Antiretroviral Therapy

The current HHS guidelines recommend treating HIV infection in all pregnant women, using the same principles and modalities as used for nonpregnant individuals. HIV-infected pregnant women should receive potent combination ART regimens comprising at least three ARVs. The choice of ARV regimen should be based on what is likely to be optimal for the woman's health, the potential effect on the fetus and infant, resistance test results, the woman's previous experience, if any, with ART, and her stage of pregnancy. ARV resistance testing should be performed before initiating or changing therapy, but should not delay the initiation of ART in late stages of pregnancy. Combination ART in pregnancy should include ZDV or another NRTI with good placental passage. ARV agents with potential teratogenic effects should be avoided in the early weeks of pregnancy (however, efavirenz may be continued during pregnancy, provided the regimen is tolerated and is providing effective virologic control). Women who have very high CD4 cell counts and are taking ART only for the prevention of perinatal transmission may delay initiation of therapy until after the first trimester, though effectiveness in preventing transmission may be decreased. For women already taking ART at the time they become pregnant, the regimen should be reevaluated for its appropriateness during pregnancy to avoid potentially toxic medications and to ensure maximal virologic

suppression. Generally, any ART regimen that is effective and tolerated by the woman may be continued during pregnancy. If necessary, the ART regimen may be changed but therapy should continue without interruption.

Discontinuation of ART could lead to an increase in viral load, which could result in a decline in immune status and an acceleration of disease progression, thereby increasing the risk of HIV transmission to the fetus.

For further information about ART during pregnancy, see chapter *Reducing Perinatal HIV Transmission* and the HHS *Perinatal ARV Guidelines*. The guidelines include recommendations regarding ARV regimens, modes of delivery (vaginal vs. cesarean section), and potential adverse events, as well as a detailed discussion of individual ARV agents. Additionally, the treatment of pregnant women with HIV/HBV coinfection and HIV/HCV coinfection is discussed.

Antiretroviral Pregnancy Registry

To improve tracking of pregnancy-related adverse events and fetal effects, an Antiretroviral Pregnancy Registry has been established as a collaborative project among the pharmaceutical industry, pediatric and obstetric providers, the CDC, and the National Institutes of Health. The registry collects observational data on HIV-infected pregnant women taking ARV medications to determine whether patterns of fetal or neonatal abnormalities occur. Pregnant women taking ARVs can be placed in this confidential follow-up study by calling 800-258-4263, 8:30 a.m. to 5:30 p.m. eastern time; the fax number is 800-800-1052. Information is confidential and patients' names are not used. Providers are encouraged to add to the available information on fetal risk by using this registry at first contact with a pregnant woman receiving ART. More information can be obtained at www.APRRegistry.com.

Pregnancy-Specific Complications and Management

Nutrition risk and inadequate weight gain

Maternal nutrition and weight must be monitored throughout the pregnancy. A food diary may be a useful tool in assessing intake, and nutritional counseling is recommended.

Nausea and vomiting

Women with signs of dehydration should be assessed and treated appropriately in collaboration with the obstetrician or nurse/midwife. Any medication used for nausea and vomiting must be assessed for drug-drug interactions with all HIV-related medications the patient is taking.

Hyperglycemia

Pregnancy is a risk factor for hyperglycemia, and women treated with PIs may have an even higher risk of glucose intolerance than other pregnant women and must be monitored carefully. New-onset hyperglycemia and diabetes mellitus, and exacerbation of existing diabetes, all have been reported in patients taking PIs. Clinicians should educate women taking PIs about the symptoms of hyperglycemia and closely monitor glucose levels. Women with HIV-infection should receive standard glucose screening at 24-28 weeks' gestation. Women who were taking a PI-based regimen prior to pregnancy may be screened earlier according to recommendations for women at high risk of glucose intolerance. The newborn should be checked for neonatal hypoglycemia at 1 and 4 hours after birth.

Lactic acidosis

Lactic acidosis is a rare but life-threatening complication that has been reported in pregnant women taking nucleoside reverse transcriptase inhibitors, particularly didanosine and stavudine. The combination of didanosine and stavudine should be avoided during pregnancy. Clinical suspicion

of lactic acidosis should be prompted by vague symptoms such as malaise, nausea, or abdominal discomfort or pain.

Hyperbilirubinemia

Women taking atazanavir or indinavir frequently develop elevated indirect bilirubin, but it is not known whether treatment during pregnancy exacerbates physiologic hyperbilirubinemia in newborns. Women who are taking indinavir may have an increased risk of nephrolithiasis, but evidence of harm to their newborns has not been demonstrated. Indinavir should be used during pregnancy only when preferred and alternative agents are not acceptable, and it must be boosted with low-dose ritonavir.

Pain management

Pain management during labor and delivery may be complicated by drug interactions with ARV agents and by the higher medication tolerance in women who have addictions. Additional pain medication may be needed for women with histories of drug use.

Invasive perinatal procedures

The risk of HIV transmission to the fetus during invasive procedures (e.g., amniocentesis, chorionic villus sampling, and percutaneous or umbilical cord blood sampling) must be weighed carefully against the possible benefits of these procedures. Current HHS guidelines suggest that women undergoing such procedures should be on effective ART, preferably with undetectable HIV RNA. The use of fetal scalp electrodes and artificial rupture of membranes should be avoided if possible, and forceps or vacuum extractors and episiotomy should be used only if there are clear obstetric indications.

Postpartum considerations

Because HIV can be transmitted to the infant through breast-feeding, breast-feeding is contraindicated in the United States and other resource-adequate countries where safe

replacement feeding is available. Breast-feeding information should be removed from patient educational material pertaining to labor and delivery. Lactation suppression techniques can be used as needed to reduce lactation discomfort. Clinicians should recognize that women in some cultural groups are expected to breast-feed and they may need additional support to use formula rather than breast-feed.

ART should be continued, unless the woman refuses ARVs. Maternal and infant medication adherence must be discussed with the new mother. Adherence barriers for the mother during the postpartum period may be different from those during pregnancy (e.g., because of changes in daily routine, sleep/wake cycles, and meals).

New mothers should be observed carefully for signs of bleeding or infection.

If the mother's glucose tolerance test result was abnormal during pregnancy, she should be reevaluated 6-12 weeks postpartum and should be screened yearly for diabetes.

At the infant's 2-week follow-up visit, the HIV pediatric clinician should address the mother's concerns, screen for postpartum depression, assess adherence to her own and the infant's ARV medications, and ensure follow-up for the 6-week postpartum visit with the obstetric provider and soon thereafter with the primary HIV care provider. These visits provide an opportunity to address the woman's contraceptive needs and options, if this was not done previously (see chapter *Health Care of HIV-Infected Women Through the Life Cycle*).

Contraception

Many contraceptive choices are available for HIV-infected women; considerations are discussed in chapter *Health Care of HIV-Infected Women Through the Life Cycle*. Consistent condom use should be emphasized, and for women who wish to avoid pregnancy a "dual-protection" strategy, condom use plus another method of birth control, should be

emphasized. This strategy effectively prevents pregnancy, prevents transmission of HIV to sex partners, and prevents the acquisition of sexually transmitted diseases. It is important to provide women with all contraceptive options including long-acting reversible contraceptive methods such as the intrauterine device and implants.

Patient Education

- Reinforce regularly and clearly the notion that, when the mother cares for herself, she is caring for her infant. Talk with the patient about stress, the importance of adequate mild-to-moderate exercise, and sufficient rest.
- Emphasize that regular prenatal care is extremely important to prevent complications of pregnancy.
- Use of a prenatal vitamin supplement is important, but cannot replace healthy food intake. Develop a plan with the patient for attaining the desired weight gain during pregnancy, while maintaining a healthy nutritional intake.
- Cigarette, alcohol, and drug use contribute to poor maternal nutrition and can harm the developing fetus. Illicit drug use increases the risk of transmitting HIV to the infant. Injection drug use can transmit HBV, HCV, and CMV to the mother and to the baby. Encourage cessation of cigarette, alcohol, and drug use, and offer referrals for treatment, as needed.
- Be sure the woman understands all planned procedures and treatments and understands their potential risks and benefits both to herself and to the fetus.
- Discuss the risks and benefits (to the woman and fetus) of each medication to be taken during pregnancy, including those for which there are limited data on teratogenicity.
- Discuss ART as a benefit to the woman's health and as part of the strategy to reduce the risk of perinatal HIV transmission to the fetus or newborn. Also discuss the effect of ART on reducing risk of HIV transmission to sex partners.
- For women at risk, diligent use of “safer sex” during pregnancy is important for preventing infection with STDs and CMV, which can cause more complications when HIV is present. STDs can harm fetal development and may increase the risk of HIV transmission to the baby. New genital herpes infections during pregnancy can cause severe complications and even death in neonates.
- For women with negative *Toxoplasma* titers, explain the need to avoid undercooked meat, soil, and cat feces.
- Teach the pregnant woman how to obtain medical attention quickly at the first signs of OI or other complication. Discuss what to watch for and how to get help when emergencies arise in the evenings or on weekends or holidays.
- Help the patient clarify her child care options and support systems for raising a family.

Health Care of HIV-Infected Women Through the Life Cycle

Background

Women with HIV infection have the same reproductive and life cycle health needs and concerns as women without HIV infection. However, for women with HIV infection, certain gynecologic problems may be more common or more frequent. In addition, issues regarding antiretroviral therapy (ART), contraception, and preconception counseling require special attention. This chapter addresses some of the unique health care needs of HIV-infected women across the lifespan, from menarche through postmenopause, and describes the essential elements of care. For further information, see chapters *Reducing Perinatal HIV Transmission*, *Care of HIV-Infected Pregnant Women*, and *Antiretroviral Medications and Hormonal Contraceptive Agents*.

Epidemiology and Factors Affecting HIV Transmission

Heterosexual transmission of HIV is more efficient from man to woman than from woman to man. Transmission can occur through intact vaginal tissue; no damage to the vaginal lining is required. Women have specific risks of HIV acquisition at different phases of the lifespan:

- Young adolescents have immature genital tracts and increased cervical ectopy (increased vulnerability to HIV and other sexually transmitted diseases [STDs])
- Women of reproductive age may desire pregnancy and childbearing (potentially increasing risky sexual behaviors)
- Married or partnered women may be monogamous with male partners who have risk factors for HIV infection (women may lack awareness of partner's risk behaviors)
- Postmenopausal or posthysterectomy women may have vaginal atrophy (decreasing the anatomic barrier to HIV), or may have no fear of pregnancy or have a perception that they are at low risk of infection (increasing risky sexual behaviors)
- Additionally, woman-to-woman transmission may occur if risk factors are present

Psychosocial/Emotional Factors Unique to Women

Women may inherit social roles and responsibilities as caretakers for extended family members and often for friends, and may not give sufficient priority to their own medical care. Furthermore, heterosexual women frequently are faced with unequal power and socioeconomic relationships with their male partners. These women may be more likely to exchange sex for money, less likely to successfully negotiate protected sex, and less likely to leave a relationship they perceive as risky. They may be fearful about disclosing their HIV status.

Sexual abuse appears to increase the risk of HIV transmission to HIV-uninfected women. For HIV-infected women, intimate partner violence and sexual coercion appear to occur at about the same rates as for HIV-uninfected women (>60% in one review). However, HIV-infected women appear to be subjected to more frequent and more severe abuse. HIV-infected women should be screened for intimate partner violence and referred to intervention services, if indicated. The U.S. Centers for Disease Control and Prevention (CDC) and the U.S. Preventive Services Task Force recommend several screening tools (see "References," below). The Abuse Assessment Screen (AAS) is one tool recommended by the

CDC. It originally was intended for screening pregnant women but has since been used more widely.

Abuse Assessment Screen

- Have you ever been emotionally or physically abused by your partner or someone important to you?
- Within the last year, have you been hit, slapped, kicked, or otherwise physically hurt by someone? If yes, by whom? How many times?
- Since you have been pregnant, have you been hit, slapped, kicked, or otherwise physically hurt by someone? If yes, by whom? How many times and where?
- In the last year, has anyone forced you to have sexual activities? If so, whom? How many times?
- Are you afraid of your partner or anyone you listed above?

ART Issues Particular to Women

In general, women on ART have virologic and immunologic responses comparable to those of men; however, several studies have shown that women discontinue ART more frequently than men. Women have higher rates of adverse effects from a number of antiretroviral (ARV) medications, in part because serum levels of at least some ARVs are higher in women. Pregnancy may require changes in ART, either because of pharmacokinetic changes or because of toxicity. See Table 1.

Table 1: Special Considerations for Use of Antiretrovirals with Women

ARV Issues for Women	Considerations
ARV adverse effects	Some ARV adverse effects may be more severe in women: • Abacavir hypersensitivity • Anemia (zidovudine) • Bone loss, especially after menopause • Hepatotoxicity (nevirapine) • Lactic acidosis (particularly with stavudine + didanosine) • Lipoaccumulation: central fat accumulation in breasts, abdomen; lipoatrophy: face • Neuropathy (stavudine, didanosine) • Severe rash (nonnucleoside reverse transcriptase inhibitors [NNRTIs], darunavir, tipranavir)
Pregnancy	Teratogenicity: • Efavirenz (EFV) is associated with neural tube defects in primates with in utero exposure. Consider alternatives, if feasible, in women who 1) are planning to become pregnant or 2) are sexually active with male partners and not using effective contraception. In women who become pregnant while taking EFV, EFV may be continued because the risk of neural tube defects is restricted to the first 5-6 weeks of pregnancy and pregnancy is rarely recognized before 4-6 weeks of pregnancy. Efavirenz is classified by the U.S. Food and Drug Administration (FDA) as a Pregnancy Category D drug. Pharmacokinetic (PK) changes: • Serum levels of some ARVs may be decreased during pregnancy (e.g., unboosted protease inhibitors [PIs], and boosted PIs including atazanavir/ritonavir, darunavir/ritonavir, and lopinavir/ritonavir). • Some ARVs should be avoided and certain ARVs may require dosage adjustment in the third trimester. • PK studies in pregnancy are not available for some ARVs. See chapter <i>Reducing Perinatal HIV Transmission</i>
Contraception	There are significant interactions between some hormonal contraceptive agents and certain ARVs; see “Contraception,” below.

Baseline Reproductive History

Taking a careful reproductive history should be a part of routine primary care for any woman. Important information to gather includes the following:

- Age of menarche
- Menstrual history: last menstrual period (LMP), amenorrhea, menstrual irregularity, uterine fibroids, endometriosis
- Obstetrical history: G-P-A-L
- G (gravida, or number of pregnancies), P (parity, or number of births), A (abortion; number of miscarriages or terminations), L (number of living children)
 - Pregnancy complications and outcomes: full-term, premature births, mode of deliveries
 - Use of ART during pregnancy
 - HIV status of children
- Sexual activity: vaginal, oral, anal; condom use; number of partners; sex of partners; HIV status of partners
- Plans and desires for childbearing
- Contraception, past and current
- Date of last Papanicolaou (Pap) test and results; history of abnormal Pap test results
- Gynecologic procedures: colposcopy/biopsy, loop electrosurgical excision procedure (LEEP), cervical surgery, tubal ligation, partial or total hysterectomy; and indication for these

- History of STDs, bacterial vaginosis, vulvovaginal candidiasis, herpes, warts; especially recurrence
- Current symptoms: vaginal discharge, vulvar/vaginal/anal pain, dysuria, dyspareunia (pain with intercourse), lesions, intermenstrual bleeding, postcoital bleeding

Elements of Gynecological Care

Women with HIV infection should receive routine screening for gynecologic cancers and infections. The incidence, prevalence, and persistence of human papillomavirus (HPV) infection and cervical, vaginal, vulvar, and anal dysplasia are more common in women with HIV infection, especially among women with low CD4 counts. It is not clear that initiation of suppressive ART improves clinical outcomes of women with dysplasia (see chapter *Cervical Dysplasia*). Other common gynecological problems include recurrent yeast vaginitis, pelvic inflammatory disease; vaginal, vulvar, and anal warts; and perineal/perianal herpes.

Women also should be evaluated for risk of breast cancer, for contraceptive needs, and for preconception counseling

Table 2: Routine Gynecologic Screening and Counseling for Women

Medical Service	Comments
Cervical and anal cancer screening	Women with HIV infection should have more frequent screening than uninfected women: • Screen all HIV-infected women for cervical cancer (cervical Pap test) at initial visit, at 6 months, then annually unless abnormal. • For HIV-infected women (any age) with ASCUS or higher-grade abnormality, colposcopy generally is recommended; alternatively, the Pap can be repeated in 6-12 months. • Consider anal cancer screening (anal Pap test) for all HIV-infected women if high resolution anoscopy is available to evaluate abnormal findings. • See chapters <i>Cervical Dysplasia</i> and <i>Anal Dysplasia</i> • Perform pelvic examination. • Include vulvar and anal examination • Assess for potentially dysplastic lesions • CDC recommendations for HPV vaccination of children and young women should be followed.
STD screening	Gonorrhea, chlamydia, syphilis at least annually, and more frequently depending on risk factors or symptom exam findings
Breast cancer screening	Mammography • Mammogram every 1-2 years recommended for women 50-69 years of age • Consider annual mammogram for women 40-50 years of age • Consider starting earlier if risk factors are present • For women ≥ 70 years of age, decisions about whether to continue screening should take into account the woman's life expectancy and clinical status Clinical breast examination • Annually • Breast self-examination (BSE) monthly (assess technique)
Contraceptive counseling	• Assess life dynamics and need for contraception at every visit. • Stop only after hysterectomy or sterilization. • See "Contraception," below.
Preconception counseling	Annually or more often for all women of reproductive age • Ask about pregnancy desires at every visit • See "Preconception Counseling," below

Contraception

Many contraceptive choices are available for HIV-infected women; some considerations are presented in the table below. For more information about interactions between ARVs and hormonal agents, see chapter *Antiretroviral Medications and Hormonal Contraceptive Agents*. Depending on the woman's (and her partner's) risk factors, consistent condom use should be emphasized, with or

without other methods of contraception, to prevent the transmission of HIV and the acquisition or transmission of other STDs. Dual contraception (e.g., use of condoms plus additional contraception) is the optimal contraceptive strategy for serodiscordant heterosexual couples since it reduces the risk of transmission of HIV and other STDs as well as providing effective contraception.

Table 3: Advantages and Disadvantages of Various Contraceptives

Contraceptive Type	Advantages	Disadvantages
Barrier Methods		
Male and female condom	Only contraceptive method that also protects against transmission of HIV and STDs	- Requires partner cooperation and correct technique - High failure rate when used incorrectly or inconsistently
Diaphragm and cervical cap		- Requires correct technique - High failure rate when used incorrectly or inconsistently - Use of diaphragms with spermicide can disrupt the cervical mucosa, which may increase risk of HIV transmission to uninfected sex partners
Hormonal Methods*		
Oral	- Very effective contraception if used as prescribed - Lighter menstrual flow	- Do not prevent STD or HIV transmission - May have significant drug-drug interactions with PIs, some NNRTIs, and elvitegravir/cobicistat that may affect the efficacy and toxicity of estradiol or the progestin, and of certain PIs* - Alternative or additional methods recommended for women taking certain PIs or NNRTIs, or elvitegravir/cobicistat.
Injectable depot medroxyprogesterone acetate (DMPA, Depo-Provera)	- Effective contraception for 3 months - May cause amenorrhea	- Concern about osteoporosis with long-term use - Irregular bleeding, especially initially - Weight gain - Limited and conflicting data show possible increased risk of HIV transmission (from HIV-infected woman to male partner) or acquisition (by uninfected woman from HIV-infected man) for women on DMPA (note: no study participants were on ART)
Transdermal (patch)	- Effective contraception if used as prescribed - Lighter menstrual flow	No data on pharmacokinetic interactions with ARVs, but of possible significance; use same precautions as with oral hormonal agents (see above)
Vaginal ring	Effective contraception if used as prescribed	- Lighter menstrual flow - No data on pharmacokinetic interactions with ARVs, but of possible significance; use same precautions as with oral hormonal agents (see above)
Intrauterine devices (IUDs) (copper IUD and levonorgestrel-containing IUD)	- Effective for long-term use - No evidence of increased HIV viral shedding - Progestin-releasing IUD may cause lighter menstrual flow	- Possible blood loss with Copper T IUD - Insertion of IUD not recommended for women with advanced immunosuppression
Etonogestrel implant	- Effective - Amenorrhea	No data on pharmacokinetic interactions with ARVs, but of possible significance; Use same precautions as with oral hormonal agents (see above)

Contraceptive Type	Advantages	Disadvantages
Emergency contraception: - Levonorgestrel - Ulipristal acetate - Copper T IUD	- Effective - Appropriate for women who present 4-5 days after intercourse	- Efavirenz lowers levonorgestrel levels; use alternative method - No data on pharmacokinetic interactions with ARVs, but of possible significance; use same precautions as with oral hormonal agents (see above) - Heavy blood loss
Surgical Methods		
Bilateral tubal ligation (female)	Effective; permanent	- Does not prevent transmission of HIV or other STDs - No future fertility (usually not reversible)
Vasectomy (male)	Effective; permanent	- Does not prevent transmission of HIV or other STDs - No future fertility (usually not reversible)
Spermicides		
Spermicides		- Not currently recommended - Nonoxynol-9 causes mucosal damage to vagina - Do not prevent transmission of HIV or other STDs

Preconception Counseling

As discussed above, every visit with an HIV-infected woman in her reproductive years presents an opportunity to discuss pregnancy desires and options, including gathering information about her partner. It is important to assess the couple's sexual history, sexual decision making, and control of reproductive options. The goals of preconception counseling are to improve the health of the woman prior to conception and identify, and when possible intervene around, risk factors for adverse maternal and fetal outcomes. When a woman desires pregnancy, it is important to discuss the topics listed below, with the goals of educating her and decreasing risk of HIV transmission to an HIV-uninfected partner or to the fetus. Ideally, the partner will take part in the discussion.

- Options for conception that decrease risk of HIV transmission to an HIV-uninfected partner (see below)
- Recommendations for ART before and during pregnancy, at delivery, and postpartum

- Optimization of maternal health status and suppression of HIV viral load before pregnancy
- Effect of HIV and ARVs on pregnancy and outcomes
- Effect of non-HIV-related factors (e.g., age, drug use) and other medical conditions (e.g., hypertension, diabetes, depression) on pregnancy course
- Counseling on safer sexual practices
- Counseling on other aspects of health promotion (e.g., smoking and alcohol cessation, drug treatment)
- Perinatal HIV transmission risk and prevention: ARVs for mother and infant, mode of delivery, avoidance of breast-feeding
- Treatment and care of an HIV-exposed or HIV-infected infant
- Long-term planning including advance directives and guardianship of a child if one or both parents were to become ill or die

Any history of infertility or low fertility in either the patient or her partner should be

evaluated and options for having children should be discussed, including current information on gamete donation, other assisted reproductive techniques, and adoption.

If the heterosexual couple is serodiscordant, techniques to minimize the risk of transmission to the uninfected partner should be discussed. These same techniques should be explained to couples when both partners are HIV infected, if there is a risk of transmitting different HIV “strains.” Some of the recommended techniques include the following:

- If the male partner is HIV uninfected: the woman does self-insemination of ejaculate using a syringe (no HIV exposure risk to the male partner)
- Maximal suppression of the HIV viral load of the infected partner with ART
- Screening for and treatment of STDs
- Assisted reproductive technology
 - Sperm washing with polymerase chain reaction (PCR) testing and intrauterine insemination (IUI), in vitro fertilization (IVF), or intracytoplasmic sperm injection (ICSI), if the male partner is HIV infected and the female partner is HIV uninfected

The couple should be fully educated about other options, including the following:

- Preexposure prophylaxis (PrEP) for the uninfected partner
- Estimating the time of ovulation and limiting unprotected intercourse to this period, with or without use of PrEP. This approach should be considered only if HIV viremia is maximally suppressed and intercourse is limited to times when conception is most likely.
- Postexposure prophylaxis for an uninfected partner

The CDC has issued interim guidelines on use of PrEP by heterosexually active individuals as well as a fact sheet on PrEP (see “References,”). Both address the use of PrEP during attempts to conceive. Few clinical data are available at this time to guide practice; when treating serodiscordant couples who wish to conceive using PrEP, providers should review current guidelines and consult with experts in the field.

If an HIV-infected woman who is considering pregnancy initiates ART, an appropriate regimen should be started before pregnancy, avoiding agents with increased risk of teratogenicity (e.g., efavirenz), hepatotoxicity (e.g., nevirapine, in women with CD4 counts of >250 cells/ μ L), or metabolic complications such as lactic acidosis (e.g., didanosine and stavudine). See chapter *Reducing Perinatal HIV Transmission* and the U.S. Department of Health and Human Services *Perinatal HIV Guidelines* (see “References,” below). It should be noted that most fetal organogenesis occurs in the early weeks of pregnancy, before most women know that they are pregnant. Thus, any medication with potential teratogenicity or fetal toxicity, whether an ARV or another drug, should be avoided for use by women who are intending to become pregnant or who may become pregnant. Certain medications (e.g., ribavirin) should be avoided by male partners of women who may become pregnant.

Folate supplementation to reduce the risk of neural tube defects in the developing fetus should be started at least 1 month before conception, if possible, because the neural tube forms in the early weeks of pregnancy (see chapter *Care of HIV-Infected Pregnant Women*).

Menopause

There is evidence that HIV-infected women may be more likely to undergo premature physiologic menopause. Earlier onset of menopause also is associated with non-HIV factors such as ethnicity and a history of intravenous drug use. Menopausal women are more at risk of premature bone loss, osteopenia, and osteoporosis; this risk may be increased by HIV infection and certain ARVs. If indicated, bone density screening (DEXA) should be considered.

Hormone replacement therapy (HRT), especially of long duration, has been associated with an increased risk of breast cancer and cardiovascular and thromboembolic events, and its routine use is not recommended. HRT may be considered for women who experience severe vasomotor symptoms and vaginal dryness, but should be used only for a limited period of time and at the lowest effective dosage.

Palliative Care and HIV

Background

Palliative care is not curative care, but is supportive, symptom-oriented care. It may be needed at any point in the course of disease progression to relieve patients' suffering and promote quality of life. Palliative care is important for patients with any medical condition, even if they are not actively in hospice. It may be used in conjunction with disease-specific care or as the sole approach to care. Palliative care includes the following:

- Management of symptoms (e.g., fatigue, pain)
- Treatment of adverse effects (e.g., nausea, vomiting)
- Psychosocial support (e.g., depression, advance care planning)
- End-of-life care

The U.S. Health Resources and Services Administration (HRSA) HIV/AIDS Bureau Working Group on Palliative Care in HIV has provided the following working definition of palliative care:

Palliative care is patient- and family-centered care. It optimizes quality of life by active anticipation, prevention, and treatment of suffering. It emphasizes use of an interdisciplinary team approach throughout the continuum of illness, placing critical importance on the building of respectful and trusting relationships. Palliative care addresses physical, intellectual, emotional, social, and spiritual needs. It facilitates patient autonomy, access to information, and choice.

(Excerpted from: HRSA Working Group on HIV and Palliative Care.
Palliative and Supportive Care. HRSA Care ACTION, July 2000)

Palliative care for patients with HIV infection comprises a continuum of treatment consisting of therapy directed at AIDS-related illnesses (e.g., infection or malignancy) and treatments focused on providing comfort and symptom control throughout the lifespan. This care may involve multidimensional and multidisciplinary services, including HIV medicine, nursing, pharmacy, social work, complementary or alternative medicine, and physical therapy.

Palliative Care in the Era of Antiretroviral Therapy

With advances in HIV-specific therapy and care, HIV infection is no longer a rapidly fatal illness. Instead, patients who are able to tolerate antiretroviral therapy (ART) usually experience a manageable, chronic illness.

The death rate from AIDS, however, continues to be significant: approximately 15,000 deaths per year in the United States. In many parts of the world, patients still are not able to obtain specific treatments for HIV or for opportunistic illnesses, and supportive or palliative care may be the primary mode of care available to patients with advanced AIDS. Regardless of access to disease-specific treatment, people living with HIV continue to experience symptoms from HIV disease and its comorbid conditions, and those taking ART may experience adverse effects. Integrating palliative care and disease-specific care is important for treating patients with HIV in order to promote quality of life and relieve suffering.

S: Subjective

The patient with advanced HIV disease complains of one or more of the following:

- Agitation
- Anorexia
- Chronic pain
- Constipation
- Cough
- Decubitus ulcers or pressure sores
- Delirium
- Dementia
- Depression
- Diarrhea
- Dry mouth
- Dry skin
- Dyspnea
- Fatigue
- Fever
- Hiccups
- Increased secretions (“death rattle”)
- Nausea
- Pruritus
- Sleep disturbance
- Sweats
- Vomiting
- Weakness
- Weight loss

O: Objective

Conduct a complete symptom-directed physical examination.

To evaluate pain, please refer to chapter *Pain Syndrome and Peripheral Neuropathy*.

**A/P: Assessment and Plan
Treatment**

Common symptoms of persons with late-stage HIV infection and their possible causes are listed in Table 1. Also included are disease-specific treatments and palliative interventions. Depending on the situation, either or both of these types of treatments may be appropriate. Consider the patient’s disease stage and symptom burden, the risks and benefits of therapies, and the patient’s wishes.

When assessing each of the patient’s symptoms, include the psychiatric review of symptoms (depression, anxiety, psychosis), and consider the following aspects of each symptom:

- Onset, progression, frequency, severity
- Degree of distress and impact on function
- Aggravating and alleviating factors
- Previous treatments and their efficacy
- What the patient believes is causing the symptom
- Coping strategies and supports
- The patient’s personal goals of care with this particular symptom

Practitioners should note that some of the palliative treatments may have substantial long-term adverse effects and should be used to alleviate symptoms only in late-stage or dying patients.

Table 1. Common Symptoms in Patients with AIDS and Possible Disease-Specific and Palliative Interventions

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
CONSTITUTIONAL			
Fatigue, weakness	• AIDS • Opportunistic infection • Anemia • Hypoandrogenism	• ART • Treat specific infections • Erythropoietin, transfusion • Testosterone/androgens in men with concomitant hypogonadism; for women, androgens are investigational and not approved by the U.S. Food and Drug Administration for this use	• Psychostimulants: give in the morning; also useful as treatment for depression and sedation owing to opioids; avoid in patients with anxiety and agitation (e.g., methylphenidate, dextroamphetamine, modafinil; pemoline is not first-line because of hepatotoxicity risk) • Corticosteroids (prednisone, dexamethasone)
Weight loss/anorexia	• HIV • Malignancy	• ART • Specific treatment of malignancy • Nutritional support	• Testosterone/androgens in men with hypogonadism (see above) • Oxandrolone for 2-4 week courses; an anabolic steroid that may be a useful adjunct, can help increase lean body mass but also has virilizing effects • Megestrol acetate can improve appetite and fatigue but has not been shown to improve nutritional status; possible adverse effects include deep vein thrombosis, glucose intolerance, and hypoandrogenism in men • Dronabinol is a cannabinol derivative that helps increase appetite but over the long term (≥ 12 months) does not significantly increase weight • Recombinant human growth hormone can improve lean body mass, but is associated with significant side effects (headache, edema, myalgias) and is expensive; consider for patients with severe wasting if no other therapies are effective • Corticosteroids can help increase appetite in the short term but not increase weight, and the duration of effect is short-lived

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
Fevers, sweats	- Disseminated <i>Mycobacterium avium</i> complex and other infections (opportunistic or other) - Lymphoma and other malignancies - Immune reconstitution inflammatory syndrome - Medication reaction	- Specific treatment of opportunistic infection or malignancy - ART - Discontinue causative medication (if drug reaction)	- Acetaminophen - NSAIDs (ibuprofen, naproxen, indomethacin) - Anticholinergics can be useful for sweats (hyoscyamine, glycopyrrolate) - H2 antagonists can be useful for sweats (ranitidine, famotidine; dose at least 12 hours apart from atazanavir or rilpivirine; note that cimetidine should be avoided in patients taking fosamprenavir or delavirdine because of drug interactions)
PAIN			
Nociceptive, somatic, visceral	- Opportunistic infections - HIV-related malignancies, nonspecific	Specific treatment of disease entities	- See chapter <i>Pain Syndrome and Peripheral Neuropathy</i> for detailed treatment options - Refer to the World Health Organization (WHO) analgesic ladder: NSAIDs and opioids - Corticosteroids can be useful for treating inflammatory-mediated pain, often as an adjunct to opioids (may worsen some conditions) - Benzodiazepines or muscle relaxants for muscle spasms (clonazepam, diazepam, baclofen) - Nonpharmacologic therapies (e.g., massage, physical therapy)
Neuropathic	- HIV-related peripheral neuropathy - Cytomegalovirus - Varicella-zoster virus - Medications (e.g., stavudine, isoniazid, vincristine)	- ART - Discontinue offending medication - Change antiretroviral or other regimen	- See chapter <i>Pain Syndrome and Peripheral Neuropathy</i> for detailed treatment options - Refer to the WHO analgesic ladder: NSAIDs and opioids - Neuropathic pain medications: - Tricyclics (nortriptyline, imipramine) - Anticonvulsants (gabapentin, pregabalin, lamotrigine) - Muscle relaxants (e.g., baclofen) - Benzodiazepines can be useful adjuncts (clonazepam, diazepam) - Corticosteroids can be useful for treating inflammatory-mediated pain, often as an adjunct to opioids (may worsen some conditions) - Acupuncture

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
GASTROINTESTINAL			
Nausea, vomiting	• Antiretroviral medications • Esophageal candidiasis • Cytomegalovirus esophagitis	• Specific treatment of disease entities • Change antiretroviral regimen	• Dopamine antagonists (prochlorperazine, haloperidol) • Prokinetic agents (metoclopramide) • Serotonin antagonists (granisetron, ondansetron, dolasetron) • Antihistamines (diphenhydramine, promethazine, meclizine) • Anticholinergics (hyoscyamine, scopolamine) • Somatostatin analogues in patients with bowel obstruction, to reduce gut motility; can be used with anticholinergics (octreotide) • Benzodiazepines (lorazepam) • Marijuana, dronabinol can help increase appetite
Diarrhea	• <i>Mycobacterium avium</i> complex • Cryptosporidiosis • Cytomegalovirus colitis • Microsporidiosis • Other intestinal infections • Malabsorption • Medications (e.g., protease inhibitors)	• Specific treatment of disease entities • Discontinue offending medication	• Bismuth, methylcellulose • Psyllium • Kaolin • Diphenoxylate + atropine • Loperamide • Calcium carbonate • Ferrous sulfate • Tincture of opium for severe chronic diarrhea unresponsive to other therapies • Crofelemer for ARV-related diarrhea • Octreotide for profuse, refractory watery diarrhea; expensive and needs subcutaneous administration
Constipation	• Dehydration • Malignancy • Anticholinergic medications • Opioids • Reduced activity	• Hydration • Radiation and chemotherapy • Medication adjustment	• Activity/diet modification • Prophylaxis for patients taking opioids with docusate + senna • Peristalsis-stimulating agents: • Anthracenes (senna) • Polyphenolics (bisacodyl) • Softening agents: • Surfactant laxatives (docusate) • Bulk-forming agents (bran, methylcellulose) • Osmotic laxatives (lactulose, sorbitol) • Saline laxatives (magnesium hydroxide)

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
RESPIRATORY			
Dyspnea	• <i>Pneumocystis jiroveci</i> pneumonia • Bacterial pneumonia • Anemia • Pleural effusion, mass, or obstruction • Decreased respiratory muscle function	• Specific treatment of disease entities • Erythropoietin, transfusion • Drainage, radiation, or surgery	• Use of fan, open windows • Relaxation techniques, massage, guided imagery • Oxygen supplement titrated to comfort, if the patient is hypoxic • Bronchodilators (albuterol, ipratropium, inhaled steroids) if there is bronchospasm • Opioids, particularly morphine, to decrease sense of air hunger and respiratory rate • Benzodiazepines (e.g., lorazepam) to reduce the anxiety that often accompanies dyspnea
Cough	• <i>Pneumocystis jiroveci</i> pneumonia • Bacterial pneumonia • Tuberculosis • Acid reflux • Postnasal drip	• Specific treatment of disease entities	• Cough suppressants (dextromethorphan, codeine, hydrocodone, morphine, aerosolized lidocaine) • Bronchodilators (albuterol, ipratropium, inhaled steroids) if there is bronchospasm • H2 blockers or proton-pump inhibitors (ranitidine, omeprazole) if there is acid reflux (caution: interactions with atazanavir, rilpivirine) • Decongestants (pseudoephedrine, phenylephrine, steroid nasal sprays) for postnasal drip
Increased secretions ("death rattle")	• Fluid shifts • Ineffective cough • Sepsis • Pneumonia	• Antibiotics as indicated	• Atropine, hyoscyamine, transdermal scopolamine, glycopyrrolate • Fluid restriction, discontinue intravenous fluids
Hiccups	• Aerophagia (swallowing air) • <i>Candida</i> and other causes of esophagitis, including GERD • Vagus and phrenic nerve irritation • CNS mass lesions • Uremia • Alcohol intoxication • Anesthesia	• Treatment of underlying etiology (e.g., antifungals for <i>Candida</i> esophagitis, acid reducers for GERD)	• Metoclopramide can promote gastric emptying • Chlorpromazine (antipsychotic) can reduce the CNS response, start at low dosage to reduce the risk of dystonia and drowsiness • Baclofen can reduce the CNS response

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
DERMATOLOGIC			
Dry skin	• Dehydration • End-stage renal disease • End-stage liver disease • Malnutrition • Medications (e.g., indinavir)	• Hydration • Dialysis • Nutritional support • Discontinue offending medication	• Avoid soaps, most of which dry the skin further • Emollients with or without salicylates • Emollients with urea (e.g., Ultra Mide 25) • Emollients with lactate (e.g., Lac-Hydrin) • Lubricating ointments or creams (e.g., petrolatum, Eucerin)
Pruritus	• Fungal infection • End-stage renal disease • End-stage liver disease • Dehydration; dry skin • Eosinophilic folliculitis • Opioid side effect	• Antifungal agents (e.g., itraconazole for eosinophilic folliculitis) • Dialysis • Hydration • Topical corticosteroids	• Avoid soaps and hot baths/showers • Warm compresses • Treatments for dry skin, as above • Topical agents (menthol, phenol [e.g., Sarna lotion], calamine, doxepin, capsaicin) • Antihistamines (hydroxyzine, doxepin, diphenhydramine) • Corticosteroids (topical or systemic) • Opioid antagonists (naloxone, naltrexone) can be useful for treating uremic and biliary-associated pruritus • Antidepressants • Anxiolytics • Thalidomide in intractable pruritus, but beware of side effects, including neuropathy
Decubitus ulcers, Pressure sores	• Poor nutrition • Decreased mobility, prolonged bed rest	• Increase mobility • Enhance nutrition	• Prevention (nutrition, mobility, skin integrity) • Wound protection (semipermeable film, hydrocolloid dressing) • Debridement (normal saline, enzymatic agents, alginates)

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
NEUROPSYCHIATRIC			
Delirium/ agitation	• Electrolyte imbalances, glucose abnormalities • Dehydration • Hypoxia • Toxoplasmosis • Cryptococcal meningitis • CNS masses and metastases • Sepsis • Medication adverse effects (e.g., benzodiazepines, opioids, efavirenz, corticosteroids) • Intoxication or withdrawal	• Correct imbalances • Hydration • Oxygen supplementation • Specific treatment of disease entities • Discontinue offending medications	• Neuroleptics (haloperidol, risperidone, chlorpromazine) to induce sedation in severe agitation • Benzodiazepines (e.g., lorazepam, diazepam, midazolam) in the “terminal restlessness” of the last few days of life to relieve myoclonus, seizures, restlessness (Note: in some patients, these may have adverse effects)
Dementia	• HIV-associated dementia • Other dementia (e.g., Alzheimer dementia, Parkinson dementia, multi-infarct dementia)	• ART	• Psychostimulants (methylphenidate) • Memantine (NMDA antagonist) has been used in patients with Alzheimer dementia but has unclear benefit for patients with HIV-associated dementia • Low-dose neuroleptics (haloperidol, chlorpromazine) can be useful in psychotic delirium

Symptom	Possible Causes	Disease-Specific or Curative Treatment	Palliative Treatment
Depression	- Chronic illness - Reactive depression, major depression	Antidepressants	- Antidepressants are useful when the patient has a life expectancy of several months or more: SSRIs, SNRIs, mirtazapine (useful in lowest dosages for insomnia), bupropion, (though beware of lowering the seizure threshold); note that tricyclic antidepressants are not considered first- or second-line therapy owing to side effects, though they may be useful for treating refractory melancholic or delusional depression (see chapter <i>Major Depression and Other Depressive Disorders</i> for further information, including dosages) - Psychostimulants are useful for patients who have urgent, severe depression or are weeks from death (methylphenidate, pemoline, dextroamphetamine, modafinil)

Abbreviations: ART = antiretroviral therapy; CNS = central nervous system; GERD = gastroesophageal reflux disease; NMDA = N-methyl- D-aspartate; NSAID = nonsteroidal antiinflammatory drug; SNRI = serotonin norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor

Advance Care Planning

Advance care planning involves planning for future medical care. Two main documents are produced:

- Advance directive (living will)
- Health care proxy (a person to speak for the patient or make decisions if the patient is too sick to do so)

The clinician should initiate these conversations and make referrals to helpful resources.

Patient Education

- Discuss advance care planning with patients, and the option of hospice care, if appropriate.
- Provide patients and their family members with detailed information so that they understand the illness and associated treatments.
- Instruct patients to discuss their pain or other bothersome symptoms with their health care provider.
- Encourage patients to talk with their health care provider if they are feeling anxious, depressed, or fearful.
- Discuss with patients what their death might be like. Some patients may feel relieved to be able to talk openly about their last days. Assure them that their pain will be controlled and that their health care provider will be there to help them.

Adherence

Background

For HIV-infected patients with wild-type virus who are taking antiretroviral therapy (ART), adherence to ART is the major factor in ensuring the virologic success of an initial regimen and is a significant determinant of survival. Adherence is second only to the CD4 cell count as a predictor of progression to AIDS and death. Adherence rates approaching 100% are needed for optimal viral suppression, yet the average ART adherence in the United States is approximately 70%. Individualized assessment of and support for adherence are essential for patients to be successful with ART.

Patients with suboptimal adherence are at risk not only of HIV progression, but also of the development of drug resistance (see chapter *Resistance Testing*) and consequent narrowing of options for future treatment. In one cohort study, it was estimated that drug-resistant mutations will occur in 25% of patients who report very high but not perfect (92-100%) adherence to ART. It is important to note, though, that the relationship between suboptimal adherence and resistance to antiretroviral (ARV) medications is very complex and is not thoroughly understood.

Characteristics of the ARV regimen and individual patient pharmacokinetic variables also influence the likelihood of both virologic suppression and the development of resistance mutations. For example, in patients with wild-type virus on initial ART regimens, it appears that more drug resistance occurs in regimens that are based on an unboosted protease inhibitor or a nonnucleoside reverse transcriptase inhibitor, where the genetic barrier to resistance is relatively low, than in regimens that include a ritonavir-boosted protease inhibitor. In patients with suboptimal adherence, these factors can influence outcomes of therapy more strongly.

S: Subjective

Studies indicate that health care providers' assessments of their patients' adherence often are inaccurate, so a calm and open approach to this topic is very important.

Adherence assessment is most successful when conducted in a positive, nonjudgmental atmosphere. Patients need to know that their provider understands the difficulties associated with taking an ARV regimen. Within a trusting relationship, a provider may learn what is actually happening with the patient's adherence rather than what the patient thinks the provider wants to hear. See Table 1 for examples of questions to assess adherence in patients who are on ART. For patients who are considering initiation of ART, it is important to lay the groundwork for optimal adherence in advance, and to anticipate barriers to adherence; see Table 2 for exploratory questions.

Common reasons for nonadherence include the following: experiencing adverse drug effects, finding the regimen too complex, having too many pills, having difficulty with the dosing schedule (not fitting into the daily routine), forgetting to take the medications, being too busy with other things, oversleeping and missing a dose, being away from home, not understanding the importance of adherence, and being embarrassed to take medications in front of family, friends, or coworkers. Other contributors to incomplete adherence include psychosocial issues (e.g., lack of social support, homelessness), psychiatric illness, and active substance abuse. It is important to look for these and other potential barriers to adherence. (See chapter *Initial History*.)

O: Objective

Evaluate the following:

- CD4 cell count
- HIV viral load (indicating the effectiveness of ART in suppressing viremia; an indirect indicator of adherence)
- Current drug list (including over-the-counter medications, vitamins, and herbal remedies); check for potential adverse drug-drug interactions with ARV medications
- Pharmacy refill records or missed doses remaining in pill organizers (e.g., medi-sets pill boxes, bubble packs)

A: Assessment

Assess adherence at each visit using questions such as those in Tables 1 and 2, and assessment scales such as those found in Tables 4, 5, and 6 (Appendix). Ask these questions in a simple, nonjudgmental, structured format and listen carefully to the patient to invite honesty about issues that may affect adherence. Asking about adherence over the last 3 to 7 days gives an accurate reflection of longer-term adherence.

Ideally, a multidisciplinary team that includes primary providers as well as nurses, pharmacists, medication managers, and social workers works together to evaluate and support patient adherence.

Table 1. Important Questions to Ask Patients Taking ART

- Do you manage your own medications? If not, who manages them for you?
- What HIV medications do you take and what is their dosage? When do you take these?
- What is your average daily schedule like? How well does taking your HIV medications at this time fit into your daily schedule?
- How do you remember to take your medications?
- How many doses of your HIV medication have you missed in the past 72 hours, past week, past 2 weeks, and past month?
- On a scale of 1 to 10, where would you say you are? A score of 1 indicates that you do not take your medicines as directed at all; for example, not every day or not at the same time every day; 10 indicates that you take your medications perfectly every day, at the same time every day. (Visual analog scales are also used to assess adherence; see Appendix.)
- If not a 10, what causes you not to be a 10?
- When are you most likely to miss doses?
- Do you have any adverse effects from your HIV medications? If so, what are they?
- Are you comfortable taking medications in front of others?
- What is most difficult about taking your medications?
- How do you like working with your pharmacy?

Table 2. Important Questions to Ask Patients Considering Initiation of ART

- What is your attitude toward ART?
- Do you believe that ART is effective?
- What are your biggest concerns about starting ART?
- What do you hope these medications will do for you?
- Are you ready to take the medication every day, around the same time each day?
- What is your level of commitment and motivation to take the medication every day for the rest of your life?
- Who knows about your HIV status?
- What other medications are you taking: prescription, over-the-counter, herbals?
- Are you a morning or afternoon person?
- What is your daily routine, including waking and bed times?
- How many meals and snacks do you eat per day, and at what times?
- Do you use alcohol, marijuana, cocaine, or injectable drugs? If so, how much do you use and how long have you used them?
- What are your ARV regimen preferences? What are some of the most important things you want to avoid in an ARV regimen (e.g., specific side effects, number of pills, frequency of dosing)?

The patient’s self-report has been shown to be the most effective measure of adherence. Although, according to some studies, self-report of good adherence has limited value as a predictor

of good adherence; self-report of suboptimal adherence should be taken seriously and considered a strong indicator of nonadherence.

Before initiating (or changing) ART, it is important to assess the patient's readiness for ART. Patient factors that have been associated with poor adherence in the United States and western Europe include:

- Active alcohol or drug use
- Competing priorities (e.g., housing, childcare, food, work)
- Depression
- Lack of belief in treatment efficacy
- Lack of social support
- Lack of support from a partner
- Low literacy
- More advanced HIV infection
- Unstable housing
- Young age

Most of these factors are modifiable. Before starting ART, appropriate interventions should be made, and sources of adherence support should be identified to help patients overcome potential barriers to adherence.

It is important to note that sociodemographic variables such as sex, HIV risk factors, and education level generally are not associated with adherence. In addition, a history of substance or alcohol abuse is not a barrier to adherence.

Assess the patient's support system, and ask who knows about his or her HIV status. Supportive family members or friends can help remind patients to take their medications and assist with management of adverse effects. For patients who have accepted their HIV infection as an important priority in their lives, taking medications can become routine despite other potential adherence barriers such as alcohol or drug use.

Assess patients' willingness to accept and tolerate common adverse effects of ART. Patients may identify some adverse effects that they wish to avoid completely and others that they are willing to accept and manage; this may help

in tailoring the selection of ARV medications to the individual patient. Describe strategies for the management of adverse effects before starting a regimen (see chapters *Patient Education* and *Adverse Reactions to HIV Medications*), and emphasize that adverse effects often can be treated quite effectively, and that they should notify their providers if they experience them.

For patients taking ART, it is important to assess adherence at every clinic visit. Tools such as those in the Appendix to this chapter may be useful in predicting adherence. Adverse effects are a common cause of suboptimal adherence to ART. Continue to ask whether the patient has adverse effects from the ARV medications and assess his or her ability to accept and tolerate these. Work closely with the patient to treat adverse effects, and consider changes in ART if adverse effects are not tolerated. Continue to offer support to improve or maintain optimal adherence.

Before prescribing ARVs, some clinicians have their patients conduct adherence trials using placebo tablets or jelly beans to measure the patients' readiness to start therapy and their ability to adhere to a regimen. Such a trial allows patients to experience what a regimen will entail in real life, how therapy will affect their daily lifestyles, and what changes will be needed to accommodate the regimen. The shortcoming of placebo trials is that patients are not challenged with adverse effects as they might be with an actual regimen.

P: Plan

Start the ARV regimen when the patient is ready (recognizing that in some cases the need for ART is urgent). Starting it too early may result in poor acceptance of ART by the patient, inadequate adherence, failure of the regimen, and increased risk of ARV resistance. Comorbid conditions that may interfere with adherence, such as mental health issues or depression, may need to be treated initially. It is important to consider the patient's preferences and to involve her or him in selecting the drug regimen. The

regimen must fit into the patient's daily routine, and the patient must believe in the potential success of ART. It is extremely important to simplify the ARV regimen to the extent possible with once-daily regimens and the lowest number of pills (and lowest total expense to the patient), while maintaining efficacy and minimizing adverse effects; this will help to maximize adherence and avoid pill fatigue. Starting ART is rarely an emergency situation, so taking time to identify the patient's wishes for care, making a thorough readiness assessment, selecting the ARV regimen, and planning for adherence support are important measures for maximizing the likelihood of treatment success. (See Table 3 for additional suggestions.)

Table 3. Strategies for Improving Adherence to ART

- Use a multidisciplinary team approach
- Establish a trusting relationship with the patient
- Establish readiness to start ART
- Assess and simplify regimens if possible
- Involve the patient in ARV regimen selection
- Identify potential barriers to adherence prior to starting ART
- Provide mental health and substance abuse resources for the patient if needed
- Provide resources to obtain prescription drug coverage
- Assess adherence at every clinic visit
- Use educational aids including pictures, pillboxes, and calendars
- Identify the type of nonadherence and the reasons for nonadherence
- Anticipate and treat adverse effects
- If resources allow, select from among available effective interventions

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents. *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. Department of Health and Human Services. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2103.

Patients who can identify their medications (in their own words) and describe the proper dosing and administration have higher adherence rates. Providing patient education before writing a prescription helps ensure adherence to ARV regimens. Education

can be provided in oral, written, or graphic form to assist the patient's understanding of the medications and their dosing. Basic information, including number of pills, dosages, frequency of administration, dietary restrictions, possible adverse effects, tips for managing adverse effects, and duration of therapy, will help patients to understand their ARV regimens. Patients should understand that the success of ART depends upon taking the medications every day and that very high adherence levels (in some cases perhaps >95%) are important in preventing virologic failure.

Close follow-up by telephone, clinic visits, or other contact with the patient during the first few days of therapy is useful in identifying adverse effects, assessing the patient's understanding of the regimen, and addressing any concerns before they become significant adherence barriers. Individualized interventions should be designed to optimize outcomes for each patient. Pharmacists, peer counselors, support groups, adherence counselors, behavioral intervention counselors, and community-based case managers are useful in supporting adherence for the HIV-infected patient. Multidisciplinary teams that include nurses, case managers, nutritionists, and clinical pharmacists, in which each care provider focuses on adherence at each contact with the patient, are extremely effective, and peer support groups, in which patients share with one another their strategies for improving adherence, may be beneficial.

Many physical devices can be used to support adherence. The following are simple, inexpensive, and easy to incorporate into the routine of the HIV patient:

- Medication organizers include pillboxes and medi-sets. These are available in several shapes and sizes to fit the needs of the individual patient. They can be filled weekly so that the patient can easily determine whether a dose of medication was missed.
- Reminder devices include alarm watches, beepers, and cell phone alarms. They are ef-

fective in reminding the patient when to take medications. Medication diaries may be used for the patient to record doses that were taken.

- Visual medication schedules are calendars featuring photos or images of the patient's medications to remind the patient which drugs to take and at what dosages.
- Interventions for successful adherence are an ongoing effort, not one-time events. Studies have suggested that adherence rates decline when patient-focused interventions are discontinued. Therefore, positive reinforcement at each clinic visit or contact is extremely important. Reinforce what the patient has done well and assist the patient in identifying and problem-solving areas for improvement. Whenever possible, share positive information about the patient's health, such as improvements in quality of life, CD4 cell count, and viral load, to encourage a high level of adherence.

Special Populations and Issues

Mental Illness

Patients with mental health issues may have difficulty with adherence. In this population, it is particularly important to incorporate ARV medications into structured daily routines. Medication cassettes, reminder signs, and calendars have been very effective for these patients. Nursing care providers and family members may be instrumental in filling medication boxes or ordering prescription refills.

Pediatrics

Adherence can be a challenge for young children who rely on parents and caregivers to provide their medications, but adolescents are more likely than younger children to have poor adherence. To improve adherence in this population, it is important to support the family. The Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection* (available at aidsinfo.nih.gov/guidelines) address some of the adherence issues and considerations for this patient population.

Low Literacy

Health literacy is an important predictor of treatment adherence, particularly in low-income populations and some immigrant populations. Adherence interventions are necessary in this population to accommodate individuals who have difficulty reading and understanding medical instructions. Providers often fail to recognize this disability. In addition, adherence support is needed for patients who have difficulty navigating the health care system.

Resource-Limited Settings

Research has shown that the level of adherence in resource-limited countries is at least as good as in resource-rich settings and that rates of virologic suppression are equivalent or better. Lack of access to a consistent supply of ARV medications, including financial barriers that may cause interruptions in treatment, appears to be the primary obstacle to adherence in resource-limited settings.

Patient Education

- Educate patients about the importance of adherence and the need to take their ARV medications exactly as prescribed and to take every dose, every day.
- Advise patients that, if they miss an ARV dose on a rare occasion, that usually will not result in failure of the regimen. On the other hand, if they frequently miss or skip doses of their ARV medications, the regimen may become ineffective, and the HIV may develop resistance to ARVs.
- Tell patients to notify the clinic if they miss doses of the ARV medications.
- Work with patients to devise ways to improve their adherence, and reinforce good adherence behavior.
- Advise patients in advance that some people have adverse effects from the medications, and tell them to notify the clinic if they develop adverse effects. Discuss ways to reduce these effects.

Appendix

Table 4. Visual Analog Scale Used in a Research Study to Assess Adherence to HIV Medication Regimens

Script for Interviewing Patients About Adherence																							
Interviewer	Now I'm going to ask some questions about your HIV medications. Most people with HIV have many pills or other medications to take at different times during the day. Many people find it hard to always remember to take their pills or medicines. For example: • Some people get busy and forget to carry their pills with them. • Some people find it hard to take their pills according to all the instructions, such as "with food" or "on an empty stomach," "every 8 hours," or "with plenty of fluids." • Some people decide to skip taking pills to avoid adverse effects or to just not take pills that day. We need to understand what people with HIV are really doing with their pills or medicines. Please tell us what you are actually doing. Don't worry about telling us you don't take all your pills or medicines. We need to know what is really happening, not what you think we "want to hear." Which antiretroviral medications have you been prescribed to take within the last 30 days?																						
INTERVIEWER: LIST CODES FOR ALL ANTIRETROVIRALS THAT SUBJECT WAS PRESCRIBED TO TAKE IN LAST 30 DAYS. IDENTIFY UP TO 4 DRUGS.																							
	<table border="1"> <tr> <td>DRUG A:</td> <td>DRUG C:</td> </tr> <tr> <td>DRUG B:</td> <td>DRUG D:</td> </tr> </table>	DRUG A:	DRUG C:	DRUG B:	DRUG D:																		
DRUG A:	DRUG C:																						
DRUG B:	DRUG D:																						
Interviewer	Now, I am going to ask you some questions about these drugs. Please put an "X" on the line below at the point showing your best guess about how much (DRUGS A-D) you have taken in the last 3-4 weeks. We would be surprised if this were 100% for most people.																						
HAND INSTRUMENT AND PEN TO RESPONDENT																							
Interviewer	• 0% means you have taken no (DRUG A) • 50% means you have taken half your (DRUG A) • 100% means you have taken every single dose of (DRUG A)																						
Adherence Self-Assessment Instrument																							
Instructions for Patient:	Put an "X" on the line below at the point showing your best guess about how much of each drug you have taken in the last 3 to 4 weeks. • 0% means you have taken none of the drug • 50% means you have taken half of the drug • 100% means you have taken every single dose of the drug																						
DRUG A:	<table border="1"> <tr> <td>0</td><td>1</td><td>2</td><td>3</td><td>4</td><td>5</td><td>6</td><td>7</td><td>8</td><td>9</td><td>10</td> </tr> <tr> <td> </td><td> </td><td> </td><td> </td><td> </td><td> </td><td> </td><td> </td><td> </td><td> </td><td> </td> </tr> </table>	0	1	2	3	4	5	6	7	8	9	10

Diarrhea

Background

Diarrhea is a common complaint among HIV-infected individuals, and has a variety of causes. Episodes may be acute and brief, intermittent or recurrent, or, in some cases, chronic and severe. If diarrhea persists, it may cause dehydration, poor nutrition, and weight loss. Diarrhea may diminish patients' quality of life significantly, and may interfere with adherence to and efficacy of antiretroviral (ARV) medications.

Diarrhea is defined in various ways, but commonly as more than 4 loose or watery stools per day for more than 3 days. Duration is classified as follows:

- Acute: <2 weeks
- Persistent: 2-4 weeks
- Chronic: >4 weeks

The causes of diarrhea, both infectious and noninfectious, found in HIV-infected individuals with normal or mildly depressed CD4 cell counts are likely to be similar to those in HIV-uninfected persons. Among the noninfectious causes of diarrhea, adverse effects of ARVs and other medications are particularly common. Persons with advanced immunodeficiency are more likely to have infections, including opportunistic infections, as the cause of diarrhea.

Infectious diarrhea typically involves either the small or the large intestine, and the patient's history often suggests the site of the problem. Infections of the small intestine (enteritis) commonly produce generalized or periumbilical abdominal cramps, large-volume diarrhea without blood, and frequently dehydration. Large-intestine infections (colitis) often produce lower abdominal pain, an unproductive urge to defecate, and frequent small-volume stools with blood and pus.

S: Subjective

The patient complains of diarrhea. Take a thorough history, including the following:

- Onset of diarrhea: sudden or gradual
- Frequency (times per day, last episode)
- Stool consistency (soft vs. liquid)
- Stool color (gray, white, or greasy stools: possible cholelithiasis or pancreatitis; dark stools: possible gastrointestinal bleeding)
- Bloody stools (may indicate invasive organisms, inflammation, ischemia, or neoplasm)
- Rectal bleeding
- Straining at stool
- Pain with defecation, rectal discharge (consider sexually transmitted diseases, herpes simplex virus)
- Nausea or vomiting (within 6 hours of ingesting food, consider foodborne illness, gastroenteritis)
- Weight loss: quantify amount and time frame
- Abdominal pain or cramping; location if present
- Fever (consider invasive pathogens: *Shigella*, *Campylobacter*, *Salmonella*, *Clostridium difficile*)
- Other associated symptoms (e.g., bloating, flatus)

- Allergies (to foods or medications)
- Aggravating factors (e.g., dairy products, fatty or spicy foods)
- Alleviating factors (e.g., fasting)
- Treatments tried (e.g., over-the-counter antidiarrheals)
- Contact with others with similar symptoms
- Previous episodes of diarrhea
- History of cytomegalovirus (CMV), *Mycobacterium avium* complex (MAC), or other infections involving the gastrointestinal tract
- Family history of inflammatory bowel disease, celiac disease
- Oral-anal sexual contact (males and females)
- Receptive anal intercourse
- Exposure to unsafely prepared food (e.g., raw, undercooked, spoiled), unpasteurized milk or juices
- Exposure to possibly contaminated water (swimming in or drinking from well, lake, or stream) (consider parasites, including *Giardia*)
- Exposure to non-toilet-trained infants and children (e.g., at a daycare facility), pets, farm animals, reptiles (consider *Giardia*, *Salmonella*)
- Recent travel (enterotoxigenic *Escherichia coli*, *Shigella*, *Rotavirus*, *Salmonella*, *Campylobacter*, *Giardia*, *Entamoeba histolytica*)
- Antibiotic use or exposure in recent weeks or months or recent hospitalization (consider *C. difficile*)
- ARV medications, especially ritonavir-boosted protease inhibitors; check relationship of diarrhea onset to initiation of ARVs
- Other current and recent medications (prescribed or over-the-counter), including supplements and herbal preparations

- Dietary factors, especially “sugar-free” foods (containing nonabsorbable carbohydrates), fat substitutes, milk products, and shellfish, or heavy intake of fruits, fruit juices, or caffeine
- Alcohol and recreational drug use; withdrawal

O: Objective

Record vital signs, including temperature, orthostatic heart rate, blood pressure measurements, and weight. Compare these with recent or baseline values. Perform a thorough physical examination, including evaluation of the following:

- Hydration status (skin turgor, mucous membrane moistness)
- Nutritional status (body habitus, muscle mass, skin and hair integrity)
- Oropharynx (lesions, candidiasis, ulcerations, Kaposi sarcoma)
- Optic fundi (signs of CMV infection)
- Abdomen (distention, bowel sounds, tenderness, organomegaly, masses, adenopathy)
- Rectum (masses, tenderness, bloody stool)

Review recent CD4 cell counts. Low CD4 counts increase the risk of chronic or systemic illnesses and opportunistic infections.

A: Assessment

The differential diagnosis of diarrhea is broad and includes the following infectious and noninfectious causes. The CD4 cell count is important in stratifying risk of infection with opportunistic pathogens; some organisms cause disease only with severe immunosuppression.

Infectious Causes

Table 1. Infectious Causes

Severity	Differential Diagnosis
Active diarrhea, any CD4 count	• Viruses (especially Norwalk virus) • Viral hepatitis • Herpes enteritis • <i>C. difficile</i> (suspect in patients who have recently undergone treatment with antibiotics, or hospitalization) • <i>Salmonella</i> • <i>Shigella</i> • <i>Campylobacter</i> • <i>E. coli</i> O157:H7
Chronic diarrhea, any CD4 count	• <i>C. difficile</i> (suspect in patients who have been treated with antibiotics) • <i>Giardia lamblia</i> • <i>E. histolytica</i>
Chronic diarrhea, CD4 count <300 cells/μL	• Microsporidia • <i>Cryptosporidium parvum</i> • MAC (CD4 count <50 cells/μL) • <i>Isospora belli</i> • CMV (CD4 count <50 cells/μL)

Adapted from: *Infectious Causes of Diarrhea in Patients with HIV*, Table 8-8. In: Bartlett JG, Cheever LW, Johnson MP, et al., eds. *A Guide to Primary Care of People with HIV/AIDS*. Rockville, MD: U.S. Department of Health and Human Services, Health Resources and Services Administration; 2004. Available at hab.hrsa.gov/deliverhivaidscare/files/primary2004ed.pdf. Accessed December 1, 2013.

Noninfectious Causes

- Medication adverse effects, common with many medications including some ARVs:
 - Protease inhibitors (especially ritonavir and nelfinavir)
 - Didanosine buffered tablets (no longer available in the United States)
 - Cobicistat (present in Stribild)
- Irritable bowel syndrome
- Inflammatory bowel disease (ulcerative colitis, Crohn disease)
- Lymphoma
- Lactose intolerance
- Celiac disease
- Small intestinal bacterial overgrowth
- Pancreatic insufficiency
- Diverticulitis
- Fecal incontinence
- Laxative abuse

P: Plan
Diagnostic Evaluation

For suspected infections, perform laboratory studies including complete blood count with differential, serum electrolyte panel, and liver function tests. Check stool for white blood cells and blood. Perform stool studies as indicated by the patient’s presentation (bacterial culture, ova and parasites, microsporidia, cryptosporidia, *Giardia* antigen, *C. difficile* toxin assay). Order additional studies as suggested by the history (e.g., blood cultures, MAC cultures, hepatitis serologies, retinal examination for CMV). If noninfectious causes are suspected, perform evaluation for these etiologies as indicated (e.g., fecal fat concentration [for steatorrhea], stool osmolar gap [for osmotic diarrhea], anti-tissue transglutaminase [TTG] antibody [for celiac disease], or D-xylose [for pancreatic insufficiency]).

If the patient is febrile, perform a complete fever workup as appropriate (see chapter *Fever*).

Check the CD4 cell count and HIV viral load, if not checked recently.

If stool study results are negative (ova and parasite negative in three successive samples) and the patient has severe symptoms, particularly in the case of advanced immunodeficiency, refer to a gastroenterologist for colonoscopy or flexible sigmoidoscopy with biopsy. Endoscopy with biopsy is the best procedure for identifying certain conditions, including CMV colitis and inflammatory bowel disease. If all study results are negative but the diarrhea persists, consider repeat endoscopy in 6-8 weeks regardless of the level of immunodeficiency. Pathogens may be difficult to identify.

Treatment

Once a diagnosis is made, initiate appropriate treatment. For seriously ill patients, presumptive treatment may be started while diagnostic tests are pending. If the cause of the diarrhea cannot be identified, consult with an HIV expert or a gastroenterologist.

- For moderate to severe acute diarrhea, including dysentery (bloody diarrhea), empiric treatment can be given pending stool study results or in settings with limited resources for workup. If bacterial pathogens are suspected, use oral fluoroquinolones (e.g., ciprofloxacin 500 mg BID or levofloxacin 500 mg QD) for 5 days. Monitor effectiveness and adjust therapy according to the results of diagnostic studies and clinical response. Specific treatment with antimicrobials is guided by the pathogens identified in stool studies or on biopsy.

- For suspected small intestinal bacterial overgrowth consider treatment with an appropriate antimicrobial (e.g., rifaximin 1,200-1,600 mg per day for 7-10 days).
- For mild persistent diarrhea with no identified pathogen, treat with an antidiarrheal agent (see below). For patients whose diarrhea is suspected to be caused by ARV agents or other medications, symptomatic treatment also may be tried. Diarrhea owing to protease inhibitors often decreases after a few weeks without treatment. For persistent, daily ARV-associated diarrhea, antidiarrheal agents may be given on a scheduled basis (rather than as needed). If the diarrhea cannot be controlled, a change in ARV regimen should be considered.

Symptomatic treatments

- Antimotility agents such as loperamide (Imodium) in over-the-counter or prescription strengths and atropine/diphenoxylate (Lomotil) are useful for many patients. The suggested dosage is 2 tablets after each loose bowel movement, not to exceed 8 tablets per day. These agents should not be used if patients have bloody diarrhea or if the presence of *C. difficile* is suspected.
- Pharmaco-nutritional approaches include the use of calcium supplementation (500 mg BID or TID). Patients with diarrhea related to protease inhibitors may find that taking calcium with each dose of protease inhibitors can decrease or prevent diarrhea. Note that magnesium supplements may worsen diarrhea.

- Pancrelipase can be useful in managing chronic diarrhea caused by malabsorption. It comes in different formulations with differing amounts of pancreatic enzymes; usual dosage is 2-3 capsules TID with meals, titrated downward according to response.
- Cholestyramine or psyllium (e.g., Metamucil) may reduce diarrhea by slowing peristalsis and adding bulk to stools. Avoid administering cholestyramine with other medications because it may impair their absorption.
- Crofelermer, an antisecretory antidiarrheal agent, is approved by the U.S. Food and Drug Administration for treatment of noninfectious diarrhea in HIV-infected adults on antiretroviral therapy (ART). The dosage is 135 mg BID. Infectious causes should be ruled out before treatment with crofelermer.
- A combination of these treatments may be needed to control chronic diarrhea, and they can be continued for patients after an infectious process has been ruled out.

Nutrition and hydration

Encourage frequent intake of soft, easily digested foods such as bananas, rice, wheat, potatoes, noodles, boiled vegetables, crackers, and soups. Encourage hydration with fruit drinks, tea, “flat” carbonated beverages, and water. Patients should avoid high-sugar drinks, caffeinated beverages, alcohol, high-fiber foods, greasy or spicy foods, and dairy products. Many patients may benefit from a trial of a lactose-free, low-fiber, or low-fat diet. Patients should use nutritional supplements as needed or as recommended by a dietitian. In case of chronic or severe diarrhea, or significant weight loss, refer to a dietitian for further recommendations.

Patients with severe diarrhea must maintain adequate hydration, by mouth if possible. In severe cases, IV administration of fluids may be necessary. Oral rehydration solutions

include the World Health Organization formula, Pedialyte, Rehydralyte, Rice-Lyte, and Resol. Homemade alternatives include the following:

- Combine 1/2 teaspoon of salt, 1 teaspoon of baking soda, 8 teaspoons of sugar, and 8 ounces of orange juice; add water to make 1 liter and drink.
- Drink 1 glass containing 8 ounces of apple, orange, or other juice; 1/2 teaspoon of corn syrup or honey; and a pinch of salt; then drink 1 glass containing 8 ounces of water and 1/4 teaspoon of baking soda.
- Mix 1/2 cup of dry, precooked baby rice cereal with 2 cups of water (boil first in areas with poor water quality); add 1/4 teaspoon of salt and drink.

Patient Education

- Diarrhea can have many causes. Instruct patients to notify their health care provider if they develop new or worsening symptoms.
- Instruct patients to take their medications exactly as directed and to call their health care provider if they experience worsening diarrhea or other symptoms such as fever, nausea, vomiting, or pain.
- Patients must stay nourished and well hydrated even if they are having diarrhea. Instruct patients to eat small, frequent meals and to avoid dairy products, greasy food, and high-fat meals.
- Instruct patients to maintain good handwashing practices during diarrheal illnesses to prevent infection in close contacts or household members.
- Some diarrheal illnesses are reportable; advise patients that they may be contacted by the local health department.

Ear, Nose, Sinus, Mouth

Background

HIV-infected individuals frequently experience infections and neoplasms that affect the ears, nose, sinuses, and mouth. The degree of immunosuppression, as reflected by a patient's CD4 cell count, can affect the severity, likelihood of recurrence, and response to therapy for various infections and neoplasms.

Patients may present with ear, nose, sinus, or mouth complaints early in the course of HIV infection, perhaps even before they are aware of their infection. Some conditions arise more commonly in patients with advanced HIV infection. Certain conditions (e.g., oral candidiasis) should prompt consideration of HIV testing in patients without known infection.

Ears

HIV-infected patients may experience recurrent acute otitis media and serous otitis media. Nasopharyngeal lymphoid hyperplasia, sinusitis, or allergies may contribute to dysfunction of the eustachian tubes. Unilateral and bilateral sensorineural hearing loss has been reported and may be caused by HIV infection involving the central nervous system (CNS) or the auditory nerve. Hearing loss also may be caused by syphilis, other CNS infections, chronic otitis media, neoplasms, and certain medications (including nucleoside analogues in rare cases). The pathophysiology, causative organisms, and incidence of external-ear infections appear to be the same in HIV-infected patients as in HIV-uninfected individuals.

S: Subjective

The patient may complain of ear pain, decreased hearing or hearing loss, a feeling of fullness in the ear, vertigo, or a popping or snapping sensation in the ear.

Obtain information regarding the following during the history:

- Medications (prescription and over-the-counter) and herbal supplements, current and past
- Current or recent sinus infection
- Associated symptoms
- Drainage or blood from the ear
- Head or ear trauma

O: Objective

CD4 count is an important measure of immunosuppression and a recent CD4 count is important in determining whether the patient is at risk of opportunistic infections as causes of ear complaints.

Perform visual and otoscopic inspection, including evaluation for skin abnormalities, lesions, cerumen impaction or foreign body, lymphadenopathy, and adenotonsillar hypertrophy.

If hearing loss is reported or suspected, evaluate hearing and refer the patient for an audiogram. Perform a neurologic examination and test for syphilis (e.g., rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL] test) and other possible causes.

A/P: Assessment and Plan

Otitis Externa/Interna

Proceed as with an immunocompetent patient. A chronic or atypical presentation in an HIV-infected patient warrants a thorough evaluation, including cultures, biopsy, radiographic scans, and referral to an ear, nose, and throat (ENT) specialist.

Hearing Loss

A patient with hearing loss should be referred for evaluation or treated, depending on the cause. Avoid ototoxic medications (e.g., furosemide, aminoglycosides).

Nose and Sinuses

Nasal and paranasal sinus conditions occur frequently in HIV-infected patients. Sinusitis, nasal obstruction, allergic rhinitis, and nasal lesions are common. Epistaxis can occur in patients with platelet disorders (e.g., idiopathic thrombocytopenic purpura [ITP]).

S: Subjective

The patient may complain of “stuffy nose,” rhinorrhea, epistaxis, frontal or maxillary headaches (worse at night or early morning), pain in the nostrils, persistent postnasal drip, mucopurulent nasal discharge, general malaise, aching or pressure behind the eyes, or toothache-like pain.

Obtain information regarding the following during the history:

- Medications (prescription and over-the-counter) and herbal supplements, current and past
- Current or recent sinus infection
- Previous sinus surgery
- Recent or current upper respiratory infection (URI)
- Nasal bleeding or discharge
- Facial trauma
- Allergic rhinitis
- Positional pain; worse when patient bends forward?
- Tobacco use
- Fever
- Headache
- Mucopurulent nasal drainage

O: Objective

CD4 count is an important measure of immunosuppression and a recent CD4 count is a key element in determining whether the patient is at risk of opportunistic infections as causes of nasal and sinus complaints.

Examine the nose and sinuses. Check the nasal mucosa with a light and a speculum, looking for areas of bleeding, purulent drainage, ulcerated lesions, or discolored areas. Palpate or percuss the sinuses for areas of tenderness, look for areas of swelling over the sinuses, and visualize the posterior pharynx for mucopurulent drainage. Transillumination may be helpful. Examine the teeth and gums for caries and inflammation of the gingivae. Check maxillary teeth with the use of a tongue blade (5-10% of maxillary sinusitis is attributable to dental root infection). Refer to a dentist for tooth sensitivity or caries.

A: Assessment

- Possible causes of epistaxis include coagulopathy, ITP, lesions of herpes simplex virus (HSV), and Kaposi sarcoma (KS) or other tumors. Suspect ITP if the platelet count is low and bleeding is difficult to control.
- Acute infection of one or more of the paranasal sinuses is common. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* are seen in both HIV-uninfected and HIV-infected patients, whereas *Staphylococcus aureus* and *Pseudomonas aeruginosa* are found more often in HIV-infected patients. Fungi may be the causative agents, especially in patients with severe immunosuppression.
- Chronic sinusitis occurs frequently in patients with HIV infection and may be polymicrobial or anaerobic. In patients with low CD4 cell counts, fungal sinusitis may occur.
- Nasal obstruction may be caused by adenoidal hypertrophy, chronic sinusitis, allergic rhinitis, or neoplasm.
- Tumors may be caused by KS, squamous papilloma, or lymphoma; biopsy is necessary for determining the cause.
- Painful, ulcerated vesicles in the nasal mucosa may be caused by HSV or other infections.

P: Plan

Acute Sinusitis

Combination therapy with antibiotics, decongestants, mucolytics, saline nasal spray, and topical nasal steroids may be effective. See chapter *Sinusitis* for details. Note: For patients taking antiretroviral (ARV) regimens that include ritonavir or cobicistat, fluticasone (Flonase) nasal spray should not be used, and budesonide (Rhinocort Aqua) should be avoided if possible; see “Potential ARV Interactions,” below.

Chronic Sinusitis

Treat with a systemic decongestant (e.g., guaifenesin) or a saline nasal spray BID. Patients with exacerbations of sinusitis should be treated as for acute sinusitis. For more detailed information, see chapter *Sinusitis*. With patients taking ritonavir-boosted PIs, avoid fluticasone and budesonide nasal sprays; see “Potential ARV Interactions,” below.

Allergic Rhinitis

Patients should avoid exposure to known or suspected allergens. Nasal steroids may be very effective, but avoid fluticasone and budesonide nasal sprays with patients taking ritonavir or cobicistat (see “Potential ARV Interactions,” below). Second-generation nonsedating antihistamines such as cetirizine, fexofenadine, and loratadine are not as effective as nasal steroids, but may give additional symptom relief. Note that ritonavir may increase the serum levels and half-life of cetirizine. Daily nasal lavage with normal saline often is beneficial.

Nasal Obstruction

Perform magnetic resonance imaging (MRI) or computed tomography (CT) scan with biopsy for mass lesions or asymmetric nasal lymphoid tissue. Refer to an ENT specialist.

Epistaxis

Epistaxis caused by coagulopathy or tumor is managed the same as for immunocompetent patients with these conditions. Cauterization of an identified bleeding point or packing may be necessary. ITP should be managed in collaboration with a hematologist; antiretroviral therapy (ART) typically is used for chronic management, and corticosteroids or other therapies may be used for acute management.

Potential ARV Interactions

Caution: Protease inhibitors (PIs), particularly ritonavir-boosted PIs, and cobicistat [e.g., in coformulated elvitegravir/cobicistat/tenofovir/emtricitabine (Stribild)] may increase serum glucocorticoid levels if used concurrently with nasal steroids. Fluticasone (Flonase) nasal spray should not be used with ritonavir-boosted PIs or cobicistat unless expected benefits outweigh possible risks, and should be avoided, if possible, in patients taking unboosted PIs. Budesonide (Rhinocort Aqua) nasal spray should be avoided with ritonavir-boosted PIs and cobicistat. Interactions of PIs and cobicistat with other nasal steroids have not been well studied.

Ritonavir and cobicistat may increase serum levels of cetirizine and may prolong its half-life; start with low dosage and monitor for adverse effects.

Mouth and Throat

The oral cavity is one of the most common areas of symptoms in patients with HIV infection. Conditions that arise in the oral cavity may result from infectious, benign inflammatory, neoplastic, or degenerative processes.

S: Subjective

The patient may complain of white patches and red areas on the dorsal surface of the tongue and the palate, decreased taste sensation, white lesions along the lateral margins of the tongue, ulcers, nonhealing lesions at the corners of the mouth, sore gums, loose teeth, dysphagia, or odynophagia.

Obtain information regarding the following during the history:

- Medications (prescription and over-the-counter) and herbal supplements (note that some medications may cause aphthous ulcers)
- Usual oral hygiene (toothbrushing, tongue brushing or scraping, flossing, use of mouthwash)
- Date of last dental examination
- Use of tobacco (cigarettes, chewing tobacco)
- Involuntary weight loss

O: Objective

Because the CD4 count reflects degree of immunosuppression, a recent CD4 count is helpful in determining whether the patient is at risk of opportunistic infections as causes of oral complaints.

Thorough examination of the mouth and throat with a tongue depressor and a good light is mandatory. Observe for white patches or plaques on the mucous membranes that can be partially removed by scraping with a tongue blade (candidiasis). Examine the dorsal surface of the tongue and hard and soft palates for red, flat, subtle lesions (erythematous candidiasis). Look for ribbed, whitish lesions on the lateral aspects of the tongue that cannot be scraped off (oral hairy leukoplakia). Check for ulcerations, inflamed gums, and loose teeth (see section *Oral Health*). Look for discoloration or nodular lesions on the hard palate (Kaposi sarcoma). Check the pharynx for adenotonsillar hypertrophy. Rule out HIV-unrelated causes of pharyngitis, including streptococci or respiratory viruses.

A/P: Assessment and Plan

Perform biopsy, culture, and potassium hydroxide (KOH) preparation of lesions as indicated.

Oral Candidiasis (Thrush)

Oral candidiasis is most likely to occur when the CD4 count is <200 cells/ μ L, but it can occur at any CD4 level and in HIV-uninfected individuals. It may appear as creamy white plaques on the tongue or buccal mucosa or as erythematous lesions on the dorsal surface of the tongue or the palate. The most common treatment strategy is empiric therapy with topical or systemic antifungal agents. For more details, see chapter *Candidiasis, Oral and Esophageal*.

Angular Cheilitis

Angular cheilitis is also caused by *Candida* species, and it is characterized by fissuring at the corners of the mouth. For information on treatment, see chapter *Candidiasis, Oral and Esophageal*.

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) is caused by Epstein-Barr virus and appears as raised, ribbed, “hairy” white lesions along the lateral margins of the tongue. Lesions are primarily asymptomatic, and treatment generally is not needed. Lesions often resolve with effective ART. For more details, see chapter *Oral Hairy Leukoplakia*.

Kaposi Sarcoma

KS appears as red, blue, or purplish lesions that are flat or nodular, and solitary or multiple. Lesions appear most commonly on the hard palate but also occur on the gingival surfaces and elsewhere in the mouth. A definitive diagnosis requires biopsy and histologic examination. KS often resolves with ART and successful immune reconstitution. If lesions do not respond to ART or if they are severe or numerous, refer to an oncology specialist for chemotherapy. For more details, see chapter *Kaposi Sarcoma*.

Gingivitis

See chapter *Necrotizing Ulcerative Periodontitis and Gingivitis* for details.

Herpes Simplex Virus

HSV lesions occur on the palate, gingivae, or other mucosal surfaces. They appear as single or clustered vesicles and may extend onto adjacent skin of the lips and face to form a large herpetic lesion. Lesions tend to be more common, persist longer, recur more often, and be larger and more numerous in HIV-infected patients, especially those with significant immunosuppression, than in healthy individuals. Empiric treatment with valacyclovir, famciclovir, or acyclovir is appropriate. For more details, see chapter *Herpes Simplex, Mucocutaneous*.

Aphthous Ulcers

Aphthous ulcers are eroded, well-defined lesions surrounded by erythema, ranging in size from <6 mm to several centimeters in diameter. The ulcers can appear anywhere in the oral cavity or pharynx and may be recurrent; they are extremely painful. Treatment may involve topical steroids or other methods. For more details, see chapter *Oral Ulceration*.

Oral Warts (Human Papillomavirus)

Oral warts may appear as solitary or multiple nodules. The lesions may be smooth, raised masses resembling focal epithelial hyperplasia, or small papuliferous or cauliflower-like projections. See chapter *Oral Warts*.

***Neisseria gonorrhoeae* Pharyngitis**

Neisseria gonorrhoeae may be transmitted by orogenital exposure; the patient may have mild symptoms (e.g., sore throat) or be asymptomatic. Physical examination may reveal an erythematous pharynx or exudates. Anterior cervical lymphadenopathy also may be present. Most cases of *N. gonorrhoeae* pharyngeal infection will resolve spontaneously without treatment and usually do not cause adverse sequelae. However, treatment should be initiated to reduce the spread of the infection (see chapter *Gonorrhea and Chlamydia*). Regular screening is recommended for patients at risk of *N. gonorrhoeae* infection.

Medication-Related Causes of Mouth or Throat Lesions

- Candidiasis: antibiotics
- Xerostomia: antihistamines, anticholinergics, tricyclics, antipsychotic
- Gingival hyperplasia: phenytoin, calcium channel blockers

Other Conditions

Most of the above complications also can occur in the esophagus. See chapters *Esophageal Problems*; *Candidiasis, Oral and Esophageal*; and *Cytomegalovirus Disease*.

If patient is having mouth pain, anorexia, or problems with taste, treat the condition appropriately and refer to an HIV-experienced dentist for evaluation and further treatment as needed. Refer to a dietitian for assistance with dietary needs (e.g., nutritional supplements).

Esophageal Problems

Background

Esophageal problems in HIV-infected patients include difficulty swallowing (dysphagia) or midline retrosternal pain when swallowing (odynophagia). Pain may be diffuse throughout the esophagus or localized in specific areas.

Several conditions may cause esophageal problems. Of the infectious causes of dysphagia in HIV-infected patients, *Candida* is the most common (50-70%). Drug-induced dysphagia, gastroesophageal reflux disease (GERD), vomiting, and hiatal hernia also can cause esophagitis. Less commonly, esophageal cancer or another cause of stricture may produce symptoms. Neuromuscular or neurological causes may be seen in patients with advanced AIDS.

If untreated, esophageal problems may result in esophageal ulcers, scarring of the esophagus, dehydration, and weight loss.

S: Subjective

The patient may complain of difficulty swallowing, a feeling of something being “stuck in the throat,” retrosternal pain when eating, “hiccups,” indigestion (“heartburn”), retrosternal burning, acid reflux, nausea, vomiting, or abdominal pain. Ascertain the following during the history:

- Medications (prescription and over-the-counter) and herbal supplements, current and past
- Concurrent gastrointestinal (GI) symptoms, such as abdominal pain or diarrhea
- Recent dietary history
- Location and characteristics of pain (diffuse or focal)
- Oral thrush
- Aphthous ulcers
- Cytomegalovirus (CMV)
- *Candida* esophagitis
- Gastroesophageal reflux disease (GERD)
- Hiatal hernia
- Presence of dysphagia to solids, liquids, or both
- Hematemesis or melena

O: Objective

Include the following in the physical examination:

- Measure vital signs (temperature may be elevated with certain infections, such as CMV, but not with herpes simplex virus [HSV], candidiasis, or idiopathic ulcers).
- Record weight (and compare with previous weights).
- Assess for oral candidiasis, lesions, and masses.
- Examine optic fundi to evaluate for CMV retinitis (in patients with CD4 counts of <50-100 cells/ μ L).
- Palpate for thyroid enlargement.
- Palpate the neck and supraclavicular and infraclavicular areas for lymphadenopathy.
- Assess the abdomen for masses, tenderness, and organomegaly.
- Perform a rectal examination to obtain stool for occult blood.
- Perform a neurologic examination.
- Check the CD4 cell count and HIV viral load to determine the level of immunosuppression and assess the risk of opportunistic infections as causes of esophageal complaints.

A: Assessment

Common causes of esophageal problems are as follows:

- Candidiasis (common with a CD4 count of <200 cells/ μ L or recent exposure to steroids or antibiotics)
- Most medications, including antiretroviral agents, can cause nausea and GI-related symptoms; the following medications are commonly associated with difficulty swallowing or heartburn: aspirin, nonsteroidal antiinflammatory drugs, potassium chloride, iron, tetracycline, theophylline, anticholinergic agents, calcium channel blockers, meperidine, and progesterone tablets
- Foods can irritate the esophagus, including citrus fruits, mints, coffee, chocolate, and spicy foods
- GERD

Less-common causes of esophageal problems include:

- CMV, HSV, idiopathic or aphthous ulcers
- Kaposi sarcoma, lymphoma, tuberculosis, *Mycobacterium avium* complex (MAC), histoplasmosis
- Cardiac chest pain

P: Plan

Diagnostic Evaluation

Diagnosis often can be made on clinical grounds; in this case, empiric treatment may be initiated (see below). If the diagnosis is unclear, consider endoscopy or radiographic imaging (e.g., computed tomography or barium swallow).

If the patient has dysphagia, odynophagia, unexplained weight loss, GI bleeding, anemia, or atypical symptoms, refer promptly for GI evaluation and endoscopy, or other evaluation as suggested by symptoms.

Treatment

Determine whether the patient is able to swallow pills before giving oral medications. If pills are not tolerated, the patient may need liquids or troches.

For patients with severe oral or esophageal pain, viscous lidocaine 1% 5-10 mL 2-4 times daily (with swallowing precautions) or Magic Mouthwash (viscous lidocaine 1%, tetracycline, diphenhydramine, and nystatin compounded 1:1:1:1) may be tried.

Other treatments may depend on the underlying cause:

- **Esophageal candidiasis:** Fluconazole is the drug of choice. If symptoms resolve within 7-10 days, no further testing is required. See chapter *Candidiasis, Oral and Esophageal* for more treatment options and for dosing information.
- **Medication related:** Remove the offending drug(s), and institute a trial of H2 blockers or proton pump inhibitors (PPIs) as appropriate (caution: see “Potential ARV Interactions,” below).
- **Food related:** Modify the diet and institute a trial of H2 blockers or PPIs as appropriate (caution: see “Potential ARV Interactions,” below).
- **“Heartburn” or GERD:** Patients whose primary symptoms are more typical of “heartburn” or reflux, especially those with a history of GERD, should receive a trial of H2 blockers or a PPI as appropriate (these may decrease absorption of atazanavir and rilpivirine; see “Potential ARV Interactions,” below). Reevaluate after 2-4 weeks; if symptoms are controlled, treat for 4-8 weeks, then reduce the dosage to the lowest effective amount.

Patients may require maintenance therapy for an indefinite period because of the high likelihood of recurrence. If symptoms do not respond to full-dose acid-blocking therapy, refer for GI evaluation.

- **GERD:** For nonpharmacologic treatment, in cases of obesity, counsel patients to lose weight, stop smoking, elevate the head of the bed, eat smaller meals, avoid eating food 2-3 hours before bedtime, and reduce fat in the diet to $\leq 30\%$ of calorie consumption.
- **CMV:** Treat with anti-CMV medications (e.g., oral valganciclovir). See chapter *Cytomegalovirus Disease* for details.
- **HSV:** Treat with antiviral medications, including acyclovir, famciclovir, and valacyclovir. See chapter *Herpes Simplex, Mucocutaneous*.
- **Aphthous ulcers:** These may respond to oral corticosteroids (consult with a specialist before this is undertaken). Alternatively, a combination of H2 blockers and sucralfate may be effective. In some circumstances, thalidomide 200 mg Q24H may be used. (**Note:** Thalidomide is teratogenic, and women of childbearing potential are not candidates for this therapy unless the potential benefits clearly outweigh the risks and appropriate prevention of pregnancy is undertaken.) Up to 40-50% of patients with aphthous ulcers experience relapse and require repeat treatment.
- **Neoplastic disease:** Treating this condition requires referral to an oncologist.

Esophageal conditions that do not resolve with treatment require referral to a GI specialist for diagnostic endoscopy, with biopsy and brushing for histopathology and cultures as appropriate.

Diet

It is important that patients maintain adequate caloric intake, preferably with foods and liquids that can be swallowed easily. Nutritional supplements along with soft, bland, high-protein foods are recommended. Refer to a nutritionist as needed.

Potential ARV Interactions

Caution: H2 blockers and PPIs interfere with the absorption of atazanavir and rilpivirine. For atazanavir, specific dosing strategies are required, and some combinations are contraindicated. For rilpivirine, PPIs are contraindicated and H2 blockers require specific dose timing. Polyvalent cations (e.g., magnesium, calcium, iron) contained in antacids, supplements, and other medications may lower serum levels of integrase inhibitors and require separate administration. See package inserts for dosage recommendations.

Eye Problems

Background

The immunosuppression caused by HIV infection increases the incidence of eye infections. However, the risk of serious eye problems associated with advanced immunosuppression, such as blindness caused by cytomegalovirus (CMV) retinitis, is much lower in patients treated with effective antiretroviral therapy (ART). Common problems not unique to HIV-infected patients include dry eye, blepharitis, keratitis, and presbyopia. Infections that may affect the eye include herpes simplex virus (HSV), herpes zoster virus (HZV), and syphilis. More severely immunocompromised patients (CD4 count <100 cells/ μL) may experience CMV retinitis, Toxoplasma retinochoroiditis, cryptococcal chorioretinitis, and other conditions. Retinal detachment can result. Kaposi sarcoma (KS) also can affect the eye.

Immune reconstitution inflammatory syndrome (IRIS) may affect the eye in patients with advanced HIV disease soon after the initiation of effective ART. IRIS may lead to exacerbation of a previously treated opportunistic infection or a new presentation (often with unusual manifestations) of a previously subclinical infection. In the case of CMV, IRIS may present as retinitis, or less commonly as uveitis or vitreitis. IRIS retinitis typically occurs in patients whose CD4 counts have increased from <50 cells/ μL to 50-100 cells/ μL while receiving ART.

Drug-induced ocular toxicity can be caused by many medications, including rifabutin, ethambutol, and cidofovir, and less often by high-dose didanosine (ddI, Videx), IV ganciclovir, IV acyclovir, and atovaquone.

S: Subjective

The patient complains of dry eyes, blurred vision, floaters, sharp pains, flashing lights, central vision loss (“black holes”), vision field defects (“can only see half the page”), or peripheral vision loss (“looks like I’m in a tunnel”).

Ascertain the following during the history:

- Pain: clarify type and characteristics
- Unilateral or bilateral problem
- Visual defects (central or peripheral vision loss or distortion), scotomata (an area of lost or depressed vision surrounded by an area of less-depressed or normal vision); occurs with reading, distance, or both?
- Time course of symptoms
- Fever
- Headache
- Previous eye or vision problems

- Medications (prescription and over-the-counter) and herbal supplements, current and past
- Use of corrective lenses
- Date of last eye examination
- Recent or current varicella-zoster virus (VZV) or HSV infection

O: Objective

Evaluate recent CD4 cell count and HIV viral load to determine whether the patient is at risk of opportunistic infections as causes of eye complaints. Also, do the following:

- Consider the patient’s age.
- Check vital signs, including blood pressure and temperature.
- Administer a visual acuity examination using the Snellen chart. Test the patient’s ability to read small print, such as classified ads.

- Consider using an Amsler grid to locate areas of retinal pathology.
- Examine the eyelids for lesions, inflammation, and swelling.
- Examine the external eye for edema, ptosis, conjunctival injection, and corneal clarity.
- Test cranial nerves II, III, IV, and VI.
- Perform funduscopic examination with pupillary dilatation, if available. Note retinal appearance, lesions, and condition of the disc, vessels, and macula.
- Examine the temples and scalp for tenderness.

A/P: Assessment and Plan

Refer to an HIV-experienced ophthalmologist for dilated retinal or slit-lamp examination and definitive diagnosis. If symptoms raise suspicion of serious or vision-threatening conditions such as herpes ophthalmicus, CMV retinitis, or retinal necrosis, ophthalmologic evaluation should occur within 24-72 hours. Note that patients with HSV or VZV lesions in the V1 distribution (including the forehead, eyelids, or nose) should receive urgent ophthalmologic evaluation.

The differential diagnosis includes the following conditions:

Dry Eye (Keratoconjunctivitis Sicca)

The patient may complain of intermittent eye pain, intermittent blurred vision that clears with blinking, and mild eye irritation. The condition worsens with extended reading or computer use. Keratoconjunctivitis sicca is related to HIV-mediated inflammation with damage to the lacrimal glands. It occurs in 10-20% of HIV-infected patients, most often in those with advanced HIV disease. In patients with a CD4 count of >400 cells/ μ L and no other signs or symptoms, confirm that results of a recent eye examination were normal or refer for same, prescribe artificial tears, and monitor.

Blepharitis

Blepharitis is inflammation of the eyelids, a common condition with dry eyes. The patient may complain of discharge and erythema of the eyes or eyelids. Of the bacterial causes, *Staphylococcus aureus* is the most common. Treatment includes cleaning of the eyelashes with warm water and mild shampoo, and applying antibiotic ointment if indicated.

Infectious Keratitis

The patient may complain of photophobia, eye pain, decreased vision, and irritation. Infectious keratitis may be caused by VZV, HSV, CMV, bacteria, fungi, or *Microsporidia*. VZV and HSV are the most common infectious causes of keratitis in HIV-infected patients. Bacterial and fungal keratitis occur with equal frequency in HIV-infected and HIV-uninfected persons. Fungal infections are caused most often by *Candida* species, especially in intravenous drug users. Keratitis may be more severe and may recur more frequently in HIV-infected patients than in HIV-uninfected persons. Evaluation should include slit-lamp examination by an ophthalmologist.

Refraction Problems

The patient may complain of blurring vision with near or distance vision. Other findings include an abnormal Snellen test or inability to read fine print. The condition may be attributable to presbyopia or other causes. Refer for ophthalmologic examination.

Iridocyclitis/Anterior Uveitis

The patient may complain of redness or watering of the eyes, constriction of the pupil, and blurred vision. Anterior-chamber inflammation is fairly common among patients with HIV infection and is often associated with CMV or HSV retinitis. Ocular bacterial infections, syphilis, toxoplasmosis, and tuberculosis can cause severe symptoms. Fungal retinitis rarely causes iridocyclitis. Other causes include other systemic conditions

(e.g., reactive arthritis, sarcoidosis) and drug toxicity (e.g., rifabutin, cidofovir, ethambutol). Evaluation should include slit-lamp examination by an ophthalmologist.

Treatment should be directed at the causative pathogen or illness. If drug toxicity is suspected, the offending drug should be discontinued or reduced in dosage, if possible. Topical steroids may be indicated as an adjunctive measure. CMV IRIS may present as posterior uveitis; for suspected IRIS, consult an HIV-experienced ophthalmologist.

HIV Retinopathy

The patient typically has no symptoms, but may complain of blurred vision, visual field defects, floaters, or flashing lights. Cotton wool spots on the retina appear as small fluffy white lesions with indistinct borders and without exudates or hemorrhages. Usually, these findings are benign and do not progress. Refer for ophthalmologic examination to rule out other causes.

CMV Retinitis

Patients with retinitis caused by CMV infection may be asymptomatic or may experience blurred vision, floaters, scotomata, or central or peripheral vision loss or distortion. Retinal examination shows creamy to yellowish lesions, white granular areas with perivascular exudates, and hemorrhages (“cottage cheese and ketchup”). The abnormalities initially appear in the periphery, but progress if untreated to involve the macula and optic disc. CMV is a common complication of advanced HIV infection in patients with CD4 counts of <50 cells/ μ L. Vision loss usually is permanent. Urgent ophthalmology consultation and initiation of anti-CMV therapy are required. See chapter *Cytomegalovirus Disease*.

Acute Retinal Necrosis

The patient may complain of eye pain, decreased visual acuity, and floaters. Rapidly progressing peripheral necrosis frequently causes blindness. Retinal necrosis usually is caused by VZV, although HSV and CMV also have been implicated. Treatment should be initiated urgently.

***Toxoplasma* Retinochoroiditis**

Toxoplasma retinochoroiditis may occur in patients with CD4 counts of <100 cells/ μ L and cause blurred vision, visual field defects, floaters, or flashing lights. In HIV-infected patients, ocular manifestations often appear after the infection of the central nervous system with *Toxoplasma* (see chapter *Toxoplasmosis*). Retinal examination may reveal yellow-white infiltrates without hemorrhage and active vitreous inflammation. Evaluation requires consultation with an HIV-experienced ophthalmologist. If toxoplasmosis is confirmed or strongly suspected, treatment should be initiated as quickly as possible.

Neuro-Ophthalmologic Manifestations

Symptoms or signs of papilledema, optic neuritis, cranial nerve palsies, and visual field defects may indicate encephalopathy, increased intracranial pressure, neurosyphilis, toxoplasmosis, progressive multifocal leukoencephalopathy, meningitis, or central nervous system lymphomas. A thorough neurologic examination is required to determine whether additional diagnostic testing, such as imaging studies or cerebrospinal fluid testing, is needed in addition to ophthalmologic evaluation.

Retinal Detachment

The patient may complain of flashes of light, sudden loss of vision, or both. This condition requires immediate referral to an emergency department.

Patient Education

- Patients should report any changes in vision to their health care provider as soon as possible.
- Patients with CD4 counts of <50 cells/ μ L should be examined by an ophthalmologist at baseline and every 6 months thereafter.

Fatigue

Julie Barroso, PhD, ANP-BC, APRN, FAAN

Background

Fatigue is one of the most common and debilitating complaints of HIV-infected people, with an estimated prevalence of 33-88%. Fatigue is defined by the NIH Patient Reported Outcomes Measurement Information System (PROMIS) initiative as “mild subjective feelings of tiredness to an overwhelming, debilitating, and sustained sense of exhaustion that is likely to decrease one’s ability to carry out daily activities, including the ability to work effectively and to function at one’s usual level in family or social roles. Fatigue is divided conceptually into the experience of fatigue (such as its frequency, duration, and intensity), and the impact of fatigue upon physical, mental and social activities.” The consequences of severe fatigue may include curtailment of work and other activities, need for frequent breaks, limitations in involvement with family and friends, and difficulty completing even the simplest household chores.

In HIV-infected individuals, fatigue may be caused by comorbid conditions or by HIV itself. HIV-related fatigue is a broad term referring to fatigue that begins or significantly worsens after the patient is infected with HIV and that has no other identifiable causes. HIV-infected people with fatigue should be evaluated carefully for reversible causes, such as depression, anemia, hypothyroidism, hypogonadism, poor sleep quality, and medication adverse effects; if these are found, they should be treated aggressively. In some patients, fatigue may be related to advanced immunosuppression (e.g., low CD4 cell counts) or to high levels of circulating HIV virus. Unfortunately, for many patients, a specific cause of fatigue is not identified, and fatigue in many HIV-infected individuals may result from a complex interplay between physiologic and psychosocial variables. Recent research has examined genes that are predictive of low vs. high fatigue; abnormal neuronal circuitry involving striatal-cortical pathways that may play a role in HIV-related fatigue; prior use of didanosine or stavudine; and the presence of clinical lipodystrophy syndrome. From a psychosocial standpoint, stress, with its attendant anxiety and depression, seems to be the most consistent predictor of HIV-related fatigue.

S: Subjective

The patient complains of tiredness, easy fatigability, a lack of energy, a need for frequent rest or naps, or waking in the morning feeling unrefreshed. The patient may report difficulty working, difficulty concentrating, inability to exercise without experiencing profound fatigue, or impairment in social relations because of fatigue.

Consider the following during the history:

- No objective clinical indicators exist for fatigue; thus, making a diagnosis of fatigue rests on subjective data.
- Fatigue assessment tools may help in diagnosing fatigue and estimating its severity. One such tool, the HIV-Related Fatigue Scale, was developed specifically for use with HIV-infected individuals; this assesses the intensity of fatigue (on the day of the assessment and during the previous week), the circumstances surrounding fatigue (including patterns), and the consequences of fatigue.
- Take a thorough history of the fatigue symptoms, including onset, duration, exacerbating and alleviating factors, and associated symptoms. Evaluate

for symptoms of other conditions that cause fatigue (e.g., hypothyroidism, hypogonadism, anemia, heart failure, poor nutrition).

- Depression can cause significant fatigue and is common among HIV-infected patients with fatigue. Screen the patient for depression. A single question – “Are you depressed?” – has been shown to be as valid and reliable as most depression instruments. See chapter *Major Depression and Other Depressive Disorders* for further information.
- Inquire about social history, specifically any life stressors including those related to housing status, work stress, and personal relationships.
- Evaluate the patient’s sleep patterns. HIV infection can interfere with sleep architecture early in the illness.
- Inquire about substance use or abuse.
- Obtain a list of all current medications, including herbal and over-the-counter preparations.
- Conduct a nutritional assessment.

O: Objective

Check vital signs, including orthostatic blood pressure and heart rate measurements, if indicated. Perform a physical examination including evaluation of nutritional status, affect, conjunctivae and skin (for pallor), thyroid, lungs and heart, and deep tendon reflexes.

A: Assessment

The differential diagnosis includes the following:

- Anemia
- Depression
- Hypogonadism
- Hypothyroidism
- Insomnia or poor-quality sleep
- Malnutrition
- Medication adverse effects (e.g., zidovudine, interferon)
- Opportunistic infections, malignancy, chronic hepatitis B or C, mononucleosis, other illnesses
- Pregnancy
- Substance use or abuse

P: Plan

Diagnostic Evaluation

To rule out reversible causes of fatigue, perform laboratory tests, including:

- Hemoglobin and hematocrit
- Thyroid function tests
- Testosterone (in both men and women)
- Pregnancy test, if applicable
- CD4 and HIV viral load (if not done recently), electrolytes, creatinine, and liver function tests

Fatigue assessment tools, as mentioned above, may be used to assess the intensity of fatigue, the circumstances surrounding fatigue, and the consequences of fatigue.

Treatment

If testing reveals a specific cause of fatigue, treat appropriately. For example:

- Treat anemia, hypothyroidism, or hypogonadism, as indicated.
- Treat depression with antidepressant

medication, psychotherapy, or both; see chapter *Major Depression and Other Depressive Disorders*.

- Treat insomnia and review good sleep-hygiene practices with the patient; see chapter *Insomnia*.
- Refer for treatment of substance use or abuse, if possible.
- Provide counseling regarding any current life stressors that may be contributing to fatigue. Involve social work and case management services regarding housing issues or other social needs that may be contributing to fatigue.
- Treat malnutrition, ideally in conjunction with a nutritionist.
- Treat opportunistic infections and other illnesses. (See section *Comorbidities, Coinfections, and Complications*.)
- Control other symptoms that could be causing fatigue (e.g., diarrhea).
- If fatigue seems to be related to antiretroviral medication(s), weigh the benefits of the medication(s) against the possible adverse effects, and discuss these with the patient.

After appropriate evaluation, if the fatigue is thought to be related to HIV infection or if no specific cause is identified, consider the following:

- If HIV infection is inadequately controlled, particularly if the CD4 count is low or the HIV viral load is high, initiate or optimize antiretroviral therapy (ART), if otherwise appropriate.
- Patients taking effective ART may still experience HIV-related fatigue. Prepare patients for the possibility that fatigue may persist despite ART initiation.
- Encourage patients to track their patterns of fatigue with a fatigue diary. Once patients recognize their individual patterns, they can better cope with fatigue by planning their daily activities accordingly (e.g., performing the most strenuous tasks during times of

peak energy or staggering activities to avoid excessive fatigue).

- Ask patients what seems to aggravate their fatigue. This information, too, will help patients determine their patterns of fatigue and identify self-care actions they might take to avoid triggers that will worsen the fatigue.
- Recommend moderate exercise and frequent rest.
- Refer the patient to community-based agencies for assistance with housekeeping.
- Evaluate the need for occupational therapy (e.g., energy conservation techniques) or physical therapy (e.g., reconditioning and strengthening exercises).
- Medications such as stimulants (e.g., modafinil) may be helpful for some patients with severe or debilitating fatigue.

Patient Education

- Fatigue is often unrelated to the CD4 cell count or HIV viral load. Teach patients not to dismiss feelings of fatigue if they have higher CD4 counts and lower viral loads. Encourage them to discuss their symptoms with a health care provider.
- For patients with depression, advise them that appropriate treatment may reduce fatigue.
- Help patients identify how current life circumstances and stressors may contribute to fatigue and encourage them to seek the appropriate social services to help manage appropriately.
- Talk to patients about their sleep habits and recommend changes, as appropriate, to improve their sleep hygiene.
- Prepare patients to accept the fact that their fatigue (in some cases) may be a chronic condition, in which case it can be best managed by maintaining open communication with their providers and remaining engaged in care.

Fever

Background

Although fever may accompany HIV infection at various stages of disease, fever in a patient with a low CD4 count (<200 cells/ μ L) should prompt the clinician to rule out opportunistic infections.

S: Subjective

The patient complains of persistent fever, or new-onset fever of $>101^{\circ}\text{F}$ (38.3°C).

Assess the following during the history:

- Duration of fever
- Associated symptoms, including chills, sweats, weight loss
- Visual disturbances (see chapter *Eye Problems*)
- Nasal or sinus symptoms
- Asymmetric, tender, or new lymphadenopathy
- Cough or shortness of breath (see chapter *Pulmonary Symptoms*)
- Diarrhea, tenesmus (see chapter *Diarrhea*)
- Rash, lesions, soft-tissue inflammation
- Pain (for headache, see chapter *Headache*)
- Neurologic symptoms (see chapter *Neurologic Symptoms*)
- Vaginal or urethral discharge
- Other localizing symptoms
- Unprotected sexual contacts
- Recent injection drug use
- Intravenous line or venous access device
- Travel within the past 6-12 months
- Medications (as a cause of fever)
- Use of antipyretic agents including aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and acetaminophen; when was most recent dose taken?

O: Objective

Document fever. Check other vital signs, including orthostatic measurements. Check weight and compare with previous values.

Search for evidence of an infectious focus. Perform a complete physical examination, including evaluation of the eyes (including fundus), sinuses, oropharynx, ears, lymph nodes, lungs and heart, abdomen, joints, genitals, uterus, rectum, skin, and neurologic system.

Review recent CD4 measurements, if available, to determine the patient's risk of opportunistic illnesses as a cause of fever.

A: Assessment

The differential diagnosis varies depending on the CD4 count. Possibilities include the following:

Conditions More Likely with Low CD4 Count

- Aspergillosis
- Cryptococcosis
- Cytomegalovirus (CMV) infection
- Disseminated Mycobacterium avium complex (MAC)
- Disseminated histoplasmosis
- HIV infection itself
- Lymphoma, other neoplasms
- Pneumocystis jiroveci pneumonia (PCP)
- Toxoplasmosis
- Tuberculosis (atypical or extrapulmonary)

Conditions That May Occur with Any CD4 Count

- Abscess, cellulitis
- Acute hepatitis
- Autoimmune process
- Bacteremia or sepsis
- Bacterial pneumonia or bronchitis
- Disseminated herpes simplex virus; chickenpox
- Drug-induced fever (common culprits include abacavir, nevirapine, sulfonamides, dapsone, penicillin, clindamycin, carbamazepine, phenytoin, barbiturates, and bleomycin)
- Endocarditis
- Immune reconstitution syndromes, related to opportunistic infections, are often associated with fever (see chapter *Immune Reconstitution Inflammatory Syndrome*)
- Influenza
- Otitis
- Malaria
- Pelvic inflammatory disease (PID)
- Sexually transmitted diseases
- Sinusitis
- Tuberculosis (pulmonary)
- Urinary tract infection (UTI)

**P: Plan
Diagnostic Evaluation**

Perform laboratory work and other diagnostic studies as suggested by the history, physical examination, and differential diagnosis. These may include the following:

- CD4 count (if not done recently) to help with risk stratification for opportunistic illnesses
- Complete blood count (CBC) with differential
- Blood cultures (bacterial, mycobacterial, fungal)
- Urinalysis, urine culture if UTI symptoms are present
- Liver transaminases, renal panel
- Chest X-ray
- Sinus films if indicated by symptoms and physical examination findings
- If respiratory symptoms and signs are present: sputum evaluation (Gram stain and acid-fast bacilli smear, evaluation for PCP), with culture of sputum for bacterial pathogens, acid-fast bacilli, viruses, and fungi as indicated; consider sputum induction or bronchoscopy if indicated
- Serum cryptococcal antigen, particularly if CD4 count is <100 cells/ μ L and symptoms are consistent with cryptococcosis
- If neurological symptoms and signs are present: computed tomography (CT) or magnetic resonance imaging (MRI) of head, lumbar puncture
- For new lymphadenopathy: aspirate with culture (including acid-fast bacilli and fungal) and cytology
- For cytopenias: bone marrow aspirate and biopsy may be needed; see applicable treatment guidelines

- For fever of unknown origin (FUO), defined as persistent fever $>101^{\circ}\text{F}$ for >3 weeks without findings on initial workup, more intensive workup may be needed, such as lumbar puncture, other scans or biopsies; consult with a specialist in infectious diseases or an HIV expert to determine whether hospitalization or other laboratory tests are needed
- For patients who recently started abacavir or nevirapine, or other medications, rule out hypersensitivity reactions (see chapter *Adverse Reactions to HIV Medications*)

Treatment

Once a diagnosis is made, appropriate treatment should be initiated. In seriously ill patients, presumptive treatment may be started while diagnostic tests are pending. In some cases, the source of fever cannot be identified. Consult with an HIV expert.

Symptomatic treatment may include NSAIDs (e.g., ibuprofen, naproxen), acetaminophen, and analgesics. Monitor for adverse gastrointestinal effects with NSAIDs. Cold compresses also can be used to relieve fever symptoms. Refer to a dietitian to avoid weight loss during the hypermetabolic state. See section *Comorbidities, Coinfections, and Complications* in this manual if an HIV-related cause is identified.

Patient Education

- Patients should report any new fever to their health care provider. They should measure their temperature using a thermometer at home in order to report actual temperatures.
- Patients should know that fever usually is a sign that their bodies are battling an infection. Their health care providers may need to do special tests to find out what could be causing the fever.
- Many over-the-counter remedies are available to treat fevers. Patients should check with their care provider before taking these. Acetaminophen-containing products (e.g., Tylenol) generally are well tolerated. Persons with liver disease should use acetaminophen only as prescribed. NSAIDs (e.g., ibuprofen, naproxen) may be used, but they can cause adverse gastrointestinal effects, especially if taken without food. Patients should let their care provider know if they need to take these medicines for more than 2 or 3 days.

Headache

Background

Headache in HIV-infected persons may result from many causes, particularly if the CD4 cell count is low. Possible causes include infections (opportunistic and other) and central nervous system malignancies, HIV-related systemic illnesses, and medication toxicity. In addition, headache may be caused by any of the processes that cause headache in HIV-uninfected individuals. New or severe headache should be evaluated carefully.

S: Subjective

The patient complains of a new type of headache.

Determine the following during the history:

- History of headaches or migraines
- Characteristics of the headache (e.g., location, quality of pain, timing, duration)
- Recent head trauma
- Fever
- History of sinusitis
- Allergies
- Visual changes
- Dizziness, vertigo, nausea
- Mental status changes
- Seizures
- Focal or other neurologic symptoms (see chapter *Neurologic Symptoms*)
- New rashes or ulcerations
- Other symptoms
- Caffeine intake; recent changes in intake
- New medications (e.g., zidovudine, dolutegravir)
- Relief of headache by any medication
- Unprotected sex, new sex partner

O: Objective

Perform a physical examination as follows:

- Check vital signs. Look for fever, orthostasis, and hypertension.
- Examine the head and neck for trauma, sinus tenderness, scalp or temple tenderness, and neck mobility; check lymph nodes.
- Check the eyes, including fundoscopic examination, for lesions or papilledema.
- Look for oral lesions, dental abscess, thrush, and pharyngeal drainage.
- Examine the lungs for abnormal sounds.
- Check the skin, including palms and soles, for rashes or lesions.
- Perform a complete neurologic examination, including mental status examination.
- Review recent CD4 measurements, if available, to determine the patient's risk of opportunistic illnesses as a cause of headache.

A: Assessment

A partial differential diagnosis includes the following:

- Anemia
- Caffeine withdrawal
- Central nervous system lymphoma
- Cryptococcal meningitis
- Cytomegalovirus (CMV) meningoencephalitis or retinitis
- Dehydration
- Depression, anxiety disorder
- Fever
- Hypertension
- Medication adverse effect
- Migraine or cluster headache
- Neurosyphilis
- Other encephalitis
- Progressive multifocal leukoencephalopathy (PML)
- Sinusitis
- Stress or tension headache
- Systemic infection
- Temporal arteritis
- Toxoplasmic encephalitis
- Tuberculous meningitis; other meningitis

Other causes of headache unrelated to HIV should be considered.

P: Plan**Diagnostic Evaluation**

Evaluation should include the following:

- CD4 cell count (if not done recently), to help with risk stratification for opportunistic illnesses
- Complete blood count with differential (if fever or suspected anemia); see chapter *Fever*
- Blood chemistries, including liver function tests, electrolytes, creatinine, glucose
- Serum cryptococcal antigen (if fever is present and CD4 count is <100 cells/μL); see chapter *Cryptococcal Disease*
- *Toxoplasma* immunoglobulin G (consider if previously negative and CD4 count is <100 cells/μL; may indicate risk of toxoplasmosis); see chapter *Toxoplasmosis*
- Syphilis testing: rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) test; see chapter *Syphilis*

When indicated, also consider:

- Computed tomography (CT) scan with contrast or magnetic resonance imaging of the head; see chapter *Neurologic Symptoms*
- Lumbar puncture with cerebrospinal fluid (CSF) studies to include opening pressure, cell count, chemistries, bacterial cultures; fungal and acid-fast bacilli evaluations and cultures; India ink stain; cryptococcal antigen, VDRL, as indicated
- Sinus imaging
- Erythrocyte sedimentation rate, if temporal arteritis is suspected

Treatment

- Once a diagnosis is made, appropriate treatment should be initiated. In seriously ill patients, presumptive treatment may be initiated while diagnostic test results are pending. In some cases, the source of headache cannot be identified. Consult with an HIV expert or a neurologist.
- Refer to disease-specific treatment guidelines or primary care management guidelines as appropriate.
- Treat symptomatically with nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, or narcotics, if indicated, to control pain.

Patient Education

- Headache can be a sign of an opportunistic infection, especially in patients with low CD4 cell counts. Patients should notify their health care provider if they develop a new headache.
- Providers should inform patients that they may have to do additional tests to determine the cause of the headache.
- Many over-the-counter remedies are available for headache. Patients should check with their health care provider before taking these. Acetaminophen-containing products (e.g., Tylenol) generally are well tolerated. Persons with liver disease should use acetaminophen only as prescribed. NSAIDs (e.g., ibuprofen, naproxen) may be used, but these agents can cause adverse gastrointestinal effects, especially if taken without food. Patients should inform their care provider if they need to take these medicines for more than 2 or 3 days.

Lymphadenopathy

Background

Lymphadenopathy is very common among HIV-infected individuals and may occur at any stage of HIV infection. It may be the first indication of a serious local or systemic condition, and it should be evaluated carefully. Rapid enlargement of a previously stable lymph node or a group of nodes requires evaluation to identify the cause and to determine whether treatment is needed. Similarly, nodes that are abnormal in consistency, tender to palpation, fluctuant, asymmetrical, adherent to surrounding tissues, or accompanied by other symptoms should be evaluated promptly.

Lymphadenopathy may be generalized or localized and usually is characterized by lymph nodes that are >1 cm in diameter. A multitude of conditions can cause lymphadenopathy, including HIV itself, opportunistic or other infections, and malignancies. The likely causes of lymphadenopathy, and thus the diagnostic workup, will depend in part on the patient's degree of immunosuppression. The risk of opportunistic and certain malignant conditions increases at lower CD4 cell counts (see chapter *Risk of HIV Progression/Indications for ART*).

Many individuals with primary HIV infection (see chapter *Early HIV Infection*) have generalized lymphadenopathy that may resolve or may persist for months to years. If lymphadenopathy of >2 cm in size occurs in two or more noncontiguous sites and persists for more than 3 months, and if appropriate evaluation reveals no other cause, the patient is diagnosed with persistent generalized lymphadenopathy (PGL). PGL usually is caused by follicular hyperplasia from chronic HIV infection. Antiretroviral therapy (ART) should be initiated or optimized, but as long as enlarged nodes are stable in number, location, and size, persons with PGL require no specific management other than monitoring of nodes at each physical examination. Changes in the character of the lymph nodes should prompt further evaluation. Rapid involution of PGL may occur with advanced HIV disease and is a poor prognostic sign.

S: Subjective

The patient complains of new, worsening, or persistent glandular swellings in the neck, axilla, groin, or elsewhere.

Ascertain the following during the history:

- Symptoms that accompany the lymphadenopathy, particularly constitutional symptoms such as fever, sweats, fatigue, and unintentional weight loss
- Localized symptoms or conditions that involve areas of the body with lymphatic drainage into the area of abnormal lymph nodes (e.g., in the case of axillary lymphadenopathy, ask about breast masses and skin conditions or trauma involving the arm)
- A full review of systems
- HIV-related or other malignancies, opportunistic illnesses
- Recent travel, country or region of origin, disease exposures (e.g., tuberculosis [TB], sexually transmitted diseases [STDs]), and risk behaviors (e.g., injection drug use)
- Recent initiation of ART (may indicate immune reconstitution inflammatory syndrome [IRIS])
- Trauma or injury (including cat scratches)
- Exposure to household pets
- Current medications

O: Objective

- Review recent CD4 cell counts and HIV viral load measurements.
- Check vital signs.
- Perform a complete examination of lymph nodes, including the cervical, submandibular, supraclavicular, axillary, epitrochlear, and inguinal sites. Document the location, size, consistency, mobility, and presence or absence of tenderness of all abnormal nodes. In cases of localized lymphadenopathy, examine the area drained by the node.
- Check for hepatosplenomegaly.
- Perform a focused examination (e.g., lung, breast, skin, genitals) to identify signs of local or systemic illness.

A: Assessment

The differential diagnosis of lymphadenopathy in HIV-infected patients depends in part on the degree of immunosuppression. For further information, see chapter *Risk of HIV Progression/Indications for ART*.

Infectious Causes**Generalized lymphadenopathy**

- HIV infection, including PGL
- Mononucleosis; Epstein-Barr virus
- *Mycobacterium avium* complex
- TB
- Cytomegalovirus
- Secondary syphilis
- Toxoplasmosis

- Histoplasmosis, other fungal diseases
- *Bartonella* infection
- Hepatitis B
- Lyme disease
- Widespread skin infections
- IRIS involving various infections
- Follicular hyperplasia
- Castleman disease

Localized lymphadenopathy

- Any of the above
- Oropharyngeal and dental infections
- Cellulitis or abscesses
- TB (scrofula)
- Chancroid
- Chlamydia (lymphogranuloma venereum [LGV])
- Other STDs

Neoplastic Causes

- Lymphoma
- Acute and chronic lymphocytic leukemias
- Other malignancy; metastatic cancer
- Kaposi sarcoma

Other Causes

- Reactive process (benign)
- Sarcoidosis
- Hypersensitivity reaction to medications
- Serum sickness
- Rheumatoid arthritis

P: Plan**Diagnostic Evaluation**

After the history and physical examination, the cause of lymphadenopathy may be clear and further diagnostic testing may not be necessary. If the cause of the lymphadenopathy is still uncertain, perform diagnostic testing as indicated by the patient's presentation. This may include the following tests:

- CD4 count (with or without HIV viral load), to determine the risk of opportunistic illnesses
- Complete blood count with differential; liver function tests; urinalysis
- Chest X-ray
- TB screening (tuberculin skin test [TST] or interferon-gamma release assay [IGRA])
- Syphilis screening (rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL] test)
- Blood cultures, if patient is febrile (bacterial, mycobacterial, and fungal, as indicated)
- Testing for specific infections if suspected (e.g., *Bartonella*, LGV)

If a node is large, fixed, nontender, or otherwise worrisome, or if the diagnosis is unclear after initial evaluation, fine-needle aspiration (FNA) biopsy may provide a diagnosis. If FNA is nondiagnostic (false-negative results are relatively common), obtain an excisional biopsy for definitive evaluation. Biopsy specimens should be sent for bacterial, mycobacterial, and fungal cultures; acid-fast staining for mycobacteria; and cytologic examination.

If a node is large, inflamed, tender, or fluctuant, and a bacterial infection is suspected, consider initiating empiric

antibiotic treatment and monitoring the patient over the course of 1-2 weeks. If the node does not respond to antibiotic treatment or the patient becomes more symptomatic, arrange for FNA or open biopsy to establish the diagnosis.

Treatment

Treatment will depend on the cause of lymphadenopathy. Refer to section *Comorbidities, Coinfections, and Complications* or to OI management guidelines as appropriate. In the case of HIV-related lymphadenopathy, ART may be effective.

Patient Education

- Lymphadenopathy may come and go throughout the course of HIV infection, but it may be a sign of a serious condition.
- Advise patients to notify their care provider if lymph nodes increase in size or change in character.

Nausea and Vomiting

Background

Nausea with or without vomiting, and occasionally vomiting without nausea, can occur at any stage of HIV infection. Nausea is a common adverse effect of many antiretroviral (ARV) and other medications, and it often occurs within weeks of starting new medications. In some cases, nausea causes significant discomfort and may interfere with medication adherence. Nausea and vomiting also may be symptoms of a serious complication of ARV therapy, or signs of an opportunistic infection or neoplasm in patients with late-stage AIDS. Clinicians must identify the cause of nausea and vomiting and initiate appropriate treatment.

S: Subjective

The patient experiences nausea with or without vomiting, or vomiting without nausea.

Ascertain the following during the history:

- Duration of symptoms
- Characteristics, timing, and precipitating factors
- Vomiting, including hematemesis
- Diarrhea
- Abdominal pain
- Fever
- Jaundice
- Lightheadedness, dizziness, vertigo, or orthostatic symptoms
- Polyuria
- Polydipsia
- Headache
- Changes in vision
- Neck stiffness
- Pruritus
- Medications, new and ongoing
- Nutritional supplements and non-prescription medications
- Possibility of pregnancy (for women) (e.g., missed menses)

- Alcohol intake, substance use or abuse
- History of:
 - Hepatitis
 - Kidney disease
 - Pancreatitis
 - Cytomegalovirus
 - Central nervous system (CNS) infections, including toxoplasmosis, cryptococcosis, chronic meningitis
 - CNS lymphoma

O: Objective

Check vital signs, including orthostatic blood pressure and heart rate measurements.

Conduct a thorough physical examination, including evaluation of the following:

- Skin turgor
- Eyes and fundi (retinal abnormalities such as papilledema)
- Oropharynx (dryness of oral mucosa, thrush, ulcerations)
- Neck (stiffness or other signs of meningeal irritation)
- Abdomen (tenderness, distention, masses, organomegaly)
- Pelvis (tenderness, masses)

318 | Guide for HIV/AIDS Clinical Care

- Neurologic system (mental status, focal neurologic abnormalities)

Review recent CD4 measurements, if available, to determine the patient's risk of opportunistic illnesses.

A: Assessment

A partial differential diagnosis includes the following conditions:

- Medication effect or reaction
- Foodborne illness
- Viral or other infectious gastroenteritis
- Pancreatitis
- Hepatitis, infectious or drug related (see chapters *Hepatitis B Infection* and *Hepatitis C Infection*)
- Appendicitis
- Esophagitis (see chapter *Esophageal Problems*)
- Lactic acidosis attributable to nucleoside analogues
- Pregnancy
- Adrenal insufficiency
- CNS lymphoma
- Meningitis
- Uremia
- Diabetic ketoacidosis
- Influenza
- Pelvic inflammatory disease (see chapter *Pelvic Inflammatory Disease*)
- Myocardial infarction

P: Plan

Diagnostic Evaluation

Perform laboratory work and other diagnostic studies as suggested by the history, physical examination, and differential diagnosis. Tests may include the following:

- Complete blood count with differential
- Electrolytes, creatinine, blood urea nitrogen
- Glucose
- Amylase and lipase if symptoms of pancreatitis are present
- Liver function tests and hepatitis serologies for possible acute or chronic hepatitis
- Blood cultures and other fever workup as needed (see chapter *Fever*)
- Computed tomography scan of the brain if neurologic symptoms are present (see chapter *Neurologic Symptoms*)
- Cortisol and cosyntropin stimulation test if indicated (e.g., fatigue, weakness, unexplained abdominal pain, weight loss, orthostasis; usually in late-stage AIDS)
- If odynophagia or dysphagia is present, see chapter *Esophageal Problems*
- Lactic acid levels if lactic acidosis is suspected
- Pregnancy test if indicated
- Electrocardiogram if patient has chest pain or suspicious symptoms

Consult with an HIV expert to determine whether hospitalization or other laboratory tests are needed.

Treatment

Once the diagnosis is made, appropriate treatment should be initiated. In seriously ill patients, presumptive treatment may be started while diagnostic test results are pending. See appropriate chapters in section *Comorbidities, Coinfections, and Complications* and relevant guidelines.

In the case of significant adverse effects from ARVs or other medications, substitute a less-emetogenic ARV for the problematic medication, if possible (without compromising the efficacy of the treatment regimen). In the case of serious or life-threatening medication toxicities (e.g., lactic acidosis or abacavir hypersensitivity reaction), discontinue the problematic medication (see chapter *Adverse Reactions to HIV Medications*).

After the workup and exclusion of life-threatening illness, symptomatic treatment can be considered. If nausea and vomiting are attributable to medications that are vital to the patient, and these complications are not life-threatening, antiemetic therapy may be the best treatment. Chronic therapy is not always necessary. Some patients obtain adequate relief by breaking the “nausea cycle” with effective antiemetics for 1-2 days and then establishing meals or snacks with medications. Patients with dehydration may require administration of fluids (PO or IV) to relieve nausea. For patients with chronic nausea resulting in weight loss, refer to a nutritionist for assessment and nutritional support.

Symptomatic treatment

Consider the following strategies for symptomatic treatment:

- For nausea that occurs in relation to an event or action (e.g., after taking ARVs) antiemetics may be given preemptively (e.g., 30 minutes beforehand).
- Ginger capsules have proven effective in clinical trials for the management of pregnancy-related and chemotherapy-related

nausea. Foods and beverages containing ginger (e.g., tea, cookies, ginger ale, candies) may help provide relief.

- Promethazine (Phenergan) may be given as a 12.5-25 mg PO tablet Q4-6H as needed. For patients unable to tolerate the PO formulation, promethazine suppositories (12.5 or 25 mg) may be used.
- Prochlorperazine (Compazine) may be given as a 5 mg or 10 mg PO tablet, or a 25 mg rectal suppository, Q6-8H as needed. Extended-release spansule, 10 mg Q12H or 15 mg QAM, also can be considered.
- Lorazepam (Ativan) may be given as a 0.5 mg PO tablet 30 minutes before taking medications for symptoms of anticipatory nausea. Patients with anticipatory nausea develop significant nausea or vomiting when even thinking about medications or reaching for the medications.
- Dronabinol (Marinol) may relieve nausea, especially when nausea is accompanied by a loss of appetite. This remedy is best tolerated by patients who have tolerated inhaled marijuana. The starting dosage is 2.5 to 5 mg BID or TID.
- 5-Hydroxytryptamine (5-HT₃) receptor antagonists such as dolasetron 50 mg and 100 mg, granisetron 1 mg, and ondansetron 4 mg and 8 mg are highly effective and highly effective in relieving severe nausea and vomiting resulting from chemotherapy and other causes. However, access to these medications is limited by their cost. Their use should be considered a short-term strategy or reserved for cases of nausea/vomiting refractory to other antiemetics.
- Metoclopramide (Reglan) may be used to enhance gastrointestinal motility in patients who experience nausea and vomiting caused by gastroparesis. The typical PO dose is 5-10 mg Q4-6H, or it can be taken TID with meals if the nausea or vomiting is associated with eating.

- H2 antagonists or proton pump inhibitors may be helpful in treating nausea/vomiting related to gastritis or acid reflux (caution: these agents interfere with absorption of atazanavir and rilpivirine; consult dosing recommendations); see chapter *Esophageal Problems* and relevant tables in the U.S. Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents* (see Appendix).
- Many patients wonder whether they should take their medicines again if they vomit after taking a dose. Generally, the medicines are still in the body unless the pills actually come back up. Patients should call their health care provider if they have any questions.
- Ginger may help to relieve nausea. Ginger can be taken in a variety of ways, including ginger ale, tea, cookies, candies, and ginger capsules. Patients can choose the form of ginger that works best for them.

Patient Education

- Nausea and vomiting can have many different causes. Patients should let their health care provider know if they are having these symptoms so that the most likely cause can be determined.
- Patients should stay nourished and well hydrated even if they are experiencing nausea and vomiting. Eating small, frequent meals may be best tolerated, while avoiding dairy products, spicy or greasy foods, and high-fat meals. Taking medications with food may reduce symptoms of nausea (note that some medications must be taken on an empty stomach).
- Patients should not stop taking any of their medications without first discussing it with their health care provider. Many medications must be continued despite nausea. Nausea and vomiting owing to ARVs may resolve or become tolerable over time.

Neurologic Symptoms

Background

The nervous system may be a site of complications throughout the course of HIV infection, and neurologic complaints are common among HIV-infected individuals. Neurologic symptoms may be caused by many factors, including infections (opportunistic and other), central nervous system (CNS) malignancies, medication toxicities, comorbid conditions (e.g., diabetes, cerebrovascular disease, chronic hepatitis, mental illness), and nervous system injuries related to HIV itself.

The risk of some conditions, such as CNS infection, malignancy, and dementia, increases with advancing immunosuppression, and the CD4 cell count will help to stratify the patient's risk of opportunistic illnesses (see Table 1 in chapter *Risk of HIV Progression/Indications for ART*). This chapter presents a general approach to neurologic symptoms in HIV-infected patients, with reference to other chapters in this manual for more detailed reading. For information on peripheral neuropathy, see chapter *Pain Syndrome and Peripheral Neuropathy*; for information on neurocognitive disease, see *HIV-Associated Neurocognitive Disorders*.

S: Subjective

The patient, or a friend or family member on his or her behalf, reports new neurologic symptoms such as pain, headache, seizures, altered mental status, or weakness.

Ascertain the following during the history:

- Onset and duration: rapid (hours to days), subacute, chronic
 - Characteristics of the symptoms (e.g., location, quality, timing)
 - Progression or stability of symptoms
 - Constitutional symptoms: fever, night sweats, unintentional weight loss
 - Associated symptoms, including other neurologic, muscular, psychiatric, or behavioral symptoms
 - Recent trauma to the head or other area
 - Visual changes, photophobia
 - Dizziness, vertigo
 - Mental status changes (including changes in behavior, personality, or cognition; short-term memory loss; mental slowing; reading comprehension difficulties; changes in personal appearance and grooming habits)
 - Seizures (description, duration, number)
 - Pain
 - Sensory symptoms
 - Weakness (distinguish weakness from fatigue or pain; determine whether bilateral or focal, proximal or distal)
 - Bowel or bladder changes
 - Rash or ulcerations
 - Medications: current, past, and recently initiated medications, including antiretroviral (ARV) medications
 - Alcohol or drug use; date of last use
 - Exposures (sexual, environmental), travel history
 - Psychiatric history and past psychiatric care
 - Most recent CD4 cell count and HIV viral load, previous AIDS-defining illnesses
 - Functional impact of the symptoms: social functioning, ability to work and perform activities of daily living
- Differentiate delirium and dementia. Delirium presents as acute onset of clouded sensorium, disturbed and fluctuating

level of consciousness, disorientation, cognitive deficits, and reduced attention, sometimes with hallucinations. Delirium often is caused by medication toxicities, infections, hypoxia, hypoglycemia, electrolyte imbalances, or mass lesions, and it frequently is correctable. Dementia emerges more gradually and is characterized by cognitive impairment and behavioral, motor, and affective changes. See chapter *HIV-Associated Neurocognitive Disorders*.

O: Objective

- Check vital signs (temperature, blood pressure, heart rate, respiratory rate, and oxygen saturation) and orthostatic measurements.
- Perform a careful physical examination as guided by the history, with special attention to the following:
 - General appearance: mood, affect, mannerisms
 - Head and neck: signs of trauma, sinus tenderness, lymph node status, neck mobility
 - Eyes, including fundi: lesions, papilledema
 - Lungs, heart: abnormal sounds
 - Extremities: muscle tone and bulk
 - Skin, mucous membranes: rash, lesions
- Conduct a thorough neurologic examination, including cranial nerves, motor function, sensory function, coordination, gait, and deep tendon reflexes.
- Conduct a mental status examination.
- Review recent CD4 measurements, if available, to determine the patient's risk of opportunistic illnesses.

A: Assessment

The differential diagnosis of neurologic abnormalities in patients with HIV infection may be broad, particularly if the CD4 count is low. Both HIV-related and HIV-unrelated causes should be considered; remember that more than one cause of symptoms may be present.

Possible Causes of Neurologic Abnormalities

Causes related to the cerebrum or cranial nerves

- Toxoplasmic encephalitis
- Primary CNS lymphoma
- Cryptococcal meningitis
- Cytomegalovirus (CMV) encephalitis
- Other meningitis (bacterial, tuberculous, fungal, viral)
- Progressive multifocal leukoencephalopathy (PML)
- Neurosyphilis
- CNS coccidioidomycosis, histoplasmosis
- HIV-related dementia
- Cerebrovascular accident; stroke
- Metabolic abnormalities, including hypo- or hyperglycemia, electrolyte abnormalities
- Alcohol or drug intoxication or withdrawal (medications or illicit drugs); chronic alcohol abuse
- Medication adverse effects (e.g., efavirenz, corticosteroids, anticholinergics, many others)
- Depression, mania, anxiety, psychosis

Causes related to the spinal cord, nerve roots, peripheral nerves, and muscle

- Inflammatory demyelinating polyneuropathy (e.g., Guillain-Barré syndrome)
- Polyradiculitis (e.g., CMV, herpes simplex virus)
- Vitamin deficiency
- Myositis
- Myopathy (e.g., owing to zidovudine)
- Myelopathy (e.g., HIV vacuolar myelopathy)
- Epidural abscess or mass
- Mononeuritis multiplex
- Lactic acidosis
- Electrolyte abnormality (e.g., hypokalemia)
- Peripheral neuropathy
- Distal sensory polyneuropathy
- Antiretroviral toxic neuropathy (especially stavudine, didanosine)
- Other neuropathy (e.g., owing to diabetes, alcohol, medications [isoniazid, dapsone, many others])

Note that organic causes of neurologic symptoms must be ruled out before concluding that symptoms are psychiatric in nature.

P: Plan

Diagnostic Evaluation

Unstable or seriously ill patients should be hospitalized for evaluation and treatment. Criteria for hospitalization include acutely altered mental status, fever with focal neurologic findings, and new or unstable seizures.

Perform laboratory work and other diagnostic studies as suggested by the history, physical examination, and differential diagnosis. This may include the following:

- Establish the CD4 count (if not done recently) to help with risk stratification for opportunistic illnesses.

- Determine which laboratory tests are appropriate, depending on the patient's presentation. The initial evaluation often includes a complete blood count with differential and monitoring of electrolyte and glucose levels.
 - In patients with CNS symptoms or signs and low CD4 counts (<100 cells/ μ L), check serum levels of *Toxoplasma* antibody (IgG) if not previously checked. Check serum cryptococcal antigen (CrAg) titer.
 - In patients with symptoms of neuropathy or dementia, check serum levels of vitamin B12 and thyroid-stimulating hormone (TSH).
 - In patients with cranial nerve abnormalities, meningoencephalitis, symptoms of dementia, or any symptoms of neurosyphilis, check syphilis serology by rapid plasma reagin (RPR), Venereal Disease Research Laboratory (VDRL) test, or treponemal enzyme immunoassay (see chapter *Syphilis*).
- When CNS symptoms or signs are present, brain imaging by computed tomography (CT) scan with contrast is usually adequate as the initial test. Magnetic resonance imaging (MRI) is the modality of choice if the neurologic examination is nonfocal or if physical examination suggests a lesion in the posterior fossa.
- For patients with fever and CNS findings, perform lumbar puncture (LP) with cerebrospinal fluid (CSF) sampling. CT or MRI should be performed before the LP, if possible, to rule out a mass lesion that could cause herniation.
- Record the opening pressure, and send CSF for cell count and differential with protein and glucose measurements. Depending on the clinical suspicion, the fluid also should be sent for bacterial culture, India ink stain for fungal organisms (75-85% sensitive), acid-fast bacilli smear and culture, VDRL test, and CrAg titer (95% sensitive).

- If CMV is suspected, perform polymerase chain reaction (PCR) for CMV DNA in the CSF.
- For suspected drug or alcohol use, perform urine or serum toxicology screen. (Note that alcohol usually has been metabolized by the time withdrawal symptoms set in, typically 7-48 hours after the last alcohol intake.)
- For new-onset seizures, perform an electroencephalogram (EEG).
- Consult with neurology specialists if the workup or the diagnosis is in question.
- Advise patients who have seizures that driving and other potentially dangerous activities will be prohibited until the condition is stable.
- Counsel patients to avoid substances that impair the nervous system, such as alcohol and recreational drugs.
- If a patient is forgetful, educate other members of the household about the medication regimen and help devise a plan for adherence to medications and appointments.

Treatment

- Specific treatment will depend on the cause of neurologic symptoms. Consult relevant chapters in this manual. For complex cases, consult with an HIV-experienced neurologist.

Patient Education

- Inform patients that keeping the CD4 count >200 cells/ μ L (and preferably higher) with ART is the best way to prevent most HIV-associated neurologic diseases.
- Advise patients to take prophylaxis, as appropriate, to prevent opportunistic infections.
- When an antibiotic treatment is prescribed, advise patients to complete the entire regimen to prevent relapse of symptoms. Long-term treatment (secondary prophylaxis) will be needed to prevent recurrence of certain infections.

Pulmonary Symptoms

Background

Shortness of breath and cough are manifestations of common acute or chronic respiratory diseases, but also may be symptoms of HIV-related opportunistic infections. Further, these symptoms may indicate nonpulmonary conditions such as anemia, cardiovascular disease, and sinusitis, or adverse effects of medications such as angiotensin-converting enzyme inhibitors (ACEIs).

The onset and duration of symptoms, and the presence or absence of other factors such as sputum production, fever, and weight loss, will guide the evaluation. In addition, the patient's CD4 cell count will establish a context for the evaluation, because it will help to stratify the risk of opportunistic infections.

S: Subjective

The patient complains of dyspnea or cough.

Determine the following factors relating to the patient's history:

Recent History

- Onset and duration of symptoms: rapid (hours to days), subacute, chronic
- Progression or stability of symptoms
- Dyspnea at rest or with exertion
- Cough: productive (character of sputum), hemoptysis
- Associated symptoms (e.g., chest pain, pleuritic pain)
- Constitutional symptoms: fever, night sweats, unintentional weight loss
- Sinus congestion, facial tenderness, postnasal discharge, sore throat
- Orthopnea, paroxysmal nocturnal dyspnea (PND), peripheral edema
- Wheezing

Past History

- CD4 nadir, current CD4 count
- If the CD4 count is <200 cells/ μ L, ask whether the patient is taking *Pneumocystis jiroveci* pneumonia (PCP) prophylaxis (primary or secondary); if taking PCP prophylaxis and adhering to the regimen, the diagnosis of PCP is less likely
- Tuberculosis (TB): date and result of tuberculin skin test (TST) or interferon-gamma release assay (IGRA), risk factors for *Mycobacterium tuberculosis* infection
- PCP, bacterial or other pneumonia, bronchitis
- Smoking (and secondhand smoke exposure), pack-years, related symptoms
- Cardiovascular diseases, including congestive heart failure, coronary heart disease, arrhythmia, pulmonary hypertension
- Asthma, emphysema
- Pollen, dander, or dust allergies
- Drug allergies, specifically to penicillins and sulfa drugs
- Medications (e.g., ACEIs)
- Travel history (exposure to regions endemic for particular infections, such as coccidioidomycosis or histoplasmosis)
- Use of inhaled stimulants, injection drugs

- Prolonged exposure (via inhalation) to chemicals or other harmful pulmonary irritants (e.g., asbestos)

O: Objective

Check vital signs, oxygen saturation (resting and after exercise), and weight.

Conduct a thorough physical examination that includes evaluation of the following:

- Ears, nose, oropharynx
- Neck
- Lungs
- Heart
- Extremities

Note: If patients are coughing, strongly consider having them wear a surgical mask in the clinic or office until TB or other transmissible infection is ruled out. Covering both the nose and the mouth should prevent the discharge of infectious particles into the environment.

A: Assessment

The differential diagnosis of pulmonary symptoms is broad (see Table 1). Both HIV-related and HIV-unrelated causes should be considered; the patient's risk of HIV-related causes is strongly influenced by the CD4 count. More than one cause of symptoms may be present.

Table 1. Partial Differential Diagnosis of Pulmonary Symptoms

CD4 Cell Count	Possible Cause
Any Count	• Upper respiratory tract illness • Upper respiratory tract infection (URI) • Sinusitis • Pharyngitis • Acute or chronic bronchitis • Bacterial pneumonia • TB • Influenza • Chronic obstructive pulmonary disease • Reactive airway disease, asthma • Pulmonary embolus • Congestive heart failure • Pulmonary hypertension • Pneumothorax • Bronchogenic carcinoma • Non-Hodgkin lymphoma • Anemia • Gastroesophageal reflux (may cause cough) • Lactic acidosis • Medication adverse effect
≤500 cells/μL	• Bacterial pneumonia (recurrent) • Pulmonary <i>Mycobacterium</i> pneumonia (nontuberculous)
≤200 cells/μL	• PCP • <i>Cryptococcus neoformans</i> pneumonia or pneumonitis • Bacterial pneumonia (associated with bacteremia or sepsis) • Disseminated or extrapulmonary TB
≤100 cells/μL	• Pulmonary Kaposi sarcoma • Bacterial pneumonia (risk of gram-negative bacilli and <i>Staphylococcus aureus</i> is increased) • <i>Toxoplasma</i> pneumonitis
≤50 cells/μL	• Disseminated histoplasmosis • Disseminated coccidioidomycosis • Cytomegalovirus pneumonitis • Disseminated <i>Mycobacterium avium</i> complex • Disseminated <i>Mycobacterium</i> (nontuberculous) • <i>Aspergillus</i> pneumonia • <i>Candida</i> pneumonia

P: Plan**Diagnostic Evaluation**

Perform laboratory work and other diagnostic studies as suggested by the history, physical examination, and differential diagnosis. This may include the following:

- Chest X-ray, especially if the patient has abnormal findings on chest examination, fever, or weight loss, or if the CD4 count is <200 cells/ μ L. Consider further imaging such as chest computed tomography (CT) scan or high-resolution chest CT (HRCT) if chest X-ray result is unremarkable in a setting of suspected PCP or persistent symptoms, or if there is question of pulmonary nodules or suspected empyema.
- Arterial blood gas (ABG) on room air, particularly if PCP is suspected, or if the oxygen saturation is low.
- Complete blood count and white blood cell (WBC) count with differential, metabolic panel, and lactate dehydrogenase (LDH).
- If fever is present (especially temperature $>38.5^{\circ}\text{C}$), obtain routine blood cultures (two specimens) for bacteria. If the CD4 count is <50 cells/ μ L, obtain blood culture for acid-fast bacilli (AFB); if <100 cells/ μ L, check the serum level cryptococcal antigen (CrAg) and consider checking urine *Histoplasma* antigen.
- Induced sputum (outside, or in a negative-pressure room or area that is safely vented to the outside, to prevent TB aerosolization) for AFB smear and cultures (three specimens), Gram stain and bacterial cultures, PCP stains, fungal stains and cultures, and cytology, as indicated.
- CD4 count and HIV viral load, if recent values are not known.
- Bronchoscopy with bronchoalveolar lavage (BAL) or biopsy if sputum studies are negative, if the diagnosis is unclear after initial evaluation or if the patient is not responsive to empiric therapy.
- Pulmonary function tests if no infectious or HIV-related pulmonary diagnosis is suspected and symptoms persist.
- Lactate level if lactic acidosis is suspected (e.g., nausea, tachypnea, abdominal pain, fatigue, in the setting of long-term nucleoside analogue therapy).
- Toxicology screen if symptoms are suspected to be related to recent drug use (e.g., crack cocaine pneumonitis).

Treatment

Once the diagnosis is made, appropriate treatment should be initiated. In seriously ill patients, presumptive treatment may be started while diagnostic test results are pending. See the appropriate chapter in section *Comorbidities, Coinfections, and Complications* or relevant guidelines. In some cases, the source of dyspnea or cough cannot be identified. In these cases, consult with an HIV expert or a pulmonologist.

Patient Education

- Shortness of breath and cough can be signs of an opportunistic illness, especially in patients with low CD4 counts. Patients should notify their health care provider if they develop new or worsening symptoms.
- Patients taking antibiotics should be instructed to take their medications exactly as directed and to call their health care provider if they experience worsening fevers, shortness of breath, inability to take the prescribed medications, or other problems.
- Counsel smokers about the importance of smoking cessation; refer to tobacco cessation programs and prescribe cessation supports, as indicated; see chapter *Smoking Cessation*.
- Counsel drug users (particularly those who smoke or inject drugs) regarding the impact of illicit drugs on their overall health and especially their lungs; refer to appropriate cessation programs or rehabilitation programs.

Vaginitis/Vaginosis

Background

Vaginitis is defined as inflammation of the vagina, usually characterized by a vaginal discharge containing many white blood cells (WBCs); it may be accompanied by vulvar itching and irritation. Vaginosis presents with increased vaginal discharge without inflammation. Vaginitis usually is caused by an infection, but may be caused by other factors, such as chemicals or irritants. Vaginal infections are common among HIV-infected women. The presence of vaginal infections or inflammation, in the case of bacterial vaginosis in particular, may facilitate acquisition of HIV and other sexually transmitted diseases (STDs), and trichomoniasis may facilitate HIV transmission to HIV-uninfected partners. This chapter focuses on two of the most common types of vaginal infections: trichomoniasis and bacterial vaginosis (BV). For information on the topic of vulvovaginal candidiasis, see chapter *Candidiasis, Vulvovaginal*.

S: Subjective

The patient complains of vaginal discharge with or without odor, itching, burning, pelvic pain, vulvar pain, or pain during intercourse.

Take a focused history, including the following:

- Duration of symptoms
- Sexual history, especially recent new partners, unprotected sex
- Relationship of symptoms to sexual contacts
- Contraceptive use, especially:
 - Vaginal contraceptive film
 - Other products containing nonoxynol-9 (N-9)
 - Condoms; type of condoms
- Use of feminine hygiene products (e.g., sprays, deodorants)
- Douching
- Use of perfumed toiletries (e.g., bath salts, scented toilet tissue, or sanitary napkins)
- Use of any vaginal creams
- Postcoital bleeding
- Vulvar pain
- Pain or burning during urination

- Pain with intercourse
- Recent antibiotic use
- History of STDs, pelvic inflammatory disease (PID)
- Medications, including supplements

O: Objective

Perform a focused physical examination of the external genitalia, including perineum and anal area, for the following:

- Inflammation
- Edema
- Excoriation
- Lesions

Perform speculum examination for:

- Discharge (note color, quality; note that the character of the discharge is not diagnostic)
- Erythema, edema, erosions, lesions
- Cervical friability
- Foreign body

Perform a bimanual examination for masses or tenderness, if indicated.

A: Assessment

A partial differential diagnosis includes the following:

- BV
- Candidiasis
- Trichomoniasis
- PID
- Latex or condom allergy
- Urinary tract infection (UTI)
- Condyloma
- Herpes simplex virus (HSV)
- Contact dermatitis (e.g., from irritants, perfumes)
- Chlamydia
- Gonorrhea
- Normal vaginal discharge

P: Plan**Diagnostic Evaluation**

- Obtain a cervical sample for STD testing, if indicated.
- Obtain samples (swabs) from the vaginal wall for wet mounts and pH testing.
- Wet mounts: Perform microscopic examination of saline and potassium hydroxide (KOH) preparations for the following:
 - WBCs, clue cells, motile trichomonads (saline slide)
 - Yeast forms (KOH)
- Perform a whiff test of KOH preparation; if positive, check pH (if >4.5, likely BV or trichomoniasis).

Treatment depends on the specific diagnosis, and in general is the same as for HIV-uninfected women.

Trichomoniasis

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis*. Many infected women have a diffuse, malodorous, yellow-green discharge. Most men who are infected with *T. vaginalis* have no symptoms; others have symptoms of nongonococcal urethritis. The diagnosis usually is made by visualization of motile trichomonads on microscopic examination of wet mounts. Antigen or nucleic acid assays have greater specificity and sensitivity than wet mount preparations, and may be used if microscopy is negative. Culture of vaginal secretions is the most sensitive and specific diagnostic test for *T. vaginalis*, and also may help to rule out other infections.

Treatment: Recommended regimen

- Metronidazole 2 g PO in a single dose
- Tinidazole 2 g PO in a single dose

Treatment: Alternative regimen

- Metronidazole 500 mg PO BID for 7 days

Treatment during pregnancy

- Metronidazole, as in nonpregnant women (see above); the 7-day regimen may be better tolerated.
- Counsel patients about the potential risks and benefits of therapy. In pregnant women with asymptomatic trichomoniasis, deferring therapy until after 37 weeks' gestation may be considered; consult with a specialist.

Treatment notes:

- Single-dose metronidazole is associated with more side effects than the other treatment regimens.
- Sex partners should be treated. Patients should refrain from unprotected intercourse until both partners have resolution of symptoms and have completed treatment; this should be at least 7 days after single-dose therapy.

- Patients must avoid alcohol while taking metronidazole or tinidazole, and for at least 1 day after discontinuing metronidazole and 3 days after discontinuing tinidazole. The combination of alcohol and these drugs may cause a disulfiram-like reaction. Patients taking ritonavir capsules or tipranavir also may experience symptoms because of the small amount of alcohol in the capsules.

Treatment failure

Certain strains of *T. vaginalis* have diminished susceptibility to metronidazole and must be treated with higher dosages. If treatment failure occurs on metronidazole, consider tinidazole as above, or if single-dose metronidazole was used initially, consider metronidazole 500 mg PO BID for 7 days. If this is not effective, consult with a specialist.

Bacterial Vaginosis

BV is a clinical syndrome resulting from loss of the normal vaginal flora, particularly *Lactobacillus*, and replacement with anaerobic and other bacteria such as *Gardnerella vaginalis* and *Mycoplasma hominis*. The diagnosis is made on clinical and laboratory criteria. Usually, three of the following four characteristics should be present (note: only the clue cells are specific to BV):

- Homogeneous, gray-white, noninflammatory discharge on the vaginal walls
- Clue cells on the wet-mount slide
- Vaginal fluid pH level of >4.5
- Fishy odor to the vaginal discharge before or after the addition of KOH (whiff test)

Vaginal culture does not help establish the diagnosis. Rapid diagnostic test cards are available in some settings.

Many studies have documented an association between BV and infections such as endometritis, PID, and vaginal cuff cellulitis after gynecologic procedures. Therefore, the U.S. Centers for Disease Control and

Prevention (CDC) recommends screening for and treating BV before invasive gynecologic procedures.

The sex partners of women with BV do not need to be treated.

Treatment: Recommended regimens

- Metronidazole 500 mg PO BID for 7 days
- Metronidazole gel 0.75%, 1 full applicator (5 g) intravaginally QHS for 5 days
- Clindamycin cream 2%, 1 full applicator (5 g) intravaginally QHS for 7 days

Treatment: Alternative regimens

- Tinidazole 2 g PO QD for 2 days
- Tinidazole 1 g PO QD for 5 days
- Clindamycin 300 mg PO BID for 7 days
- Clindamycin ovules 100 g intravaginally QHS for 3 days

Treatment during pregnancy

- Symptomatic pregnant women should be treated with oral metronidazole (500 mg BID or 250 mg TID) or oral clindamycin 300 mg BID for 7 days.

Treatment notes:

- Patients must avoid alcohol while taking metronidazole or tinidazole, and for at least 1 day after discontinuing metronidazole and 3 days after discontinuing tinidazole. The combination of alcohol and these drugs may cause a disulfiram-like reaction. Patients taking ritonavir capsules or tipranavir also may experience symptoms because of the small amount of alcohol in the capsules.

Treatment failure

Consider re-treatment for 7 days with metronidazole or clindamycin. Consider the possibility of an alternative or second cause of the patient's symptoms, as multiple conditions or pathogens may present concurrently. Perform testing for other conditions as

suggested by symptoms, or if symptoms do not resolve with initial treatment:

- Perform herpes culture if indicated by lesions; see chapter *Herpes Simplex, Mucocutaneous*.
- Test for chlamydia and gonorrhea if indicated; see chapter *Gonorrhea and Chlamydia*.
- Perform urinalysis (with or without culture and sensitivities) if urinary symptoms are prominent.
- If an irritant or allergen is suspected, including N-9, discontinue use.
- If symptoms are related to the use of latex condoms, switch to polyurethane male or female condoms.
- For tenderness on cervical motion or other symptoms of PID, see chapter *Pelvic Inflammatory Disease*.
- Perform workup or obtain referral as needed for other abnormalities found on bimanual examination.

For information on other STDs or related conditions, see the CDC treatment guidelines at www.cdc.gov/std/treatment.

Patient Education

- Advise patients to avoid any form of alcohol while taking metronidazole or tinidazole and for 24 hours after taking the last dose (72 hours after the last tinidazole dose). Alcohol and metronidazole together can cause severe nausea, vomiting, and other immobilizing symptoms.
- Patients taking ritonavir capsules may experience these symptoms because of the small amount of alcohol in the capsules and should be told to contact their health care provider if nausea and vomiting occur.
- Advise patients that clindamycin cream and ovules are oil based and will weaken latex condoms, diaphragms, and cervical caps. Patients should use alternative methods to prevent pregnancy and HIV transmission.
- Recurrence of BV is common. Patients should contact their health care provider and return for repeat treatment if symptoms recur.
- Instruct patients to avoid douching.
- To avoid being reinfectd by *Trichomonas*, patients should bring their sex partners to the clinic for evaluation and treatment.

Abnormalities of Body-Fat Distribution

Background

Abnormalities of body-fat distribution are a recognized complication of HIV infection and of antiretroviral therapy (ART), and they are a common concern of patients. They include central fat accumulation (lipohypertrophy) and subcutaneous fat wasting (lipoatrophy). These morphologic changes are often referred to as lipodystrophy, though that term fails to distinguish between the two phenomena. Abnormalities in fat distribution and body shape have been noted in up to 40-50% of patients treated with older antiretroviral (ARV) medications, but the incidence may be much lower with the use of newer, less lipotoxic ARVs and with earlier initiation of ART. Lipohypertrophy and lipoatrophy are associated with other metabolic abnormalities, such as dyslipidemia and insulin resistance, and visceral fat accumulation (at least in HIV-uninfected persons) is a risk factor for cardiovascular disease.

Research on fat maldistribution has yielded varying results, in part because there are no standard clinical case definitions of lipodystrophy, lipoatrophy, or lipohypertrophy. The pathogenesis of fat abnormalities in HIV-infected individuals is not well understood, but research to date suggests that it is multifactorial and is associated with HIV-related immune depletion and immune recovery, ARV medications, dysregulation of fatty acid metabolism, hormonal influences, individual genetic predispositions, and factors that are not related to HIV such as diet and obesity. Lipodystrophy has been associated with lower nadir CD4 count as well as with gender (central lipohypertrophy may be more common in women) and age (more common in older patients), and longer exposure to ART. Lipohypertrophy has not been definitively proven to be related to specific ARVs or to specific ARV classes, but has been variably associated with protease inhibitors (PIs) and with nucleoside reverse transcriptase inhibitors (NRTIs). However, morphologic changes occasionally develop in ARV-naïve individuals. Lipoatrophy is most commonly associated with NRTIs, notably stavudine, as well as didanosine and zidovudine.

The most common morphologic changes seen in lipohypertrophy are a firm enlarged abdomen caused by central or visceral fat accumulation, breast enlargement (gynecomastia) in both men and women, development of a dorsocervical fat pad (“buffalo hump”), and neck enlargement. Lipoatrophy most commonly appears as the loss of subcutaneous fat in the face, arms, legs, and buttocks. Lipoatrophy differs from the generalized wasting seen in advanced AIDS, because lean cell mass generally is preserved. When lipohypertrophy and lipoatrophy occur together, the affected individuals show a mixed picture of abdominal obesity with thinning in the face, arms, and legs.

Severe lipoaccumulation can cause discomfort and, in some cases, impairment of breathing or other bodily functions. It may be associated with other metabolic abnormalities, including dyslipidemia, insulin resistance, and the metabolic syndrome. Both lipoaccumulation and lipoatrophy can be disfiguring, can damage self-image and quality of life, and can negatively influence ARV adherence.

S: Subjective

The patient may report any of the following: abdominal fat accumulation with change in waist size, increased neck size, “buffalo hump,” enlarged breasts, and reduced range of motion.

Alternatively (or in addition), the patient may report sunken cheeks, decreased arm or leg circumference, prominence of veins in the arms or legs, or buttock flattening.

Determine CD4 cell count nadir, ARV medication history with particular attention to past use of thymidine analogues and PIs, and duration of and response to each regimen. Ask about past medical and family history, specifically regarding hyperlipidemia, diabetes or insulin resistance, other metabolic disorders, and cardiovascular disease. Evaluate the effect of body-shape changes on the patient’s self-esteem, medication adherence, and interpersonal relationships.

O: Objective

Compare past and current weights. Calculate body mass index (BMI); see chapter *Initial Physical Examination* for information on BMI.

Measure and document waist and hip circumferences. A waist circumference of >102 cm (39 inches) in men and >88 cm (35 inches) in women is the clinical definition of abdominal obesity and is associated with the metabolic syndrome. Waist-to-hip ratios of >0.95 in men and >0.85 in women have been associated with an increased risk of coronary heart disease.

Examine the head, neck, back, breasts, and abdomen for fat accumulation, especially looking for dorsocervical fat pad and facial, neck, or breast enlargement. Examine the face and extremities for subcutaneous fat loss (e.g., in the cheeks, temples, limbs, and buttocks).

Review laboratory history (glucose, lipid panel) to identify other metabolic disorders. (See chapters *Dyslipidemia* and *Insulin Resistance, Hyperglycemia, and Diabetes on Antiretroviral Therapy*.)

A: Assessment

No uniform standard criteria are available for defining or grading lipohypertrophy or lipoatrophy in clinical practice. Clinicians must base their assessment on patient self-report, physical examination (for characteristic body-shape changes), associated symptoms, and psychological consequences.

In research settings, modalities such as dual-energy X-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI) have been used to characterize and quantify lipoaccumulation and lipoatrophy. Anthropometric measurements may be made in the clinic by trained personnel (e.g., nutritionists), but do not measure visceral fat directly. Although measurements such as waist circumference cannot be used to assess lipohypertrophy, they have been validated (in HIV-uninfected individuals) as an assessment of cardiovascular risk (see chapters *Dyslipidemia* and *Coronary Heart Disease Risk*). Bioelectrical impedance analysis (BIA) does not measure regional body composition and thus is not used to measure abnormal body-fat changes.

Differential diagnosis of lipohypertrophy includes obesity or excess weight gain, ascites, and Cushing syndrome.

Differential diagnosis of lipoatrophy includes weight loss and wasting.

P: Plan**Diagnostic Evaluation****Laboratory**

Check for other metabolic abnormalities associated with the use of ARVs, such as dyslipidemia and impaired glucose metabolism (check fasting lipids and random or fasting glucose). See chapters *Dyslipidemia* and *Insulin Resistance, Hyperglycemia, and Diabetes on Antiretroviral Therapy* for further information about workup and treatment.

Treatment

Treatments for lipohypertrophy and lipoatrophy have not reliably reversed body shape changes once these changes have occurred. In general, treatment interventions have shown poor results in patients with marked or severe fat maldistribution and inconsistent or limited responses in those with milder conditions. The best approaches to managing lipodystrophy are prevention and early intervention.

Clinicians can help to prevent body fat abnormalities by avoiding, whenever possible, ARV agents known to confer a greater risk of this disorder (particularly stavudine, didanosine, and zidovudine, which are most closely associated with lipoatrophy). All patients who take ARVs should be monitored carefully for the development of fat maldistribution. If abnormalities are noticed, the suspect ARV should be discontinued and a more benign ARV started in its place, if possible.

The optimal management strategy for established lipoaccumulation or lipoatrophy is not known, although the following approaches can be considered (see below). Also consider referring the patient to clinical studies of lipodystrophy treatment, and for psychological or adherence support and counseling, if indicated. If the patient is distressed enough to consider discontinuing or interrupting ART, review with the patient any gains he or she has made on ART and discuss treatment options (see below). In some cases the patient may insist on discontinuing ARV medications; in this situation, carefully review the risks of treatment interruption as well as the alternatives to discontinuing treatment.

ARV Substitutions

Avoiding thymidine analogue NRTIs, particularly stavudine, and avoiding the NRTI combination stavudine + didanosine have been shown to reduce the risk of lipoatrophy.

In patients with lipoatrophy, modest slow improvement in limb fat has been demonstrated after switching from thymidine analogues (stavudine, zidovudine) to nonthymidine NRTIs (such as abacavir or tenofovir) or to NRTI-sparing regimens. In patients with lipohypertrophy, similar NRTI switch strategies have had little effect on visceral or trunk fat. Studies in which PIs were eliminated from the ART regimen generally have not shown significant effects on body fat measures.

Before switching therapies, carefully assess the potential risk to the patient's long-term HIV management.

Nonpharmacologic Measures

Diet

The effects of diet on lipohypertrophy have not been evaluated thoroughly. If overall weight reduction is needed, recommend dietary changes and exercise. Avoid rapid weight loss plans, as lean body mass often is lost disproportionately. Refer to a dietitian to help the patient decrease intake of saturated fat, simple sugars, and alcohol.

Exercise

Regular, vigorous cardiovascular exercise may help control central fat accumulation, whereas resistance exercises (strength training) will improve the ratio of muscle to fat. Some studies of exercise (done alone or in combination with diet) have shown a reduction in visceral fat accumulation with minimal or no changes in peripheral lipotrophy. Moderate aerobic exercise should be encouraged for all patients.

Pharmacologic Measures

Insulin-sensitizing agents

In diabetic and non-HIV lipodystrophy, treatment with thiazolidinediones may decrease visceral fat, increase peripheral fat, and improve glycemic control. In HIV-infected patients with lipotrophy, studies of thiazolidinediones, specifically rosiglitazone and pioglitazone, have shown mixed results. Some patients have reported improvement in limb fat, particularly those with insulin resistance; however, a larger, 48-week randomized trial of rosiglitazone found no significant increase in limb-fat mass. In patients with visceral fat accumulation, thiazolidinediones have not been found to be effective.

In clinical studies, metformin has been modestly effective in treating visceral adiposity in patients with insulin resistance, but may cause worsening of lipotrophy. Metformin should be used with caution in patients with chronic liver or renal disease.

Growth hormone-releasing factor

Tesamorelin, a synthetic growth hormone-releasing factor analogue, is approved by the U.S. Food and Drug Administration (FDA) for treatment of excess abdominal fat in HIV-infected persons with lipodystrophy. It has been shown to reduce central fat accumulation by about 18% over the course of 12 months, without adverse effects on glucose or lipid parameters. Unfortunately, patients rapidly regain visceral fat when tesamorelin is discontinued. That, along with its expense, has limited the use of tesamorelin. No long-term safety data are available.

Recombinant human growth hormone

Treatment with recombinant human growth hormone (rHGH), 3-6 mg/day for 12 weeks followed by maintenance therapy with lower doses of 1-2 mg/day, has been shown to reduce visceral fat in many patients with minimal impact on peripheral fat wasting; other studies suggest efficacy (and improved tolerability) of lower dosages of rHGH. However, the high cost of rHGH, the high rate of adverse effects (including insulin resistance), and the frequent recurrence of visceral fat accumulation once rHGH is discontinued have resulted in a limited role for this treatment.

Plastic and reconstructive surgery

Various techniques have been investigated, but generally have limited applicability and efficacy. Poly-L-lactic acid (Sculptra, New-Fill) and a calcium hydroxylapatite preparation (Radiesse) are approved by the FDA as treatments for facial lipotrophy. These injectable materials have shown good cosmetic results and often significantly improve patients' satisfaction with their appearance. Treatment effects of both agents typically wane with time and the procedures often must be repeated. Other facial fillers, as well as cheek implants and autologous fat transfer, have been used successfully in some cases. For lipoaccumulation, treatments such as liposuction for focal areas of fat deposition

(e.g., dorsocervical) and breast reduction may be effective in the short term, though fat often reaccumulates.

These interventions may be covered by private- and public-payer sources, but still often are deemed to be the financial responsibility of the patient. In some cases, they may be only a temporary solution, because abnormalities may reappear after treatment.

Patient Education

- Instruct patients who are receiving ARV medications to inform their health care provider if they notice changes in the shape or appearance of their bodies.
- Review the importance and benefits of ART and assess adherence to the regimen.
- For patients with lipohypertrophy, recommend aerobic and resistance exercise to reduce fat and build muscle. Assess local resources for safe muscle-strengthening.
- If weight reduction is needed, refer to a dietitian for consultation. Remind the patient that quick weight-loss diets may result in excessive muscle loss.
- For patients with severe facial lipodystrophy, consider referral to an experienced dermatologist or plastic surgeon for restorative treatment.

Dyslipidemia

Susa Coffey, MD

Background

HIV-infected individuals, both those on antiretroviral therapy (ART) and those who are untreated, appear to have higher rates of coronary heart disease (CHD) than HIV-uninfected individuals and higher rates of various risk factors for CHD, including dyslipidemia. As the average lifespan of patients on effective ART lengthens, and as people living with HIV become older, morbidity and mortality from CHD are likely to continue to increase. Thus, identification and reduction of modifiable risk factors for CHD are important aspects of primary care for HIV-infected patients.

Dyslipidemia is a well-described independent risk factor for CHD, and it occurs in a high proportion of persons with HIV infection. Current research suggests that this dyslipidemia is caused by a combination of factors related to HIV disease, ART regimens, and individual patient characteristics. HIV itself causes lipid perturbations, particularly in persons with more advanced immunosuppression; HIV-infected individuals who are not on antiretroviral (ARV) medications often have elevations in triglyceride (TG) levels and decreases in high-density lipoprotein (HDL) as well as in low-density lipoprotein (LDL) cholesterol and total cholesterol (TC). Lipid abnormalities also may be caused by or compounded by ARVs (see chapter *Coronary Heart Disease Risk*). They may appear or worsen within a few weeks to months after starting ART. With some patients, this may, at least in part, represent a return to pre-illness lipid levels, whereas the ARVs cause the abnormality in other cases.

Not all ART-treated patients experience lipid abnormalities to the same degree. Patients with a personal or family history of dyslipidemia, glucose intolerance, diabetes, obesity, or a combination of these health problems may be genetically predisposed to lipid abnormalities that become evident once ART is initiated.

The use of potent combination ART, particularly the use of protease inhibitors (PIs), has increased the prevalence of abnormally high TG, TC, and LDL levels among HIV-infected patients. In fact, dyslipidemia has been associated not only with certain PIs but also with certain nonnucleoside reverse transcriptase inhibitors (NNRTIs) and nucleoside reverse transcriptase inhibitors (NRTIs). In the PI class, ritonavir-boosted PIs (though unusually with atazanavir or darunavir) are particularly likely to cause marked elevations of TG and LDL levels. Although NNRTIs also may contribute to increases in TC, LDL, and TG levels the effects, particularly with efavirenz, are more variable (and efavirenz may increase HDL). Of the NRTIs, stavudine, zidovudine, and perhaps abacavir may increase TC and TG levels. To date, available agents from the integrase inhibitor and CCR5 antagonist classes do not appear to have significant adverse impacts on lipid levels.

The largest prospective study of CHD events related to ARVs (the D:A:D study) showed a small but significant increase in the risk of myocardial infarction among HIV-infected patients treated with ARVs; moreover, the effect increased with cumulative years of ARV exposure. This effect was largely but not entirely associated with increases in LDL cholesterol (see chapter *Coronary Heart Disease Risk*).

HRSA HAB Performance Measures

Percentage of patients, regardless of age, with a diagnosis of HIV who were prescribed HIV antiretroviral therapy and who had a **fasting lipid panel** during the measurement year

(All-Age measure)

Identification and management of dyslipidemia in HIV-infected patients is an important part of HIV primary care. For patients with CHD or CHD risk equivalents (see below), ART regimens should, if possible, be selected to minimize the risk of hyperlipidemia.

Guidelines for the evaluation and management of dyslipidemia have been developed by the National Cholesterol Education Program (NCEP). These recommendations are based on studies of HIV-uninfected persons and may not be entirely applicable to HIV-infected persons, in whom HIV itself may increase risk of CHD events. Despite this limitation, expert panels generally recommend similar treatment goals when evaluating and managing dyslipidemia in patients with HIV infection. (For recommendations on screening, see chapter *Initial and Interim Laboratory and Other Tests*.)

Note: The American College of Cardiology and the American Heart Association released new guidelines on treatment of hyperlipidemia late in 2013. These take a different approach to many aspects of lipid management, including the evaluation of patients for lipid-lowering therapy, the use and monitoring of lipid lowering agents, and the use of treatment targets. These guidelines have generated controversy. As their appropriateness to the management of HIV-infected individuals is not clear at this time, this chapter will discuss the approach presented in the NCEP guidelines.

S: Subjective

The history should focus on factors that suggest CHD, risk equivalents, or risk factors for CHD. Both CHD risks and CHD equivalents should be the focus of lifestyle modification strategies and lipid-normalizing treatment.

- **CHD** includes the following:
 - A history of myocardial infarction
 - Angina
 - CHD procedures
 - Evidence of clinically significant myocardial ischemia
- **CHD risk equivalents** are considered to be equal in terms of risk level to known CHD. These include the following:
 - Diabetes mellitus
 - Peripheral vascular disease
 - Symptomatic carotid artery disease
 - Abdominal aortic aneurysm
 - Transient ischemic attacks
 - Two or more CHD risk factors with a 10-year risk of CHD >20% (see “Calculations to Estimate the 10-Year Risk of Cardiac Events for Men and Women,” below, or the online risk calculator at cvdrisk.nhlbi.nih.gov/calculator.asp).
- **CHD risk factors** are conditions associated with a greater risk of serious cardiac events. These are as follows:
 - Male sex
 - Age (≥45 in men; ≥55 in women)
 - Hypertension
 - Cigarette smoking
 - Low HDL (<40 mg/dL); if >60 mg/dL, subtract one risk factor
 - Family history of premature CHD (first-degree relative aged <55 [men] or <65 [women])
- Assess for causes of secondary dyslipidemias, including insulin resistance, diabetes, hypothyroidism, obstructive liver diseases, chronic renal failure, and medications such as corticosteroids and progestins.
- Screen for other factors that contribute to hyperlipidemia, including obesity, chronic liver diseases, alcohol abuse, high-fat or high-carbohydrate diet, and prothrombotic or proinflammatory states.
- Screen for health behaviors that increase CHD risk, including smoking, high-fat diet, sedentary lifestyle, and use of recreational drugs such as cocaine and methamphetamine.

- Review the patient's family history for premature CHD (as discussed above), obesity (body mass index [BMI] ≥ 30), diabetes, and lipid abnormalities.
- Review the patient's medications, with special attention to ARVs known to increase LDL or TG levels (particularly ritonavir and ritonavir-boosted PIs).

O: Objective

Check vital signs with special attention to blood pressure and weight. Calculate BMI (see chapter *Initial Physical Examination* for information on BMI).

Perform a focused physical examination with particular attention to signs of hyperlipidemia, such as xanthelasma and xanthoma, and to the cardiovascular system.

A: Assessment

Determine whether a specific intervention is appropriate based on the patient's lipid values and identified CHD risks, as indicated in Tables 1 and 2.

LDL is the main indicator for treatment, and the main target for lipid-lowering therapy. Hypertriglyceridemia is associated with CHD risk, but thresholds of risk have not been defined precisely, and targets for intervention are not entirely clear (for persons with triglyceride levels of ≥ 500 mg/dL, the triglycerides usually are treated first; see "Treatment," below). Severe hypertriglyceridemia (e.g., TG $>1,000$ mg/dL) also increases the risk of pancreatitis.

For patients who do not have diabetes or preexisting CHD and who have two or more CHD risk factors, calculate the "10-year risk of cardiovascular events" by using the Risk Assessment Tool for estimating the 10-year risk of a major CHD event. Use the risk-estimate tool at the end of this chapter or the online risk calculator at the National Institutes of Health website (cvdrisk.nhlbi.nih.gov/calculator.asp).

Table 1. Low-Density Lipoprotein Cholesterol Goals and Thresholds for Treatment*

Risk Category	LDL Goal*	Initiate Therapeutic Lifestyle Changes	Consider Drug Therapy
Lower risk: No CHD or CHD risk equivalents and <0 -1 risk factor	<160 mg/dL (<4.1 mmol/L)	LDL ≥ 160 mg/dL (≥ 4.1 mmol/L)	≥ 190 mg/dL (≥ 4.9 mmol/L); at 160-189 mg/dL, LDL drug therapy is optional
Moderate risk: No CHD or CHD risk equivalents and ≥ 2 risk factors, with 10-year estimated risk $<10\%$	<130 mg/dL (<3.4 mmol/L)	LDL ≥ 130 mg/dL (≥ 3.4 mmol/L)	≥ 160 mg/dL (≥ 4.1 mmol/L)
Moderately high risk: No CHD or CHD risk equivalents and ≥ 2 risk factors and 10-year estimated risk 10-20%	<130 mg/dL (<3.4 mmol/L) (optional goal of <100 mg/dL)	LDL ≥ 130 mg/dL (≥ 3.4 mmol/L)	≥ 130 mg/dL (≥ 3.4 mmol/L)
High risk: CHD or CHD risk equivalent (see above)	<100 mg/dL (<2.6 mmol/L) (optional goal of <70 mg/dL#)	LDL ≥ 100 mg/dL (≥ 2.6 mmol/L)	≥ 100 mg/dL (≥ 2.6 mmol/L)

This goal (LDL <70 mg/dL) is preferred by many cardiologists for persons with CHD or risk equivalents.

Adapted from Adult Treatment Panel III, National Cholesterol Education Program. *Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults*. September 2002; NIH publication 02-5215. Available at www.nhlbi.nih.gov/guidelines/cholesterol/index.htm. Accessed December 1, 2013.

Table 2. Classification of Triglyceride Levels

Risk Category	Triglyceride Measurement	Initiate therapy
Normal triglycerides	<150 mg/dL	
Borderline-high triglycerides	150-199 mg/dL	
High triglycerides	200-499 mg/dL	Start therapeutic lifestyle changes; consider medication if CHD, CHD equivalents, or high risk
Very high triglycerides	≥500 mg/dL	Start therapeutic lifestyle changes; consider medication

Adapted from Adult Treatment Panel III, National Cholesterol Education Program. *Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults*. September 2002; NIH publication 02-5215. Available at www.nhlbi.nih.gov/guidelines/cholesterol/index.htm. Accessed December 1, 2013.

P: Plan

Diagnostic Evaluation

The fasting serum lipid panel should be performed at least 8 hours, but ideally 12 hours, after last food and beverage intake. It measures TC, HDL, TG, non-HDL cholesterol with calculated LDL, and TC/HDL cholesterol ratio.

A fasting lipid panel should be checked at baseline, before patients start ART.

Repeat the fasting lipid panel within 3-6 months after ARVs are started, and sooner for patients who have abnormal values at baseline.

Patients with normal lipid values should be rechecked annually (sooner if ARVs are changed). Those with dyslipidemia may need more intensive monitoring (e.g., every 4-6 weeks) until the LDL goal is met, after which monitoring every 4-6 months is adequate.

Treatment

Treatment of dyslipidemia usually involves a multimodal approach, including diet and exercise in all cases, lipid-modifying medication, and consideration of changes in ARV medication. The primary goal of lipid-lowering therapy is to reduce LDL to target levels. For persons with CHD and CHD risk equivalents, the type and intensity of LDL lowering therapies are adjusted according to LDL baseline levels. Note that other interventions to reduce CHD risk also should be undertaken (e.g., smoking cessation if appropriate).

For patients with serum TG level of >400 mg/dL, the LDL cholesterol calculation is unreliable. In this situation, non-HDL cholesterol (TC minus HDL) can be used as a surrogate target of therapy; the non-HDL goal is 30 mg/dL higher than the LDL goal. For these individuals, dietary intervention is warranted, and drug therapy to decrease LDL (or non-HDL) can be considered if TC is >240 mg/dL or HDL cholesterol is <35 mg/dL. For those with TG levels of 200-500 mg/dL, achieving the LDL cholesterol target is the primary goal, and lowering non-HDL cholesterol levels is a secondary goal (see Table 1 for LDL intervention levels).

The NCEP guidelines recommend that very high TG levels (≥500 mg/dL) be reduced before LDL is treated directly (see “Treatment of hypertriglyceridemia,” below).

The LDL levels at which either therapeutic lifestyle change (TLC) or drug therapy should be initiated are shown in Table 1, along with the target goals for LDL cholesterol. The response to therapy should be monitored and therapeutic interventions should be intensified or augmented until lipid targets are met.

Therapeutic lifestyle change

TLC, consisting of diet modification and exercise, is fundamental to the management of dyslipidemia for HIV-infected patients.

Target goals for lipid abnormalities are difficult to achieve without prioritizing these behavioral change efforts. Although TLC is hard to maintain, it can yield significant results in reducing CHD risk and improving quality of life. Effective TLC is best achieved with a multidisciplinary team approach. HIV primary care providers should be instrumental in identifying TLC as a treatment priority and providing referrals to nutritionists for dietary counseling, to mental health professionals for assessment of treatable mood disorders, and to social workers, peer counselors, or clinical nurse specialists for assistance with health-behavior changes, self-care strategies, and identification of resources in the community for smoking cessation support and exercise programs. Specific recommendations for TLC goals and behavior change strategies are contained in the Adult Treatment Panel guidelines, which are available at www.nhlbi.nih.gov/guidelines/cholesterol/index.htm.

Pharmacologic treatment for hypercholesterolemia

All patients with elevated lipid levels should initiate TLC. If pharmacologic intervention is indicated, statins (hydroxymethylglutaryl coenzyme A [HMG-CoA] reductase inhibitors) are the first-line treatment for most patients. These agents can be effective in reducing TC, LDL, and non-HDL cholesterol levels

in HIV-infected patients (see Table 3). More importantly, they have been shown to reduce the risk of cardiovascular events in persons with or at risk of CHD.

Recommended starting dosages of statins for patients taking PIs are as follows (Note: see “Potential ARV Interactions,” below):

- Pravastatin: 20 mg PO QD
- Atorvastatin: 10 mg PO QD

Fibrates may be considered as an alternative or adjunct to statins (see “Treatment of hypertriglyceridemia,” below, for further information). When given concomitantly, statins and fibrates increase the risk of rhabdomyolysis and must be used cautiously and with careful monitoring). Niacin may be effective as adjunctive therapy, but it has not been shown to decrease CHD events. It may worsen insulin resistance and may cause hepatotoxicity. It also causes uncomfortable flushing in some patients; the sustained-release formulations are better tolerated. Ezetimibe (Zetia) appears to be effective in combination with statins for patients whose cholesterol is not controlled adequately with a statin alone, but it also has not been shown to decrease CHD events. Bile acid sequestrants generally should be avoided because they may interfere with the absorption of other drugs and may increase TG levels.

Table 3. Drug Treatments for Lipid Abnormalities

Lipid Abnormality	First Choice	Second Choice	Comments
Isolated high LDL, non-HDL cholesterol	Statin	Fibrate	Start with pravastatin* or atorvastatin* (available as generics). Use low statin dosages and titrate upward; patients taking PIs have increased risk of myopathy.
Isolated high TG	Fibrate	Statin, N-3 (omega-3) fatty acids	Start with gemfibrozil or fenofibrate. Combined statin and fibrate may increase myopathy risk.
High LDL and TG (TG level 200-500 mg/dL)	Statin	Fibrate	Start with pravastatin or atorvastatin* (available as generics). Use fluvastatin,* rosuvastatin,* pitavastatin,* gemfibrozil, or fenofibrate as alternatives. Combined statin and fibrate may increase myopathy risk.
High LDL and TG (TG level >500 mg/dL)	Fibrate	N-3 (omega-3) fatty acids, niacin, statin	Start with gemfibrozil or fenofibrate. Niacin is associated with insulin resistance. May need to add statin if cholesterol is not controlled adequately.

* May have significant interactions with certain ARVs; see Table 4.

Potential ARV Interactions

Clinicians should note that there are clinically significant drug interactions between most statins and PIs, NNRTIs, and the pharmacokinetic enhancer cobicistat (see Table 4). PIs and cobicistat can increase serum levels of most statins significantly, thus increasing the risk of severe statin adverse events such as rhabdomyolysis. Of the statin drugs, pravastatin is the least affected by most PIs (darunavir is an exception) and is the recommended statin for most patients with hypercholesterolemia without hypertriglyceridemia. Atorvastatin, if used, should be initiated at low dosage (10 mg) and titrated slowly upward to achieve target lipid levels (note that atorvastatin may lower TG, TC, and LDL levels). Lovastatin and simvastatin are contraindicated for use by patients taking PIs or cobicistat. These can result in severe statin-related adverse events if prescribed. Other available statins include rosuvastatin, pitavastatin, and fluvastatin. These have not been as well studied but may be used with most PIs (there are exceptions; see table on the following page). When statins are given concurrently with interacting PIs, the statins should be started at low dosage and increased incrementally, if indicated; in general, maximum dosages should not be used.

NNRTIs decrease levels of most statins (however, etravirine increases fluvastatin levels); higher dosages of statins may be needed to overcome this interaction. Be aware that various formulations and combination products contain these statins; check the generic name of components in new or unfamiliar cardiac prescriptions to determine whether they contain lipid-lowering agents.

The integrase inhibitors dolutegravir and raltegravir, and other classes of ARV drugs (NRTI, fusion inhibitor, CCR5 antagonist), do not have recognized interactions with statins. Other types of lipid-lowering medications generally are not metabolized by hepatic cytochrome P450 and are not affected by ARVs (an exception to this is gemfibrozil, whose levels are decreased by lopinavir/ritonavir, by an unknown mechanism).

dated October 2012. Available at hivinsite.ucsf.edu/InSite?page=md-rr-30. Accessed December 1, 2013.

Treatment of hypertriglyceridemia

Patients with TG levels of 200-500 mg/dL should begin non-drug interventions such as diet modification, reduction in alcohol consumption, aerobic exercise, and smoking cessation. When the TG level is ≥ 500 mg/dL, a low-fat diet ($<15\%$ of caloric intake) is recommended to help prevent pancreatitis, and pharmacologic therapy probably will be required. Patients with CHD or CHD equivalents, those at high risk of CHD, and those with TG levels >200 mg/dL may need pharmacologic therapy.

Fibrates are the first-line drug option for isolated hypertriglyceridemia and are an alternative treatment for combined hypertriglyceridemia and hypercholesterolemia. Fenofibrate or gemfibrozil reduce TG levels effectively in patients on ARVs. Because they are not metabolized by the cytochrome P450 hepatic enzyme system, they do not have significant drug interactions with most ARVs (an exception may be gemfibrozil with dolutegravir: dolutegravir levels may be increased). Fibrates are contraindicated for use by patients with renal failure. Recommended dosages of these agents are as follows:

- Fenofibrate: 40-200 mg PO QD
- Gemfibrozil: 600 mg PO BID, 30 minutes before meals

If a fibrate alone is inadequate in reducing TG levels, several options are possible. A statin (e.g., atorvastatin, which acts on TGs as well as cholesterol) could be added cautiously, although there is an increased risk of skeletal muscle toxicity with concomitant use of a fibrate and a statin. N-3 (omega-3) fatty acid supplements (e.g., fish oils), administered at 1-2 g BID or TID, have decreased TG levels in patients taking ART. Extended-release niacin at 1,500-2,000 mg/day also decreases both TG and TC levels, although its clinical utility is restricted because of associated insulin resistance and flushing.

Switching antiretroviral therapy

For patients with CHD or CHD equivalents, ARV medications should, if possible, be selected to minimize the risk of hyperlipidemia. In patients with dyslipidemia caused by ARV agents, data suggest that it may be beneficial to discontinue ARVs known to increase lipids if reasonable alternatives exist. Substituting atazanavir or an integrase inhibitor in place of a lipogenic PI or replacing stavudine with tenofovir may improve the lipid profile. Before making ARV substitutions, however, consider carefully the possible effect of the substitution on HIV virologic control and the potential adverse effects of new ARVs. In some cases, antihyperlipidemic agents may be necessary even after ARV substitution.

Appendix:

Calculations to Estimate the 10-Year Risk of Cardiac Events for Men and Women — Framingham Calculator

To calculate the 10-year risk of cardiac events, add up points from the following five tables pertaining to age, HDL, systolic blood pressure, TC, and smoking status (Tables 5.1-5.5). Note that in Tables 5.3-5.5, women's points are in parentheses. After adding points from all of the tables, consult Table 5.6. (Alternatively, an online calculator is available at cvdrisk.nhlbi.nih.gov/calculator.asp.)

(The Framingham Heart Study risk calculator has not been validated for HIV-infected individuals and may underestimate the risk in this population.)

Table 5.1. Estimate of 10-Year Risk of Cardiac Events: Age

Age (Year)	Points (Men)	Points (Women)
20-34	-9	-7
35-39	-4	-3
40-44	0	0
45-49	3	3
50-54	6	6
55-59	8	8
60-64	10	10
65-69	11	12
70-74	12	14
75-79	13	16

Table 5.2. Estimate of 10-Year Risk of Cardiac Events: High-Density Lipoprotein Cholesterol

HDL (mg/dL)	Points (Men)	Points (Women)
≥60	-1	-1
50-59	0	0
40-49	1	1
<40	2	2

Table 5.3. Estimate of 10-Year Risk of Cardiac Events: Systolic Blood Pressure

Systolic Blood Pressure	Points if Untreated — Men (Women)	Points if Treated — Men (Women)
<120	0 (0)	0 (0)
120-129	0 (1)	1 (3)
130-139	1 (2)	2 (4)
140-159	1 (3)	2 (5)
≥160	2 (4)	3 (6)

Table 5.4. Estimate of 10-Year Risk of Cardiac Events: Total Cholesterol

Total Cholesterol (mg/dL)	Points for Men (Women)				
	Age 20-39	Age 40-49	Age 50-59	Age 60-69	Age 70-79
<160	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)
160-199	4 (4)	3 (3)	2 (2)	1 (1)	0 (1)
200-239	7 (8)	5 (6)	3 (4)	1 (2)	0 (1)

Patient Education

- Review the importance of reducing cardiovascular risk factors. This is of increasing importance for all patients with HIV infection, particularly as they age.
- Educate patients about the benefits of diet and exercise in improving lipid levels and reducing cardiovascular risk.
- If lipid-lowering medications are prescribed, advise patients on possible adverse effects, and advise them to contact their health care provider if these develop.
- Advise patients to talk with their health care provider before starting any new medications so they can be evaluated for possible drug-drug interactions.

Insulin Resistance, Hyperglycemia, and Diabetes on Antiretroviral Therapy

Background

Diabetes is a substantial risk factor for coronary artery disease, stroke, and peripheral vascular disease, as well as for a number of other conditions including retinopathy and kidney disease. Patients taking antiretroviral (ARV) medications, especially certain protease inhibitors (PIs) and nucleoside reverse transcriptase inhibitors (NRTIs), appear to have an increased risk of hyperglycemia and diabetes mellitus. In particular, the ARVs indinavir and stavudine (now seldom used in the United States) have been shown to induce insulin resistance in short-term studies of healthy HIV-uninfected volunteers, but other ARVs also perturb glucose homeostasis.

Disorders of glucose metabolism may present as the following:

- **Insulin resistance:** a state in which higher concentrations of insulin are required to exert normal effects; blood glucose levels may be normal but fasting insulin levels may be high because of compensatory insulin secretion by the pancreas
- **Impaired glucose tolerance:** glucose 140-199 mg/dL 2 hours after a 75 g oral glucose load
- **Impaired fasting glucose:** glucose 100-125 mg/dL after an 8-hour fast
- **Diabetes mellitus:** any of the following four criteria may be used (results must be confirmed by retesting on a subsequent occasion):
 - Fasting glucose ≥ 126 mg/dL
 - Glycosylated hemoglobin (HbA1c) level $\geq 6.5\%$ (note that HbA1c testing has not been validated in HIV-infected persons; see “Diagnostic Evaluation,” below)
 - 2-hour glucose level ≥ 200 mg/dL during glucose tolerance testing
 - Random glucose values ≥ 200 mg/dL in the presence of symptoms of hyperglycemia

The incidence of new-onset hyperglycemia among HIV-infected patients on ARV therapy (ART) has been reported as about 5%, on average. Even if fasting glucose levels remain normal in patients taking ARVs, up to 40% of those on a PI-containing regimen will show impaired glucose tolerance. The etiology of insulin resistance and hyperglycemia in HIV-infected patients probably is multifactorial, with varying contributions from traditional risk factors (e.g., obesity, family history), comorbid conditions (e.g., hepatitis C virus infection), and ARV-related factors (e.g., direct effects of PIs, cumulative exposure to NRTIs, hepatic steatosis, and fat redistribution).

Patients who have preexisting diabetes should be monitored closely when starting ART; some experts would consider avoiding PIs for these patients, if other options are feasible. Alternatively, PIs with favorable metabolic profiles (e.g., atazanavir) may be preferred for such patients. Patients with no history of diabetes should be advised about the warning signs of hyperglycemia (polydipsia, polyuria, and polyphagia) and the need to use diet and exercise to maintain an ideal body weight.

S: Subjective

Clinicians should consider the potential for abnormal glucose metabolism in the following types of patients:

- Those who are about to begin ART
- Those on an ARV regimen that includes a PI
- Those with extensive exposure to NRTIs
- Those who are obese or overweight
- Those with central fat accumulation or lipoatrophy

Although most patients with hyperglycemia are asymptomatic, some (rarely) may report polydipsia, polyuria, polyphagia, or blurred vision.

When recording the patient's history, ask about the following:

- **Risk factors:**
 - Family history of diabetes
 - Obesity
 - Habitual physical inactivity
 - Racial or ethnic heritages (higher risk: African-American, Hispanic, Native American, Asian/Pacific Islander)
 - Gestational diabetes or delivery of an infant weighing >9 lb (4.1 kg)
 - Current pregnancy
 - Hepatitis C virus coinfection
 - Polycystic ovary syndrome
 - Medications, including PIs, NRTIs, niacin, corticosteroids, antipsychotics
- **Comorbidities:**
 - Hypertension
 - Low level of high-density lipoprotein (HDL)
 - Elevated triglycerides
 - Coronary artery disease
 - Fat redistribution on ARVs (see chapter *Abnormalities of Body-Fat Distribution*)
 - Smoking

O: Objective

Perform a physical examination that includes the following:

- Blood pressure, weight, body mass index (BMI) (see chapter *Dyslipidemia*)
- Heart and lung examination
- Peripheral pulses
- Examination of neck, dorsocervical area, breasts, and abdomen for fat accumulation; measurement of waist circumference
- For patients with hyperglycemia or diabetes:
 - Retinal examination (refer to ophthalmologist for dilated examination)
 - Visual inspection of feet (for ulcers)
 - Sensory examination of feet (for neuropathy)

**A/P: Assessment and Plan
Diagnostic Evaluation**

Determine whether the patient has normal blood glucose, impaired fasting glucose, or diabetes.

Most experts recommend routine checks of fasting blood glucose levels at baseline and within 3-6 months after starting or changing ART, if baseline results are normal. For patients with normal glucose levels, recheck every 6-12 months. Monitoring should be more frequent if abnormalities are detected or if any additional risk factors exist. Patients with risk factors for diabetes must be counseled about prevention of hyperglycemia before starting ART.

The role of 2-hour postprandial glucose measurements or the 75 g oral glucose tolerance test for diabetes is uncertain but these screenings may be appropriate for patients with multiple risk factors. The use of HbA1c testing to screen for diabetes has yet to be validated for the HIV-infected population. Of note, HbA1c values may underestimate glycemia in HIV-infected patients, especially

in the setting of elevated red blood cell mean corpuscular volume (MCV) (e.g., owing to zidovudine) or anemia.

For patients with diabetes, monitor the following:

- HbA1c, every 3 months for patients who have elevated HbA1c or whose therapy has changed, every 3-6 months for patients with stable and adequate glucose control
- Fasting lipid panel
- Electrolytes, creatinine, estimated glomerular filtration rate (eGFR) (see chapter *Renal Disease*)
- Urine albumin/creatinine ratio (microalbuminuria: 30-299 mg/g)

Treatment

Patients with insulin resistance

For patients with insulin resistance who have normal blood glucose levels, current evidence is inadequate to recommend drug treatment. However, it may be possible to prevent the development of diabetes, and lifestyle modifications can be recommended, including exercise, avoidance of obesity, weight loss if indicated, and diet changes. Weight loss is strongly recommended if the patient is overweight. Refer the patient to a dietitian, if possible. Studies of insulin resistance in HIV-infected individuals are under way, and patients with access to clinical trials may be referred to these studies.

Patients with insulin resistance and hyperglycemia require treatment. A trial of lifestyle modifications may be attempted, including weight loss (if indicated), diet changes, and exercise.

For patients with diabetes and those whose lifestyle changes are not adequate to control blood glucose, specific treatment should be started.

Patients with diabetes

- Treatment should be instituted to control blood sugar and to modify other cardiovascular risk factors, with the aim of preventing heart disease and other end-organ disease.
- Control glucose: maintain the HbA1c level at <7%, while avoiding hypoglycemia.
- For hyperglycemia that is associated with the use of PIs, switching to an alternative agent (e.g., a nonnucleoside reverse transcriptase inhibitor, an integrase inhibitor, or a different PI) may be effective if the HIV treatment history and resistance profile permit.
- Metformin usually is the initial drug of choice for overweight patients; other options include sulfonylureas and thiazolidinediones.
- Metformin can worsen lipoatrophy and should be avoided in the presence of significant lipoatrophy. Metformin increases risk of lactic acidosis; it should not be used for patients with elevated serum creatinine (>1.5 mg/dL in men or >1.4 mg/dL in women), hepatic impairment, or metabolic acidosis.
- Sulfonylureas may cause hypoglycemia. In starting therapy, shorter-acting agents (e.g., glipizide) may be preferable to longer-acting agents (e.g., glyburide). Some agents should not be used for patients with renal impairment (CrCl <50 mL/min).
- Thiazolidinediones should be avoided in patients with significant liver disease. Rosiglitazone may increase the risk of myocardial infarction and death (study results conflict); both rosiglitazone and pioglitazone have been associated with congestive heart failure and are contraindicated for use by patients with this condition.

- In some cases, insulin may be the safest drug therapy for patients with symptomatic hyperglycemia, although episodes of hypoglycemia are much more common with insulin than with most oral agents.
- Treat dyslipidemia: maintain low-density lipoprotein (LDL) at <100 mg/dL and maintain triglycerides at <150 mg/dL. (Note that diabetes is considered a coronary heart disease equivalent state when evaluating goals for lipid management; see chapter *Dyslipidemia*.)
- Treat hypertension: Maintain systolic blood pressure at <130 mm Hg and diastolic blood pressure at <80 mm Hg.
- Reduce cardiovascular risks through lifestyle modifications such as smoking cessation, exercise, weight loss, nutritional counseling, and moderation of alcohol intake.
- Decrease the risk of end-organ complications:
 - Measure urine microalbumin and creatinine; if the urine albumin/creatinine ratio is >30 mg/g, treat with an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB) to slow the progression of nephropathy.
 - Schedule annual retinal examination by an ophthalmologist.
 - Perform an annual foot examination.
- Start aspirin therapy (75-162 mg daily) if the patient has evidence of macrovascular disease or a history of vascular events. Consider daily aspirin for those with increased coronary heart disease risk (e.g., men >50 years and women >60 years of age with ≥1 coronary heart disease risk factor, such as a family history of coronary artery disease or a history of smoking) (see chapter *Coronary Heart Disease Risk*).

For further information, see the American Diabetes Association, Clinical Practice Recommendations, Diabetes Care, available at care.diabetesjournals.org.

Patient Education

- ART can increase the risk of diabetes in some individuals. Patients should report any difficulty with excessive hunger and thirst and increased urination. Health care providers will monitor blood glucose when doing laboratory work, but it is important for the patient to report the presence of any symptoms.
- Review the patient's eating habits and explain the need to work with a dietitian to keep blood glucose (and triglycerides) within normal limits. Eating a proper diet can reduce the risk of permanent damage to the blood vessels of the eye, the kidney, and the brain, and it can reduce the risk of a heart attack.
- Emphasize other lifestyle modifications, such as weight loss (if appropriate).
- Encourage patients to get regular cardiovascular exercise; work with them to identify activities that might be realistic and acceptable for them.
- Provide medication-specific education, especially if the patient will be taking diabetes medications.
- Consider referral to a diabetes clinic for specialty needs.

Coronary Heart Disease Risk

Marshall Glesby, MD, PhD

Background

Epidemiologic studies suggest that the incidence of myocardial infarction or hospitalization for coronary heart disease (CHD) is increased up to twofold in HIV-infected individuals compared with age-matched controls without HIV infection. This increased risk of ischemic events likely is attributable to a higher prevalence of certain CHD risk factors that are independent of HIV status, such as smoking, as well as to both HIV infection and antiretroviral (ARV) medications. These various factors may interact in ways that are complex and incompletely understood.

Among the traditional CHD risk factors, dyslipidemia is common among persons with HIV infection, and can be caused both by HIV itself (e.g., resulting in low high-density lipoprotein [HDL] cholesterol) and by ARV therapy (ART); see chapter *Dyslipidemia*. Insulin resistance and diabetes also appear to be more prevalent in HIV-infected patients. (See chapter *Insulin Resistance, Hyperglycemia, and Diabetes on Antiretroviral Therapy*.) Visceral fat accumulation, a poorly understood complication of HIV or ART, also may contribute to CHD risk in certain patients (see chapter *Abnormalities of Body-Fat Distribution*).

Several studies have suggested that low CD4 cell counts are associated with myocardial infarction and stroke. Additionally, a number of studies suggest that inflammation and immune activation owing to uncontrolled HIV infection also likely contribute to atherosclerosis. For example, in the Strategic Management of Antiretroviral Therapy (SMART) study, CHD events were more common in patients on intermittent ART than in those on continuous ART, possibly because of adverse effects of intermittent HIV viremia on inflammation, coagulation, and lipid parameters. There is even preliminary evidence that so-called elite controllers – patients with undetectable HIV viremia and preserved CD4 counts in the absence of ART – have increased carotid intima-medial thickness (a marker of atherosclerotic burden) compared with HIV-uninfected subjects, after adjusting for other CHD risk factors. Limited data also suggest that initiation of ART leads to improvement of endothelial dysfunction (an early marker of atherosclerosis that is predictive of future CHD events) and to improvement in markers of inflammation and immune activation. Taken together, these observations suggest that earlier initiation of ART could reduce CHD risk.

On the other hand, even patients with virologic suppression on ART appear to have higher levels of various physiologic markers of cardiovascular risk than the HIV-uninfected persons, perhaps owing to persistent immune activation. Additionally, exposure to ARVs has been linked to risk of myocardial infarction in large cohort studies such as the D:A:D study. In particular, the risk has been associated with use of ARV regimens that are based on protease inhibitors (PIs) rather than nonnucleoside reverse transcriptase inhibitors (NNRTIs). The risk is attributable in part to adverse changes in lipid profiles, but there appears to be additional risk associated with PIs that is not accounted for by changes in lipids; this remains poorly understood. Among the nucleoside reverse transcriptase inhibitors (NRTIs), abacavir and didanosine have been associated with increased risk of myocardial infarction in some but not all studies. The mechanism of this potentially increased risk has not been determined.

S: Subjective

Clinicians should ask all patients about CHD, CHD risk equivalents, and CHD risk factors. Assess the following during the history:

- Age (>45 for men, >55 for women)
- History of angina, myocardial infarction, or other heart disease
- Family history of premature CHD in first-degree relatives (men aged <55, women aged <65) and diabetes mellitus
- Smoking history
- Glucose intolerance or diabetes mellitus
- Hypertension
- Dyslipidemia
- CHD risk-equivalent states:
 - Diabetes mellitus
 - Peripheral vascular disease
 - Cerebrovascular disease
 - Abdominal aortic aneurysm
- Use of cocaine or amphetamines
- Physical inactivity

O: Objective

Perform a physical examination to include the following:

- Vital signs, including blood pressure, pulse, weight, and body mass index (BMI); see chapter *Dyslipidemia*
- Jugular venous distention
- Heart and lung examination
- Auscultation for carotid or femoral bruits
- Peripheral pulses and evaluation of extremities for peripheral edema
- Abdominal examination for fat accumulation, ideally with measurement of waist circumference

A: Assessment

- Determine whether the patient has established CHD or a CHD risk-equivalent state (see above).
- Stratify risk based on the number of CHD risk factors and the Framingham risk calculator if two or more major CHD risk factors are present. The risk calculator is available at cvdrisk.nhlbi.nih.gov/calculator.asp.
- Check fasting lipids and glucose annually; more frequently if abnormal.
- Patients with established or suspected CHD should undergo standard evaluations such as electrocardiography and exercise stress testing; refer to a cardiologist as appropriate.

P: Plan

- Work closely with patients to reduce their risks of CHD events.
- For patients who smoke, smoking cessation is the single most important intervention to reduce risk of CHD events (see chapter *Smoking Cessation*).
- Manage dyslipidemia according to established guidelines (see chapter *Dyslipidemia*).
- Manage hypertension by lifestyle intervention (e.g., sodium restriction, exercise, weight loss) and pharmacologic therapy as indicated.
- Optimize glycemic control in patients with diabetes mellitus (see chapter *Insulin Resistance, Hyperglycemia, and Diabetes on Antiretroviral Therapy*).
- Encourage weight loss in overweight and obese patients, with referral to a dietitian as appropriate.
- Encourage exercise, ideally 30 minutes at moderate intensity 5-6 times per week.
- Encourage a healthy diet that is low in saturated fats.

- Consider aspirin 81 mg QD for primary prevention of CHD in patients at moderate to high risk who do not have contraindications to aspirin use.
- For patients who use cocaine or amphetamines, encourage cessation.

Patient Education

- Both HIV infection and ARV medications may contribute to the risk of CHD, and the available data suggest that the risk of CHD is increased in HIV-infected patients relative to the general population.
- Review the benefits of smoking cessation.
- Review exercise possibilities to determine which activities might be realistic and acceptable for the patient.
- Review the patient's eating habits and explain the need to work with a dietitian to optimize lipid levels and keep blood glucose within normal ranges.
- Emphasize the importance of other lifestyle modifications, such as weight loss (if appropriate).
- Educate patients about any pharmacologic therapy that is indicated.

Renal Disease

Alfredo Tiu, DO

Background

The prevalence of renal complications among patients with HIV infection has increased as more patients with HIV are living longer as a result of effective antiretroviral therapy (ART) and opportunistic infection prophylaxis. More widespread access to and earlier initiation of ART has decreased the incidence of HIV-associated nephropathy (HIVAN), but other causes of renal disease persist, and in some cases are increasing in prevalence. These may be infections and other conditions related to HIV infection, other comorbidities (e.g., hypertension, diabetes), or medication adverse effects, including those caused by some antiretroviral (ARV) medications (see “Kidney disease associated with HIV infection” and Table 2, below).

Risk factors for renal disease in HIV-infected patients include the following:

- CD4 count <200 cells/ μ L
- HIV viremia, particularly RNA levels >4,000 copies/mL
- African-American race
- Family history of kidney disease
- Use of nephrotoxins (including medications; see Table 2, below)
- Comorbidities
 - Diabetes mellitus
 - Hypertension
 - Hepatitis C

Renal disease in HIV-infected individuals can occur as a primary disease, as a secondary disease in the setting of other systemic illness, or as an adverse effect of medications. In the United States, the most common causes of end-stage renal disease in the general population are diabetes mellitus and hypertension. HIV-infected patients are at a fourfold higher risk of developing diabetes mellitus and a threefold higher risk of developing hypertension compared with seronegative individuals. Chronic hepatitis C, seen in 30–40% of HIV-infected individuals in the United States, is associated with several types of chronic kidney disease, including progressive secondary glomerulonephropathy, membranoproliferative glomerulonephropathy, and mixed cryoglobulinemia.

Note that ART should be given to HIV-infected individuals with renal disease, according to usual criteria for ART initiation; however, some ARVs must be avoided and some should be given at modified dosages according to the degree of renal dysfunction (see Table 3). Additionally, for patients with HIVAN, ART is the primary treatment.

Screening

Screening for kidney disease in HIV-infected persons is an important aspect of primary care, as patients typically have no symptoms until very late. High-risk patients (see list of risk factors, above) should be identified and monitored. Early identification of patients with renal dysfunction allows early intervention targeted at reversing the process of renal injury or slowing its progression. Current guidelines of the U.S. Department of Health and Human Services (HHS) and the Infectious Diseases Society of America recommend screening at entry to care, with subsequent screening as indicated by the patient's risk factors.

Screening consists of three tests:

- **Serum creatinine (Cr) and calculated estimate of renal function (eGFR);** the eGFR usually is provided by the laboratory but may be calculated as follows:

- *eGFR by the Modification of Diet in Renal Disease (MDRD) equation:*

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 186 \times [\text{serum Cr (mg/dL)}]^{-1.154} \times [\text{age (years)}]^{-0.203} \times [0.742 \text{ if female}] \times [1.212 \text{ if African-American}]$$

Normal GFR: $\geq 90 \text{ mL/min/1.73 m}^2$

Chronic kidney disease (CKD): $\text{GFR} < 60 \text{ mL/min/1.73 m}^2$

An online eGFR calculator is available at www.nkdep.nih.gov/lab-evaluation/gfr-calculators.shtml.

- The creatinine clearance (CrCl) can be used as a surrogate for eGFR but is considered to be less accurate. Note that CrCl is used in determining medication dosages.

CrCl (Cockcroft-Gault equation):

$$\frac{(140 - \text{age}) \times (\text{weight in kilograms})}{72 \times \text{serum Cr (mg/dL)}}$$
 multiply by 0.85 for females

- **Urinalysis, for proteinuria, hematuria**
- **Quantitative test for proteinuria** (if eGFR $< 60 \text{ mL/min/1.73m}^2$ or $\geq 1+$ protein on dipstick):
 - Random urinary protein to urinary Cr ratio (U Pr/U Cr)
 - This estimates 24-hour protein excretion and correlates well with grams per day of proteinuria; for example, a random U Pr/U Cr of 1.0 correlates with 1 g/day of proteinuria (normal is ≤ 0.2)

Suggested follow-up for patients with normal screening test results is shown in Figure 1; suggested follow-up of abnormal screening test results is shown in “Diagnostic Evaluation.”

Figure 1. Follow-Up for Patients with Normal Screening Test Results

S: Subjective

As noted above, patients usually have no symptoms until late in the course of kidney disease and are diagnosed on the basis of laboratory abnormalities.

In symptomatic patients, presenting signs or symptoms are nonspecific. Patients with renal failure may present with fatigue, weakness, anorexia, nausea, pruritus, vomiting, edema, diminished urine output, discolored urine, altered mental status, and seizures. Those with renal disease associated with systemic illnesses may present with fever, arthralgias, respiratory symptoms, flank pain, abdominal pain, and diarrhea.

For patients with renal disease suspected on the basis of laboratory abnormalities (e.g., elevated serum Cr [azotemia], electrolyte disturbances, acid-base disorders, proteinuria, hematuria, and anemia), and for symptomatic patients with known kidney disease, ask about the risk factors and symptoms described above, and about the following:

- Systemic illness
 - Night sweats, fever, weight loss
 - Shortness of breath, cough, hemoptysis, nasal congestion, rhinorrhea
 - Diarrhea, hematochezia, melena
 - Dysuria, frequency, urgency, polyuria, decreased urine output, discoloration of urine
 - Skin rash or skin lesions
 - Edema, arthralgias, painful swollen joints, myalgias
- Family history of kidney disease, hypertension, diabetes mellitus
- Recent radiographic imaging with IV contrasts (including those containing gadolinium or iodinated agents)

Review the patient’s medication list (see Table 1).

- Include over-the-counter medications, nonsteroidal antiinflammatory drugs, phosphate-containing enemas

O: Objective

Check blood pressure, temperature, and weight. Compare these with values from previous readings. Perform a physical examination, including evaluations of the following:

- Volume status (blood pressure, pulse, skin turgor, mucous membrane moistness, edema)
- Optic fundi (signs of retinopathy)
- Cardiovascular system (peripheral pulses, bruits), to assess for peripheral vascular disease
- Abdomen (auscultate for unilateral bruit [renal artery stenosis], distention, mass, organomegaly, tenderness)
- Musculoskeletal system (bruises, muscle pain, muscle weakness, swollen joints)
- Skin (rash to help evaluate for drug reaction, vasculitis)
- Rectum (enlarged prostate, if obstruction is suspected)

Review previous laboratory values (e.g., serum Cr, blood urea nitrogen [BUN], electrolytes, urinalysis) to determine whether the kidney disease is acute or chronic.

- Acute kidney injury (AKI) is assumed if there are no previous serum Cr values.

The presence of an abnormal GFR (≤ 60 mL/min for at least 3 months) suggests chronic kidney disease (CKD).

Review the CD4 cell count and HIV viral load.

A: Assessment

Once the duration of the elevated serum Cr is assessed, a differential diagnosis can be made.

The causes of renal failure are classified traditionally based on the area of the renal anatomy where the injury occurred: prerenal, renal, and postrenal (obstructive uropathy). Acute tubular necrosis (ATN) is the most common cause of acute kidney injury.

Table 1. Causes of Renal Failure

Prerenal	Renal	Postrenal
Laboratory Data		
• Urine sodium (Na) <30 mEq/L • Fractional excretion of Na (FeNa) $<1\%$ (see below) • Fractional excretion of urea $<35\%$ • Serum BUN: serum Cr ratio ≥ 20	• Urine Na >30 mEq/L • FeNa $>1\%$ (see below) • Fractional excretion of urea >50 • Serum BUN: serum Cr ratio ≥ 10	Hematuria Imaging showing obstruction

Prerenal	Renal	Postrenal
Partial Differential Diagnosis		
Decreased renal perfusion • Volume depletion • Effective volume depletion • Heart failure • Cirrhosis • Shock Vascular disease • Renal artery stenosis Medication induced • Prostaglandin inhibition (NSAID) • ACE inhibitors and angiotensin receptor blockers	Acute Tubular Necrosis Ischemia leading to ATN • Prolonged hypotension attributable to any cause • Sepsis syndrome • Volume depletion (gastrointestinal bleeding) • Atheroembolism and thromboembolism • Systemic vasculitis • Thrombotic microangiopathy (TTP, HUS) Endogenous toxins • Myoglobin (rhabdomyolysis) • Uric acid and calcium-phosphate complexes (tumor lysis syndrome) Exogenous-induced ATN • Aminoglycosides • Amphotericin B • Foscarnet • Ganciclovir • Intravenous pentamidine • Tenofovir • Chemotherapeutic agents (methotrexate, cisplatin) Glomerulonephropathy • Many specific types; some associated with HIV (including HIVAN) or associated infections and other conditions Other intrarenal lesions • Acute interstitial nephritis (AIN) • Drug induced • Infections associated with AIN • Bacterial (<i>Streptococcus</i>, <i>Mycobacteria</i>, <i>Legionella</i>, <i>Pneumococcus</i>) • Viral (Epstein-Barr, herpes simplex type 1, cytomegalovirus, BK virus) • Fungal (histoplasmosis, candidiasis) • Other infections (toxoplasmosis, syphilis, schistosomiasis, malaria, leptospirosis) • Infectious • Granulomatous (mycobacterial disease, coccidioidomycosis, histoplasmosis) • Tumors • Multiple myeloma • Lymphoma • Nephrolithiasis • Intratubular obstruction • Drug-induced crystalluria ▶ Antiviral (acyclovir, indinavir, atazanavir) ▶ Antibiotic (trimethoprim/sulfamethoxazole)	Prostate hypertrophy Tumors Stones or crystal deposition

Abbreviations: ACE = angiotensin-converting enzyme; HUS = hemolytic uremic syndrome; NSAID = nonsteroidal antiinflammatory drug; TTP = thrombotic thrombocytopenic purpura

Kidney Disease Associated with HIV Infection

A discussion of glomerulonephropathy is beyond the scope of this chapter, but HIV and associated comorbidities (e.g., infections such as hepatitis C, hepatitis B, and cytomegalovirus, along with malignancies, heroin use, nephrotoxic medications, diabetes mellitus, and hypertension) are among the many causes of glomerulonephropathy. The condition most closely associated with HIV is HIVAN. This is a collapsing focal segmental glomerulosclerosis (FSGS) that usually occurs in persons of African heritage, and particularly those with a low CD4 count or high HIV RNA level. The clinical presentation includes the following:

- Nephrotic syndrome or nonnephrotic proteinuria
- Normal blood pressure
- Elevated Cr, often with rapid progression to end-stage renal disease (<6 months)
- Renal ultrasound usually reveals normal size or slightly enlarged echogenic kidneys
- Renal biopsy shows a collapsing FSGS

In addition, several conditions may be caused by ARV medications. Tenofovir may cause, though rarely, AKI with type 2 renal tubular acidosis (RTA) and Fanconi syndrome.

Alternatively, it more commonly causes a gradual increase in serum Cr over a period of months or years; this appears to occur more frequently in persons concomitantly taking ritonavir-boosted PIs and perhaps also in those taking cobicistat. Patients who take tenofovir should have renal function monitored every 3-6 months. Indinavir can cause crystalluria, nephrolithiasis, and acute interstitial nephritis, and atazanavir can cause nephrolithiasis.

Some other medications commonly used in the treatment of patients with HIV infection and associated conditions may cause acute or chronic kidney injury. See Table 1, above, and Table 2, below.

It should be noted that several ARVs (including the NNRTI rilpivirine and the integrase inhibitor dolutegravir) as well as the pharmacokinetic inhibitor cobicistat (in the coformulation elvitegravir/cobicistat/tenofovir/emtricitabine, Stribild) may inhibit renal tubular secretion of creatinine and thus cause modest increases in serum Cr (in the range of 0.1-0.2 mg/dL) and modest decreases in eGFR. This does not result from kidney injury, and actual GFR remains stable. These creatinine increases occur in the initial weeks of treatment with one of these agents and remain stable afterward (if increases in Cr exceed what is expected for these drugs, it is important to conduct an evaluation for other causes).

Table 2. Selective Drugs Causing Acute or Chronic Kidney Injury in HIV-Infected Patients

Drugs	Acute Tubular Necrosis	Acute Interstitial Nephritis	Other Associated Abnormalities
Antiretroviral Medications			
Abacavir		+/-	
Atazanavir		+	Nephrolithiasis
Indinavir		+	Crystalluria
Tenofovir	+		Fanconi syndrome (hypokalemia, non-gap metabolic acidosis, hypophosphatemia, glycosuria) May cause a slow increase in Cr
Other Medications			
TMP-SMX (Bactrim, Septra)		+++	Hyperkalemia, crystalluria
Beta-lactams		++	
Sulfonamides		++	
Fluoroquinolones		+	
Aminoglycosides (e.g., streptomycin, gentamycin, amikacin)	+++		
Rifampin	+	+	
Isoniazid		+	Overdose leads to high anion gap metabolic acidosis
Dapsone	+/-		Papillary necrosis
Amphotericin B	+++		Hypokalemia, hypernatremia (nephrogenic diabetes insipidus)
Pentamidine	+++		Crystalluria
Foscarnet	+++		
Ganciclovir	+		
Acyclovir	+		Crystalluria
NSAIDs		+	Proteinuria, secondary minimal change disease, papillary necrosis

P: Plan**Diagnostic Evaluation****Figure 2. Workup of Abnormal Screening Test Results**

Determine whether the renal disease is acute or chronic, as above (see “O: Objective”).

Perform a targeted laboratory evaluation, depending on results of initial tests, history, and physical examination.

- Urinalysis with microscopy and examination of urine sediment (e.g., hematuria, pyuria, casts) can help in identifying etiologies such as nephritic syndrome, ATN, or infection.
- Quantify the proteinuria by obtaining a random urine protein-to-urine creatinine ratio (U Pr/U Cr), if not done already; this correlates well with grams per day of proteinuria, as discussed above.
- Fractional excretion of sodium (FeNa) may be helpful in distinguishing causes of acute kidney injury.
 - $$\text{FeNa} = \frac{\text{Urine sodium} \div \text{Serum sodium}}{\text{Urine Cr} \div \text{Serum Cr}}$$
 - FeNa <1 is highly suggestive of prerenal state
 - FeNa >1 is suggestive of intrinsic renal injury
- Urine culture, if urinary tract infection is suspected

Further workup will depend on the findings and the suspected cause.

Proteinuria

Proteinuria can be present in patients with primary renal disease, and also in those with hypertension, diabetes mellitus, vascular disease, collagen vascular disease, malignancy, or certain infections. Proteinuria is not always pathologic and may be caused by

transient conditions such as pregnancy, strenuous exercise, fever, seizure, or congestive heart failure; in some cases, it may be benign. However, proteinuria should be evaluated if it persists. If

present with hematuria, proteinuria is highly suspicious for a glomerular disease.

The major classifications of persons with proteinuria are as follows:

Nephrotic syndrome:

- >3.5 g/day proteinuria
- “Bland” sediment, with no or few red or white blood cells
- Edema
- Hyperlipidemia
- Hypoalbuminemia
- Check serum complements (C3 and C4):
 - Low complements: glomerulonephritis associated with subacute bacterial endocarditis, infection (postinfectious), lupus, membranoproliferative glomerulonephritis, and mixed cryoglobulinemia

Glomerulonephritis:

- Proteinuria
- “Active” sediment, with white and red blood cells; may see red blood cell casts
- Further categorized into those with normal renal function and those with abnormal renal function

Hematuria

For asymptomatic isolated microscopic hematuria, obtain a follow-up urinalysis. If hematuria is persistent, obtain a renal and bladder ultrasound. If the result is normal, the eGFR is normal, and there are no other urine abnormalities, conduct routine follow-up with urinalysis and serum Cr testing. Refer patients aged ≥ 40 with persistent hematuria to a urologist for formal evaluation. Consider checking urine cytology, though that test is not sensitive enough to rule out genitourinary malignancy.

Red blood cell casts

Red blood cell casts strongly suggest glomerulonephritis, which can progress rapidly.

ATN

ATN is the most common cause of AKI. A history of certain medication exposures, recent IV contrast, and concurrent illness may provide important clues to ATN. Laboratory findings that are consistent with ATN include increasing serum Cr and a characteristic urine sediment that shows “muddy brown” casts, which are casts that contain densely packed tubular cells.

AIN

During AIN, the classic triad of AKI, fever, and rash is not always present. Laboratory findings suggestive of AIN in the setting of AKI include sterile pyuria and eosinophiluria.

Sterile pyuria

Sterile pyuria also may occur in malignancy (e.g., renal, bladder), and in genitourinary tuberculosis. If tuberculosis is suspected, further testing usually requires three first-void urine specimens sent for acid-fast bacilli culture.

Crystalluria and nephrolithiasis

Usual causes of nephrolithiasis should be considered in patients with hematuria, particularly if symptoms consistent with nephrolithiasis are present. Other causes in

persons with HIV infection include some medications, including the ARVs indinavir and (rarely) atazanavir; see Table 2 above.

Obtain radiographic imaging (see below) as part of the initial evaluation, and send the passed renal stone, if available, for analysis in order to provide more specific recommendations for management. If there is suspicion that the condition is caused by a medication, order specific chemical analysis (e.g., for atazanavir).

In patients with multiple renal stones, active renal stone formation, and recurrent kidney stones, a metabolic evaluation should be done. This includes a serum intact parathyroid hormone measurement and 24-hour urine collection for Cr, sodium, calcium, oxalate, uric acid, and citrate.

Imaging

Radiographic imaging of the kidneys is important in the evaluation of renal disease. The size and echogenicity of the kidneys may help differentiate acute and chronic kidney disease. Small and echogenic kidneys are consistent with CKD, though HIV, diabetes, and some other chronic conditions are associated with normal size or large kidneys. Imaging also helps identify obstruction (though the absence of hydronephrosis does not completely rule that out), malignancy, and other conditions.

Both spiral computed tomography (CT) scan and renal ultrasound are acceptable radiographic imaging studies for nephrolithiasis. The advantage of spiral CT scan is its ability to localize stones and assess their size without the use of contrast. Gallium renal scan may be helpful in AIN.

Renal biopsy

Biopsy is not always indicated for patients with renal disease, but it can be very helpful in establishing some diagnoses and determining treatment options.

Treatment

Patients with proteinuria will benefit from angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs). Follow the serum potassium and Cr during treatment with an ACEI or ARB (check 1 week after initiation, then periodically). Follow the JNC VII (Joint National Committee on Prevention, Detection, Evaluation and Treatment of Blood Pressure) guidelines for blood pressure control. For patients with hypertension and proteinuria, the target blood pressure is <125/80 mm Hg.

The cornerstone of HIVAN management is fully suppressive ART, and this should be quickly initiated or optimized in all patients, if possible. An ACEI or ARB also should be used to treat proteinuria. A trial of corticosteroids can be considered for patients with deteriorating kidney function while on effective ART plus an ACEI or ARB; consult with a specialist.

For ATN and AIN, discontinue the offending medications and provide supportive care, which may include gentle volume repletion, replacement of bicarbonate deficit, and management of electrolyte abnormalities (e.g., hyperkalemia); consult with a renal specialist.

Other modalities of treatment such as steroids or immunomodulators may be needed, depending on the specific glomerular disease diagnosed by renal biopsy.

Uncomplicated nephrolithiasis can be managed with hydration and pain control. Oral fluid intake should be titrated to produce ≥ 2 liters of urine output per day. Recommendations for dietary modifications should be based on the 24-hour urine metabolic evaluation. A low-calcium diet usually is not helpful for patients with normal serum calcium and may be detrimental to patients with oxalate renal stones. If the crystalluria is caused by medications, discontinue the offending medications, if possible (in the case of ARVs, make substitutions to maintain optimal virologic suppression).

Patients with complicated nephrolithiasis or pyelonephritis require urgent urologic evaluation.

Follow-Up

- Acute kidney injury
 - Monitor serum electrolytes, BUN and Cr
 - After these normalize, perform routine follow-up
- Acute interstitial nephritis
 - Avoid offending medications
- Chronic kidney disease
 - Follow blood pressure closely
 - If hypertensive, consider an ACEI or ARB as first-line medication, as above
 - Target blood pressure is <130/80 mm Hg
 - If evidence of nephropathy, target blood pressure is <125/75 mm Hg
- For patients with diabetes, optimize blood glucose control
- Address other risk factors for cardiovascular disease (see chapter *Coronary Heart Disease Risk*)
 - Dyslipidemia
 - Cigarette smoking
 - Obesity
 - Physical inactivity
- Monitor serum electrolytes, BUN, Cr, and hemoglobin
- Risk of secondary hyperparathyroidism:
 - Serum calcium <9.5 mg/dL
 - Parathyroid hormone level >35 pg/mL
 - Management:
 - Low-phosphate diet
 - Phosphate binders with meals
 - Vitamin D supplement

- Anemia
 - Consider recombinant human erythropoietin and iron supplement (consult with a nephrologist)
 - Target hemoglobin 11-12 g/dL
- Avoid nephrotoxins, if possible
- Adjust medication dosages based on renal function (eGFR); see below

Patients with severe or chronic renal disease should be referred to Nephrology for further evaluation and assistance with the following:

- Management
- Education
- Evaluation for renal replacement therapy
 - Peritoneal dialysis
 - Hemodialysis
- Kidney transplant evaluation

Medication Dosage Adjustment

Dosages of many medications, including most nucleoside analogues (NRTIs), must be adjusted for patients with CKD, and for those on hemodialysis; see Table 3, below.

Table 3. Dosing of Antiretroviral Drugs in Adults with Chronic Kidney Disease and Hemodialysis

Drug	Standard Dosage	Dosing in Chronic Kidney Disease and Hemodialysis		
Abacavir	300 mg PO BID	Dosage adjustment for CKD does not appear necessary		
Didanosine (enteric-coated capsules)	250 mg to 400 mg PO QD, depending on weight	CrCl (mL/min)	Weight ≥60 kg	Weight <60 kg
		≥60	400 mg QD	250 mg QD
		30-59	200 mg QD	125 mg QD
		10-29	125 mg QD	125 mg QD
		<10	125 mg QD	Formulation not suitable
		HD	125 mg QD	Formulation not suitable
Emtricitabine	200 mg PO QD	CrCl (mL/min)		
		≥50	200 mg QD	
		30-49	200 mg Q48H	
		15-29	200 mg Q72H	
		<15	200 mg Q96H	
		HD	200 mg Q96H, take after dialysis	
Lamivudine 150 mg PO BID or 300 mg PO QD	150 mg PO BID or 300 mg PO QD	CrCl (mL/min)		
		≥50	150 mg BID or 300 mg QD	
		30-49	150 mg QD	
		15-29	150 mg first dose, then 100 mg QD	
		5-14	150 mg first dose, then 50 mg QD	
		<5	50 mg first dose, then 25 mg QD	
		HD	50 mg first dose, then 25 mg QD, take after dialysis	
Stavudine	20 mg to 40 mg PO BID, depending on weight	CrCl (mL/min)	Weight ≥60 kg	Weight <60 kg
		>50	40 mg BID	30 mg BID
		26-50	20 mg BID	15 mg BID
		10-25	20 mg QD	15 mg QD
		HD	20 mg QD, take after dialysis	15 mg QD, take after dialysis

372 | Guide for HIV/AIDS Clinical Care

Drug	Standard Dosage	Dosing in Chronic Kidney Disease and Hemodialysis	
Tenofovir	300 mg PO QD	Experience in patients with CrCl <60 mL/min is limited.	
		CrCl (mL/min)	
		≥50	300 mg QD
		30-49	300 mg Q48H
		10-29	300 mg BIW (i.e., Q 3-4 days)
		<10	Not recommended
Zidovudine	300 mg PO BID	HD	300 mg once weekly, after dialysis
		CrCl (mL/min)	
		<15	100 mg TID (or 300 mg QD)
		HD	100 mg TID (or 300 mg QD); take after dialysis

Fixed-Dose Combinations

Drug	Standard Dosage	Dosing in Chronic Kidney Disease and Hemodialysis	
Atripla (efavirenz/tenofovir/emtricitabine)	1 tab PO QHS	Substitute component drugs, adjusting dosage of each drug for CrCl	
Combivir (zidovudine/lamivudine)	1 tab PO BID	Substitute component drugs, adjusting dosage of each drug for CrCl	
Complera (rilpivirine/tenofovir/emtricitabine)	1 tab PO QD	Substitute component drugs, adjusting dosage of each drug for CrCl	
Epzicom or Kivexa (abacavir/lamivudine)	1 tab PO QD	Substitute component drugs, adjusting dosage of each drug for CrCl	
Trizivir (zidovudine/abacavir/lamivudine)	1 tab PO BID	Substitute component drugs, adjusting dosage of each drug for CrCl	
Stribild (elvitegravir/cobicistat/tenofovir/emtricitabine)	1 tab PO QD	Do not initiate if CrCl <70 mg/mL; discontinue if CrCl <50 mg/mL	
Truvada (emtricitabine/tenofovir)	1 tab PO QD	CrCl (mL/min)	
		≥50	1 tablet QD
		30-49	1 tablet Q48H
		<30	Substitute component drugs, adjusting dosage of each drug for CrCl

Abbreviations: CrCl = creatinine clearance; HD = hemodialysis

Adapted from McNicholl I, Rodriguez R. *Dosing of Antiretroviral Drugs in Adults with Chronic Kidney Disease and Hemodialysis*. In: HIV InSite, Coffey S, Volberding P, eds. San Francisco: UCSF Center for HIV Information. Available at hivinsite.ucsf.edu/InSite?page=md-rr-18. Accessed December 1, 2013.

Protease inhibitors (PIs) and nonnucleoside reverse transcriptase inhibitors (NNRTIs) do not appear to require dosage adjustment in persons with CKD. Some PIs and NNRTIs, however, do require changes in dosing strategy for patients on hemodialysis. (It should be noted that most PIs have not been studied in the setting of hemodialysis.) The CCR5 antagonist maraviroc should not be used for certain patients with CKD. Available recommendations for hemodialysis patients include the following:

Atazanavir

- Unboosted atazanavir should not be used.
- Treatment-naïve patients: atazanavir must be boosted by ritonavir.
- Treatment-experienced patients: atazanavir (boosted or unboosted) is not recommended.

Lopinavir/ritonavir

- QD dosing should not be used.
- In patients with PI resistance, lopinavir/ritonavir levels may be subtherapeutic.

Maraviroc

- CrCl <30 mL/min or on HD: not recommended with potent CYP3A inhibitors or inducers. Without potent CYP3A inhibitors or inducers: 300 mg BID (150 mg BID if postural hypotension occurs).

Nevirapine

- An additional dose (200 mg) should be given after each dialysis session.

Patient Education

- Early diagnosis of kidney disease is important. Acute kidney injury usually is reversible but may take time and may require temporary hemodialysis support.
- Advise patients to report all the medications they take, including over-the-counter medications and herbs or supplements.
- Risk factors for kidney disease are uncontrolled HIV infection (viral load above 4,000 copies/mL and CD4 count <200 cells/ μ L), coexisting conditions (diabetes mellitus, hypertension, hepatitis C), and ethnicity (African-Americans, Hispanic Americans, Asians, Pacific Islanders, and American Indians). Advise patients that it is important to reduce any modifiable risks, including optimizing HIV control and diabetes mellitus or hypertension management.
- Advise patients that control of blood pressure is important in slowing the progression of renal disease. Hypertension control can be maximized by both lifestyle modifications (e.g., weight lost, exercise, avoiding excessive alcohol intake) and antihypertensive medications. ACEIs or ARBs are the drugs of choice for patients with hypertension and kidney disease. Target blood pressure is <125/75 mm Hg for patients with proteinuric kidney disease.
- Educate patients that management of chronic kidney disease helps avoid or control complications such as high blood pressure, weak bones (osteodystrophy), anemia, and nerve damage (neuropathy).
- When the kidney disease progresses to end-stage renal disease, several options can be explored. These are dialysis, kidney transplant, or palliative care. There are two modes of dialysis, hemodialysis and peritoneal dialysis. A nephrologist and the patient can decide which option is best. HIV control (suppressed viral load, optimal CD4) is required if kidney transplant is to be considered.

Immune Reconstitution Inflammatory Syndrome

Background

For most patients, initiating antiretroviral therapy (ART) improves immune responses to a wide range of opportunistic pathogens. The process of ART-induced immune reconstitution typically is uneventful. However, a small percentage of patients develop inflammatory disease in response to specific opportunistic pathogens within a few weeks or months after initiating therapy. This exuberant inflammatory response has been called the immune reconstitution inflammatory syndrome (IRIS), also known as immune reconstitution syndrome (IRS) or immune reconstitution disease (IRD).

The term IRIS is used to describe two distinct entities:

- An exacerbation of a partially or successfully treated opportunistic infection (OI), referred to as paradoxical IRIS
- An inflammatory response to a previously undiagnosed (subclinical) OI, often more pronounced than the typical presentation of this OI, referred to as unmasking IRIS

IRIS may occur in response to many pathogens. IRIS commonly occurs in association with *Mycobacterium tuberculosis*, *Mycobacterium avium* complex (MAC), cytomegalovirus (CMV), and *Cryptococcus*, and it may occur with *Pneumocystis*, *Toxoplasma*, hepatitis B and C, human herpes virus 8 (HHV-8, which causes Kaposi sarcoma), and JC virus (which causes progressive multifocal leukoencephalopathy, PML).

Risk factors for development of paradoxical IRIS include low CD4 cell count (particularly <50 cells/ μ L) at time of ART initiation and high baseline HIV RNA. Starting ART in close proximity to initiation of treatment for a recognized OI also increases the risk of IRIS, though data also show that earlier ART initiation tends to reduce mortality and AIDS progression, particularly in persons with advanced immunosuppression (see “Timing of ART initiation,” below).

Paradoxical IRIS also can occur in the absence of ART, as has been reported during tuberculosis (TB) treatment. The specific mechanisms involved in the pathogenesis of IRIS are not well understood and may vary from one infection to another. However, experts believe that IRIS is caused by an enhanced and dysregulated immune response to disease-specific antigens, which leads to an overproduction of inflammatory mediators.

IRIS may be difficult to identify in clinical practice because the clinical presentation is nonspecific and, currently, there are no laboratory markers to identify the syndrome. To make the diagnosis of IRIS, the following must be excluded:

- Presence of a new OI or concomitant illness
- Failure of treatment for a known OI (e.g., owing to drug resistance, inadequate treatment, or poor adherence)
- Failure of treatment for HIV infection (e.g., owing to poor adherence or drug resistance)

The severity of IRIS varies widely, from mild to life-threatening. Treatment varies according to the specific pathogen and clinical situation, but typically includes continuing ART if possible, treating the OI as indicated, and adding antiinflammatory therapy (including corticosteroids) as needed.

Clinical Presentation

IRIS is largely a clinical diagnosis, and other conditions must be excluded, as indicated above. To consider IRIS in the differential diagnosis, clinicians must recognize the clinical findings (typical or atypical) of a specific OI and the temporal association with treatment (usually after ART initiation, but IRIS may occur with treatment of the OI alone). For example, for a patient with TB who has recently initiated ART after responding to treatment of TB, the “red flags” for a diagnosis of IRIS (rather than progression of the TB) would include new or worsening fever, new effusions, and new or worsening lymphadenopathy, in the absence of poor adherence to TB treatment or drug-resistant TB.

The clinical manifestations of IRIS associated with some common OIs are described below. (This is not an exhaustive list, but it includes most of the important IRIS manifestations seen in patients with HIV infection.)

Tuberculosis

The signs and symptoms of TB IRIS may include various clinical or radiologic features (e.g., new or worsening enlarged lymph nodes, fevers, weight loss, pulmonary symptoms, and radiographic features of TB such as infiltrates and pleural effusions). Nonpulmonary presentations may include expanding central nervous system (CNS) deficits or lesions, lymphadenopathy (mediastinal or peripheral), ascites, pericardial effusions, skin or visceral abscesses, bone lesions, and hypercalcemia. In a patient who is receiving therapy for active TB, the onset of TB IRIS typically occurs within weeks to several months after the patient begins ART and is more common among patients with low CD4 cell counts at the time of ART initiation (see chapter *Mycobacterium tuberculosis*).

Mycobacterium avium Complex

Lymphadenitis and fever are the characteristic symptoms of MAC IRIS, but pulmonary symptoms, abdominal pain, bone and hepatic involvement, and CNS manifestations may develop. Signs and symptoms of MAC IRIS may be clinically indistinguishable from active MAC. In contrast to disseminated MAC, MAC IRIS is associated with a rapid and striking increase in CD4 count (usually from <50 cells/ μ L to ≥ 100 cells/ μ L), and MAC bacteremia usually is absent. MAC IRIS can be mild and localized or it can be severe, requiring systemic antiinflammatory therapy (sometimes for long periods), in addition to anti-MAC therapy.

Cytomegalovirus

CMV IRIS is usually localized to the eye, as described below. However, CMV IRIS will rarely present with extraocular disease such as colitis, pancreatitis, or pneumonitis.

CMV retinitis

CMV retinitis may occur in patients with a history of CMV retinitis or in patients with no previous evidence of retinitis. In those with a previous diagnosis of CMV retinitis, a new opacified retinal lesion develops, frequently at the site of an earlier lesion. CMV retinitis IRIS is identical to active CMV retinitis on ophthalmologic examination. Clinical information, therefore, will guide the diagnosis, and patients should be monitored closely. As with other IRIS reactions, symptoms often are associated temporally with initiation of ART.

In order to initiate appropriate treatment, and to avoid IRIS, an ophthalmic examination to assess for the presence of CMV retinal infection should be performed for all patients with CD4 cell counts of <50 cells/ μ L), preferably prior to the initiation of ART. This is particularly important for patients who report visual symptoms such as floaters or abnormal vision.

For patients who experience IRIS after being adequately treated for CMV retinitis, serial ophthalmologic examinations will reveal that the lesions clear without a new or different therapy for CMV. This clinical picture differs from that of retinal lesions caused by active CMV infection and uncontrolled CMV replication, in which lesions will increase in size or new lesions will appear, if appropriate CMV therapy has not been introduced (see chapter *Cytomegalovirus Disease*).

CMV vitreitis and CMV uveitis

CMV vitreitis and CMV uveitis are seen exclusively in patients with previous CMV retinitis infection who responded to ART.

CMV vitreitis

CMV vitreitis IRIS is an alarming syndrome, but a benign one. Patients who are receiving anti-CMV therapy typically present with acute onset of blurred vision and “floaters” caused by posterior segment inflammation. Ophthalmologic examination reveals numerous inflammatory cells in the vitreous humor. Symptoms usually resolve in 1 month without specific treatment and without any lasting visual effects.

CMV uveitis

In patients with a history of CMV retinitis, CMV uveitis IRIS may occur within months of ART initiation, but typically is a late complication, occurring about 3 years after patients begin ART. Uveitis is painless and primarily involves inflammation in the iris, the ciliary body, and the choroid layers. However, CMV uveitis may have serious sequelae. It often results in macular edema, epiretinal membrane formation, or cataracts, which can lead to permanent vision loss. Because of the risk of vision loss, clinicians should have a high index of suspicion for CMV uveitis.

Cryptococcal Meningitis

In patients with or without previously diagnosed cryptococcal meningitis, presentation of cryptococcal IRIS typically includes fever, headache, eye pain, and photophobia, and may include meningeal signs. In cryptococcal IRIS, analysis of cerebrospinal fluid (CSF) is characterized by high opening pressure and, unlike initial presentation of cryptococcal meningitis, an elevated white blood cell count and sterile fungal cultures. Onset has been reported between 1 week and 11 months after initiation of ART. Lymphadenitis, pulmonary disease, and cutaneous involvement also have been reported (see chapter *Cryptococcal Disease*).

Pneumocystis jiroveci Pneumonia

Pneumocystis jiroveci pneumonia (PCP) IRIS may occur in patients with current or recent PCP who are starting ART in the early weeks after initiation of PCP treatment. IRIS may present as worsening pulmonary symptoms (typically after corticosteroids given for the initial PCP treatment have been tapered or discontinued) and high fever in patients who had been improving on PCP therapy or in patients with recent successful treatment of PCP. Chest X-rays may show worsening lung involvement, and oxygen saturation or arterial blood gas measurements may show worsening hypoxia or alveolar-arterial oxygen gradient. PCP IRIS sometimes causes severe acute respiratory failure (see chapter *Pneumocystis Pneumonia*).

S: Subjective

Symptoms of IRIS will vary according to the specific illness.

Include the following in the history:

- Specific symptoms and time course of symptoms
- History of OIs, including recently diagnosed OIs
- Treatment of OIs, including date of initiation, medication adherence, duration of therapy, and clinical response
- ART initiation date, specific antiretroviral regimen, medication adherence, and previous history of ART
- CD4 cell count and HIV viral load before ART initiation
- Current CD4 cell count and HIV viral load, if known
- Other medications, especially new medications, including over-the-counter and herbal preparations

O: Objective

Obtain vital signs, including temperature, heart rate, blood pressure, respiratory rate, and oxygen saturation.

Perform a thorough physical examination based on symptoms and suspicion of systems involved.

A: Assessment

In the appropriate clinical setting (especially in patients with advanced AIDS who recently initiated ART), IRIS should be considered in the differential diagnosis of patients who present with new or worsening symptoms. In these patients, the differential is broad, and causes other than IRIS should be considered carefully, including:

- Worsening or progression of a known OI despite treatment (e.g., owing to drug resistance or inadequate therapy)
- A new infection or illness
- Drug toxicity (e.g., hypersensitivity reaction)
- Failure of ART; progression of AIDS

Perform the appropriate diagnostic tests to exclude other etiologies. Consider consulting with an HIV specialist if the diagnosis is in question.

P: Plan**Diagnostic Evaluation**

It is important to rule out new, incompletely treated, or untreated infections; malignancy; and other illnesses before concluding the patient has IRIS.

The workup of the patient with possible IRIS will depend on the specific clinical presentation. Perform laboratory tests, blood cultures, and other diagnostic tests as appropriate for the individual patient. These may include the following:

- Complete blood count (CBC) with differential, electrolytes and creatinine, liver function tests
- CD4 cell count and HIV viral load
- Blood cultures for bacteria, acid-fast bacteria (MAC), fungi
- Chest X-ray; other radiographic studies
- Sputum stain and culture

- Biopsy or culture of skin or other lesions
- Lumbar puncture and cerebrospinal fluid studies, if a CNS process is suspected
- Ophthalmologic examination
- Drug resistance testing for the OI being treated, if indicated

Treatment

Prevention and treatment recommendations from randomized prospective trials are lacking for most IRIS syndromes. However, the majority of cases of IRIS reported in the medical literature are not life-threatening and appear to have resolved within a matter of weeks to months with the following:

- Continuing the current ART regimen (unless the clinical presentation is life-threatening)
- Treating any newly identified, untreated OI
- If indicated, administering antiinflammatory medications to suppress the inflammatory process (prednisone was shown in one study to decrease hospital days and improve symptoms in TB IRIS in sub-Saharan Africa; anecdotal data support the use of nonsteroidal antiinflammatory drugs in mild-to-moderate IRIS)

For patients with recent OIs that resolved with a full course of appropriate therapy, it is not always necessary to resume antimicrobial therapy or to change maintenance therapy. For example, if a patient with TB IRIS has finished a full course of treatment for TB, repeat treatment is not indicated, once recurrent TB infection has been ruled out. If a patient with previously treated cryptococcal meningitis is receiving maintenance therapy and IRIS develops, the therapy does not need to be altered. However, if IRIS reveals a new, untreated OI, that infection should be treated appropriately. For instance, if new cryptococcal meningitis presents as IRIS, the cryptococcus should be treated as indicated. If treatment is in question, consult with an HIV specialist.

Timing of ART initiation

The risk of IRIS is highest for patients who start ART with low CD4 counts (<50-100 cells/ μ L) and those for whom ART is initiated soon after OI treatment is begun. The optimal time for ART initiation in the setting of some OIs is not known, but increasing evidence, including from randomized controlled trials, suggests a mortality benefit to early ART initiation in patients with a variety of newly diagnosed OIs. For patients with TB and HIV infection, for example, data from three randomized studies show reductions in mortality and/or AIDS progression with early initiation of ART, though the urgency of ART varied with CD4 count: for those with CD4 counts of <50 cells/ μ L, benefit was seen if ART was initiated within 2 weeks of TB treatment start (compared with delaying until week 8-12 of TB treatment). For those with CD4 counts of 50-200 cells/ μ L, data support ART initiation between 2 weeks and 2 months after the start of TB treatment. ART should not be deferred until after TB treatment for any patient, regardless of the CD4 cell count. In TB meningitis, however, the optimal ART start time is not clear; in one study, immediate ART increased the risk severe adverse effects and death. In cryptococcal meningitis, data about timing of ART initiation are conflicting; many experts advise delaying ART until 2-10 weeks after the start of cryptococcus treatment.

Decisions about the timing of ART initiation may depend on a number of variables, including the specific pathogen, the severity of the OI, whether the CNS is involved (IRIS in the CNS may be life-threatening), the medication burden, and the potential for drug toxicity or drug interactions. In most cases, ART initiation should be considered within 1-2 weeks after initiation of OI therapy, particularly in patients with TB and CD4 counts of <50 cells/ μ L. For patients with TB meningitis, cryptococcal meningitis, or other CNS or ocular infections, many specialists

would recommend delaying ART until they have received appropriate OI treatment for at least 2 weeks. For decisions about initiating ART in patients with active OIs, consult with an HIV specialist.

IRIS in resource-limited settings

As access to ART improves in resource-limited countries, IRIS increasingly is being recognized in patients receiving ART. Clinicians should include IRIS in the differential diagnosis when evaluating patients who recently have begun ART and present with new or worsening symptoms of an OI. However, limited diagnostic testing resources may make it difficult to establish IRIS and other diagnoses.

Given that coinfection with HIV and TB is epidemic in many countries, and because IRIS is not uncommon in patients with TB, clinicians should be particularly vigilant about symptoms that may signal IRIS. As in resource-sufficient countries, consultation with a clinician trained in caring for patients with HIV is recommended if diagnosis or treatment is in question.

Patient Education

- Patients starting ART who have CD4 counts of <100 cells/ μ L or known concomitant OIs should be counseled about the likelihood of IRIS.
- All patients starting ART should be advised to contact the clinic promptly if they experience new or worsening symptoms.
- Advise patients to take their medications for HIV and for the treatment or prevention of OIs exactly as prescribed.

Anal Dysplasia

Background

Anal cancer is a squamous cell cancer associated with human papillomavirus (HPV), the same virus that is associated with cervical cancer (see chapter *Cervical Dysplasia*). The anal canal and cervical canal share a common embryologic origin: both have a squamocolumnar transition zone and are prone to infection with HPV, a sexually transmitted virus. HPV infection, in combination with cofactors, may stimulate dysplastic changes in the cervix or anus that may develop through precursor stages into squamous cell cancer. In the United States, the incidence of anal cancer in the general population is approximately 1:100,000 per year. In HIV-infected men and women, the incidence of anal cancer and the prevalence of its precursors are significantly higher than in the general population. Advanced immunosuppression, as demonstrated by lower CD4 cell counts, appears to increase the risk of anal intraepithelial neoplasia (AIN), a precursor to cancer, and anal cancer.

Rates of anal cancer also are higher among men who have sex with men (MSM), whether HIV infected or uninfected, compared with the general population. Current rates in an HIV-infected MSM population have been estimated to be as high as 70-144 per 100,000. Although most studies have examined anal dysplasia and cancer in MSM, its prevalence also is high among HIV-infected women and heterosexual men. Some studies of HIV-infected individuals have shown that anal HPV infection is present in 93% of MSM and 76% of women, and that anal dysplasia (any grade) is present in 56% of MSM and 26% of women. In some studies of HIV-infected women, anal dysplasia has been seen more frequently than cervical dysplasia, and it has not been exclusive to those with behavioral risk factors (e.g., history of receptive anal intercourse). HIV-infected heterosexual men with no history of receptive anal intercourse also have elevated risks of anal HPV infection. Thus, although receptive anal intercourse may increase the likelihood of anal HPV infection, it is not a prerequisite for anal HPV or dysplasia.

Screening strategies for anal dysplasia and cancer and the optimal management of abnormal test results are areas in which questions remain unanswered. The rationale for screening for anal cancer and its precursors is based on the success of cervical Papanicolaou (Pap) screening in reducing cervical cancer incidence and mortality. Because of the similarities between cervical and anal dysplasia, many experts postulate that many of the paradigms of managing cervical cytologic abnormalities may be translated to management of anal dysplasia. However, there are no randomized clinical trials that document the value of screening for anal precancers.

Current guidelines from the HIV Medicine Association of the Infectious Diseases Society of America recommend anal pap tests for MSM, women with a history of abnormal cervical Pap tests or a history of anal receptive sex, and all HIV-infected persons with genital warts, though they do not specify screening intervals. The New York State Department of Health AIDS Institute recommends that an anal Pap test be done at baseline and annually thereafter for MSM, patients with a history of anogenital warts, and women with abnormal cervical or vulvar histology, and many HIV clinics elsewhere do routine screening. Further investigations are ongoing to define appropriate screening intervals, diagnostic approaches, indications for therapy, and modalities of treatment.

ART and subsequent immune reconstitution does not appear to alter the prevalence or distribution of anal cancers and anorectal disease nor does it appear to reduce the progression of AIN and other cancer precursors.

For information on prevention of HPV infection, see “Prevention,” below.

S: Subjective

Patients with anal dysplasia usually are asymptomatic, and the condition cannot be identified without screening tests. Exophytic anal condylomata may cause itching, discomfort, or bleeding, but are usually associated with low-risk phenotypes of HPV and low-grade dysplasia (note, however, that oncogenic HPV types also may be present). Anal cancer may cause nonspecific symptoms such as pain (with defecation or after intercourse), itching, bleeding, or sensation of a rectal mass.

Risk factors for anal dysplasia and cancers include the following:

- HIV infection
- CD4 count of <200 cells/μL
- RAI
- HPV infection
- Genital warts (or history of genital warts)
- Immunosuppression
- High-grade cervical or vulvar dysplasia
- Cigarette smoking
- Multiple sex partners

Ask patients about these risk factors, about previous history of anal dysplasia or cancer, and about previous screening.

O: Objective

Examine the genital and perianal region, and perform a digital anorectal examination. Look and feel for masses, condylomata, and other abnormalities such as hypo- or hyperpigmented plaques or lesions, and lesions that bleed. Note that simple visual examination may not reveal abnormalities. In women, also examine the vulva, vagina, and cervix. Examine the inguinal lymph nodes.

If the digital examination is performed in conjunction with an anal Pap test, the Pap specimen should be obtained before the

introduction of lubrication.

Anoscopic examination with the naked eye may not reveal any abnormality because dysplastic tissue tends to be flat and difficult to differentiate from normal anal tissue; application of 3% acetic acid is required (see below for a description of how high-resolution anoscopy [HRA] is performed).

A: Assessment

HIV-infected individuals with anal dysplasia have an increased risk of progression to anal cancer. If the history or physical examination reveals abnormalities suggestive of anal dysplasia or anal cancer, an appropriate evaluation should be undertaken. Because most patients with anal dysplasia have no symptoms, anal cancer screening using a Pap test can be considered if follow-up evaluation of an abnormal cytologic result (ASCUS or higher, see Bethesda 2001 grading system, below) by high-resolution anoscopy is available either on-site or by referral.

P: Plan Screening

As mentioned above, some organizations and many experts recommend that anal Pap tests and digital anal examination be part of the initial evaluation of both male and female HIV-infected patients. The intervals for screening have not been established, but (based on recommendations for cervical cancer screening) if the first test result is normal, the anal Pap usually is repeated in approximately 6 months. If both results are normal, then anal Pap tests can be performed annually. Some clinicians would consider more frequent screening in patients with genital warts, cervical dysplasia, or a history of treatment for anal dysplasia. Any patients with positive results should be referred for further evaluation; see below.

An anal Pap test is done using a standard Pap

kit. The swab or cytobrush should be inserted into the anal canal, past the anorectal junction, and withdrawn while rotating it against the anal walls to collect cells. The sample should then be handled according to the kit manufacturer's instructions. (See "References," below, for information about a video on how to conduct an anal Pap screen that is available from the Johns Hopkins University Local Performance Site of the Pennsylvania/MidAtlantic AIDS Education and Training Center.)

As with cervical cytology, anal cytology is graded using the Bethesda 2001 system, which categorizes disease in increasing order of severity as follows:

- Negative for intraepithelial lesion or malignancy
- Atypical squamous cells of undetermined significance (ASCUS)
- Atypical squamous cells – cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL)
- High-grade squamous intraepithelial lesion (HSIL)
- Squamous cell carcinoma (SCC)

Other abnormalities, such as atypical glandular cells (AGC), may be noted.

All individuals with abnormal anal cytology, defined as ASCUS or higher, should be referred for HRA and biopsy to grade the lesion. HRA typically is performed at specialty anal cancer practices or clinics, colorectal surgery and gastrointestinal specialty facilities, and some academic medical centers.

There currently are no recommendations concerning HPV testing of anal specimens.

Evaluation of Cytologic Abnormalities

HRA of the anal canal should be performed using a colposcope for magnification (16x) and the application of 3% acetic acid with or without Lugol iodine solution to aid in visualization of dysplastic lesions. Abnormal

areas should be examined by biopsy. Anoscopic features of high-grade disease are similar to those seen in the cervix; these include coarse punctation, mosaicism, and the presence of ring glands.

Treatment

The goal of treatment is to prevent progression to anal cancer. Treatment of HSIL to prevent anal cancer is biologically plausible, following the model of cervical dysplasia treatment. However, the indications for treatment of anal dysplasia, the efficacy of treatment, and the most effective treatments have not been optimally defined.

The focus of treatment is on high-grade, premalignant AIN. Patients should be referred to an anal dysplasia specialist specialty clinic, if possible. Specific treatment may vary depending on the size, location, extent of the lesions, and histological grade. Therapies include topical 5-fluorouracil, cryotherapy, infrared coagulation, laser therapy, and surgical excision. Infrared coagulation, an in-office procedure, has been shown to be effective in treating HIV-infected patients with high-grade dysplasia. With some therapies, treatment-associated pain and other complications may occur, and recurrence of dysplastic lesions is common.

LSIL is not considered premalignant, but it frequently progresses to high-grade dysplasia. Some specialists do not treat LSIL but monitor regularly instead with HRA, whereas others choose to treat LSIL to prevent progression.

Prevention

Prevention of HPV infection can be challenging. Latex or plastic barriers may block transmission of HPV in areas covered by these barriers and their use is recommended to prevent transmission or acquisition of HPV (as well as HIV and other sexually transmitted diseases). However, infection may occur through bodily contact outside the area covered by the barriers.

A quadrivalent HPV vaccine against certain oncogenic (types 16 and 18) and wart-causing (types 6 and 11) types of HPV is FDA approved for prevention of anal dysplasia and anal cancer caused by the covered types in males and females 9-26 years of age, and for prevention of genital warts, its use is recommended. (The quadrivalent vaccine also is approved for prevention of cervical cancer and cervical, vaginal, and vulvar dysplasia). A second vaccine against HPV types 16 and 18 has been approved for females (see chapter *Cervical Dysplasia*).

The vaccine is not effective against HPV types other than those covered by the vaccine, and it may not be protective against a covered type to which a patient has been exposed previously. For optimal protection, the vaccine should be given before the individual is exposed to HPV through sexual activity. It is likely to be less effective in older adolescents and adults who may already have been infected with one or more of the covered HPV types. There are few data on the use of the vaccines in persons older than 26 years, and they are not approved for this group. Importantly, vaccination does not offer perfect protection from all oncogenic HPV viruses, so consideration should be given to screening individuals who have been vaccinated in the same way as unvaccinated individuals, as described above.

Patient Education

- All HIV-infected men and women should be encouraged to use condoms during vaginal, anal, and oral sex to prevent the spread of HPV. However, condoms do not offer complete protection from HPV.
- All patients should be counseled on how to reduce or avoid unprotected anal receptive intercourse.
- Both women and men who are HIV infected have an increased risk of developing anal dysplasia and cancer. MSM are at higher risk than other men of developing anal dysplasia.
- Emphasize the importance of keeping follow-up appointments to allow for early detection of precancerous lesions, further grading of abnormalities by HRA, and appropriate monitoring and treatment of abnormalities.
- Patients who have anal dysplasia should be informed about anal cancer symptoms, such as new-onset anal pain, bleeding, or the development of a mass. Patients should call their health care provider if these symptoms develop.
- If an anal Pap test is to be performed, advise patients to avoid having anal sex, douching, or using enemas before the test.

Candidiasis, Oral and Esophageal

Background

Oropharyngeal candidiasis (“thrush”), a fungal disease of the oral mucosa and tongue, is the most common intraoral lesion among persons infected with HIV. In the absence of other known causes of immunosuppression, oral thrush in an adult is highly suggestive of HIV infection. Although thrush in the absence of esophageal disease is not an AIDS-defining condition, it usually occurs with CD4 counts of <200 cells/ μL . Three clinical presentations of thrush are common in people with HIV: pseudomembranous, erythematous, and angular cheilitis. *Candida* also may infect the esophagus in the form of esophageal candidiasis, which causes dysphagia (difficulty with swallowing) or odynophagia (pain with swallowing). Esophageal candidiasis is an AIDS-defining condition, generally occurring in individuals with CD4 counts of <200 cells/ μL . It is the most common cause of esophageal infection in persons with AIDS.

Oropharyngeal and esophageal candidiasis are caused most commonly by *Candida albicans*, although non-*albicans* species increasingly may cause disease and may be resistant to first-line therapies.

S: Subjective

Oropharyngeal Candidiasis

The patient may complain of painless white patches on the tongue and oral mucosa, smooth red areas on the dorsal tongue, burning or painful areas in the mouth, a bad or unusual taste, sensitivity to spicy foods, or decreased appetite.

Esophageal Candidiasis

The patient complains of difficulty or pain with swallowing, or the sensation that food is “sticking” in the retrosternal chest. Weight loss is common, and nausea and vomiting may occur. Fever is not common with candidal esophagitis and suggests another cause. The patient may note symptoms of oral candidiasis (as above).

O: Objective

Perform a thorough oropharyngeal examination. Patients presenting with oral candidiasis may be totally asymptomatic, so it is important to inspect the oral cavity thoroughly. Patients with esophageal

candidiasis usually have oral thrush and often experience weight loss.

Lesions can occur anywhere on the hard and soft palates, under the tongue, on the buccal mucosa or gums, or in the posterior pharynx.

Pseudomembranous oral candidiasis appears as creamy white, curdlike plaques on the buccal mucosa, tongue, and other mucosal surfaces. Typically, the plaques can be wiped away, leaving a red or bleeding underlying surface. Lesions may be as small as 1-2 mm, or they may form extensive plaques that cover the entire hard palate.

Erythematous oral candidiasis presents as one or more flat, red, subtle lesions on the dorsal surface of the tongue or the hard or soft palate. The dorsum of the tongue may show loss of filiform papillae.

Angular cheilitis causes fissuring and redness at one or both corners of the mouth and may appear alone or in conjunction with another form of oral *Candida* infection.

A: Assessment

A partial differential diagnosis for the two conditions is as follows:

Oropharyngeal Candidiasis

- Oral hairy leukoplakia
- Abrasion of the mucosa or a topical burn
- Bacterial gingivitis
- Periodontitis

Esophageal Candidiasis

- GERD
- Cytomegalovirus (CMV)
- Herpes simplex virus (HSV)
- Aphthous ulceration

P: Plan**Diagnostic Evaluation****Oropharyngeal candidiasis**

Clinical examination alone usually is diagnostic. If the diagnosis is unclear, organisms may be detected on smear or culture if necessary.

- On a potassium hydroxide (KOH) preparation of a smear collected by gentle scraping of the affected area with a wooden tongue depressor, visible hyphae or blastospheres on KOH mount indicate *Candida* infection.
- Culture is diagnostic and may detect non-*albicans* species in cases resistant to first-line therapies. Sensitivities also may be needed in such cases to diagnose azole-resistant infections.

Esophageal candidiasis

A presumptive diagnosis usually can be made with a recent onset of typical symptoms, especially in the presence of thrush, and empiric antifungal therapy may be started as a diagnostic trial. If the patient fails to improve clinically after 3-7 days of therapy, endoscopy should be performed for a definitive diagnosis.

Treatment**Treatment of oropharyngeal candidiasis**

- Oral therapy is convenient and very effective as first-line treatment. Note that azole antifungal drugs are not recommended for use during pregnancy. Topical therapy is less expensive, safe for use during pregnancy, and effective for mild to moderate disease. All therapies should be given for 7-14 days.
- Preferred oral therapy: Fluconazole 100 mg PO QD
- Preferred topical therapy:
 - Clotrimazole troches 10 mg dissolved in the mouth 5 times daily
 - Miconazole mucoadhesive tablet 50 mg PO QD
- Alternative oral therapy:
 - Itraconazole oral solution 200 mg PO QD
 - Posaconazole oral solution 400 mg PO BID for 1 day, then 400 mg PO QD (Note: These agents may present a greater risk of drug interactions (see “Potential ARV Interactions,” below) and hepatotoxicity than do fluconazole or topical treatments)
- Alternative topical therapy: Nystatin oral suspension 4-6 mL “swish and swallow” QID or 1-2 pastilles 4-5 times daily

Treatment of esophageal candidiasis

- Duration of therapy: 14-21 days
- Preferred therapy:
 - Fluconazole 100 mg PO (up to 400 mg) QD; IV therapy can be given if the patient is unable to swallow pills.
 - Itraconazole oral solution 200 mg PO QD
- Alternative therapy:
 - Voriconazole 200 mg PO or IV BID
 - Posaconazole 400 mg PO BID
 - IV therapy with an echinocandin

(caspofungin, micafungin, anidulafungin), or amphotericin, if the patient is unable to tolerate PO therapy (Note: Treatment with echinocandins is associated with a higher rate of relapse; see “Potential ARV Interactions,” below, regarding potential drug-drug interactions between voriconazole or posaconazole and ARVs)

Treatment of refractory candidiasis

Oral or esophageal candidiasis that does not improve after at least 7-14 days of appropriate antifungal therapy can be considered refractory to treatment. The primary risk factors for development of refractory candidiasis are CD4 counts of <50 cells/ μ L and prolonged, chronic antifungal therapy (especially with azoles). In such cases, it is important to confirm the diagnosis of candidiasis. As noted, other infections such as HSV, CMV, and aphthous ulcerations can cause similar symptoms. Once refractory candidiasis is confirmed, several treatment options are available, including the following:

- Posaconazole 400 mg PO BID
- Itraconazole oral solution ≥ 200 mg PO QD
- Voriconazole 200 mg PO or IV BID (see “Potential ARV Interactions,” below)
- Therapy with an echinocandin (caspofungin 50 mg QD; micafungin 150 mg QD; anidulafungin 100 mg for 1 dose, then 50 mg QD), or amphotericin B deoxycholate or lipid preparation
(Note: Treatment with echinocandins is associated with a higher rate of relapse. See “Potential ARV Interactions,” below, for information on potential drug interactions.)

The choice of treatment depends upon anticipated drug-drug interactions, the patient’s preferences and tolerability, availability of medications, and the provider’s experience. Consult with an HIV or infectious disease expert for advice about treatment regimens.

Maintenance therapy

Use caution when considering chronic maintenance therapy, because it has been associated with refractory and azole-resistant candidiasis, as noted above. Fluconazole 100 mg PO QD or TIW can be effective for patients who have had multiple or severe recurrences of oral disease (azole sensitive). Fluconazole 100-200 mg PO QD or posaconazole 400 mg PO BID (see “Potential ARV Interactions,” below) can be considered for patients who have had frequent or severe recurrent esophageal candidiasis.

There are no data to guide this decision; it is reasonable to discontinue maintenance therapy in patients who achieve immunologic responses on fully suppressive ART (i.e., with an increase in CD4 count to ≥ 200 cells/ μ L). Patients with fluconazole-refractory oropharyngeal or esophageal disease who respond to IV echinocandins are recommended to take posaconazole or voriconazole suppression until they achieve immune reconstitution on ART, because of high relapse rates.

Potential ARV Interactions

There may be significant drug-drug interactions between certain systemic antifungals (particularly itraconazole, voriconazole, and posaconazole) and ritonavir-boosted protease inhibitors (PIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), elvitegravir/cobicistat, or maraviroc. Some combinations are contraindicated and others require dosage adjustment of the ARV, the antifungal, or both. Check for adverse drug interactions before prescribing. For example, voriconazole use is not recommended for patients taking ritonavir-boosted PIs, and dosage adjustment of both voriconazole and NNRTIs may be required when voriconazole is used concurrently with NNRTIs. See relevant tables in the U.S. Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, or consult with an expert.

Patient Education

- Patients should maintain good oral hygiene by brushing teeth after each meal.
- A soft toothbrush should be used to avoid mouth trauma.
- Advise patients to rinse the mouth of all food before using lozenges or liquid medications.
- Tell patients to avoid foods or liquids that are very hot in temperature or very spicy.
- Patients who have candidiasis under a denture or partial denture should remove the prosthesis before using topical agents such as clotrimazole or nystatin. When not in use, the prosthesis should be stored in a chlorhexidine solution.
- Pregnant women and women who may become pregnant should avoid azole drugs (e.g., fluconazole, itraconazole, voriconazole) during pregnancy because they can cause skeletal and craniofacial abnormalities in infants.
- Patients should be informed of proper storage of oral solutions (e.g., refrigeration requirements).

Candidiasis, Vulvovaginal

Background

Vulvovaginal candidiasis is a yeast infection caused by several types of *Candida*, typically *Candida albicans*. This disease is common in all women, but may occur more frequently and more severely in immunocompromised women.

Although refractory vaginal *Candida* infections by themselves should not be considered indicators of HIV infection, they may be the first clinical manifestation of HIV infection and can occur early in the course of disease (at CD4 counts of >500 cells/ μ L). The frequency of vaginal candidiasis tends to increase as CD4 counts decrease; however, this may be attributable in part to increased use of antibiotics among women with advanced HIV infection.

Risk factors for candidiasis include diabetes mellitus and the use of oral contraceptives, corticosteroids, or antibiotics.

S: Subjective

The patient may complain of itching, burning, or swelling of the labia and vulva; a thick white or yellowish vaginal discharge; painful intercourse; and pain and burning on urination.

The most important elements in the history include the following:

- Type and duration of symptoms
- Previous vaginal yeast infection
- Oral contraceptive use
- Recent or ongoing broad-spectrum antibiotic therapy
- Recent corticosteroid therapy
- Sexual exposures (to evaluate for sexually transmitted diseases)
- Diabetes history
- Cushing syndrome
- Obesity
- Hypothyroidism
- Pregnancy
- Use of douches, vaginal deodorants, or bath additives

O: Objective

Perform a focused physical examination of the external genitalia, vagina, and cervix. This may reveal inflammation of the vulva with evidence of discharge on the labial folds and vaginal opening. Speculum examination usually reveals a thick, white discharge with plaques adhering to the vaginal walls and cervix. Bimanual examination should not elicit pain or tenderness and otherwise should be normal.

A: Assessment

Rule out other causes of vaginal discharge and pruritus:

- Bacterial vaginosis
- Atrophic vaginitis
- Chemical or mechanical causes
- Trichomoniasis
- Gonorrhea, chlamydia, and other sexually transmitted diseases
- Scabies
- Pediculosis

P: Plan**Diagnostic Evaluation**

A presumptive diagnosis is made on the basis of the clinical presentation and potassium hydroxide (KOH) preparation:

- Perform microscopic examination of a KOH preparation of vaginal secretions. This usually reveals pseudohyphae and *Candida* spores (presumptive diagnosis).
- Definitive diagnosis rarely is needed, but may be made by analysis of a culture of vaginal secretions; this may be useful if azole-resistant or non-*albicans* species are suspected.
- In the presence of urinary tract symptoms (beyond external vulvar burning), perform urinalysis, culture, or both on a clean-catch urine specimen.
- Consider testing for gonorrhea and chlamydia in patients with a history of possible sexual exposure.

Treatment**Uncomplicated infections****Topical medications**

- Prescribe topical vaginal antifungal agents in the form of cream or suppositories, including the following: butoconazole, clotrimazole, miconazole, nystatin, terconazole, and tioconazole. Treat for 3-7 days and offer refills depending on the time to the next scheduled clinic visit. The creams also may be used on the vulva for treatment of pruritus.

Note that the mineral-oil base in topical vaginal antifungal preparations may erode the latex in condoms, diaphragms, and dental dams. Advise the patient to use alternative methods to prevent HIV transmission or conception, or to discontinue intercourse while using these medications. Nonlatex condoms (plastic and polyethylene only) or “female” condoms (polyurethane) can be used.

Oral medications**Preferred**

- Fluconazole 150 mg PO, single dose (see “Treatment notes,” below)

Alternative

- Itraconazole oral solution 200 mg PO QD for 3-7 days (see “Treatment notes,” below)

Complicated infections**Severe or recurrent candidiasis**

Severe or recurrent candidiasis is defined as four or more episodes within 1 year. Consider the following treatments:

- Fluconazole 100-200 mg PO QD for ≥ 7 days (see Treatment notes,” below)
- Topical therapy as described above, for ≥ 7 days

For severe cases that recur repeatedly, secondary prophylaxis can be considered (e.g., fluconazole 150 mg PO once weekly).

Treatment notes

- Systemic azole drugs should not be used during pregnancy, and women taking azoles should use effective contraception. Topical azoles are recommended for the treatment of pregnant women.
- Resistance to azole medications may develop, especially with prolonged use of oral agents.
- Avoid ketoconazole: Case reports have associated ketoconazole with a risk of fulminant hepatitis (1 in 12,000 courses of treatment with oral ketoconazole). Experts agree that the risks may outweigh the benefits for women with vulvovaginal candidiasis. Ketoconazole interacts with many other drugs, including some antiretroviral drugs.

Potential ARV Interactions

There may be significant drug-drug interactions between certain systemic antifungals (particularly itraconazole, voriconazole, and posaconazole) and ritonavir-boosted protease inhibitors (PIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), elvitegravir/cobicistat, or maraviroc. Some combinations are contraindicated and others require dosage adjustment of the ARV, the antifungal, or both. Check for adverse drug interactions before prescribing. For example, voriconazole use is not recommended for patients taking ritonavir-boosted PIs, and dosage adjustment of both voriconazole and NNRTIs may be required when voriconazole is used concurrently with NNRTIs. See relevant tables in the U.S. Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, or consult with an expert.

Patient Education

- Advise patients to wash external genitals daily with a fresh washcloth or water-soaked cotton balls and to wipe the vulva and perirectal area from front to back after toileting. Women should not use baby wipes on inflamed vulval tissue because they may increase irritation.
- Women should avoid the use of perfumed soaps, bubble baths, feminine hygiene or vaginal deodorant products, and bath powders.
- Advise women not to douche.
- Women should wear cotton underwear and avoid tight, constrictive clothing, particularly pantyhose.
- If patients are prescribed medication for vaginal candidiasis, they should take the medication exactly as prescribed and finish the medicine even during a menstrual period.
- Women who continue to have symptoms can purchase miconazole (e.g., Monistat) or clotrimazole (e.g., Gyne-Lotrimin) vaginal cream over the counter. Advise patients to start using these as soon as symptoms return and to contact the clinic if symptoms worsen while they are taking these medicines.
- Women taking oral fluconazole, ketoconazole, or other azoles must avoid pregnancy. Some birth defects have been reported.
- The mineral-oil base in topical vaginal antifungal preparations may erode the latex in condoms, diaphragms, and dental dams. Advise patients to use alternative methods to prevent HIV transmission or conception or to discontinue intercourse while using these medications. Nonlatex condoms (plastic and polyethylene only) or “female” condoms (polyurethane) can be used.
- Sex toys, douche nozzles, diaphragms, cervical caps, and other items can reinfect patients if not properly cleaned and thoroughly dried after use.
- Some studies have suggested that eating yogurt with live cultures (check labels) can reduce the occurrence of vaginal yeast infections.

Cervical Dysplasia

Background

Precancerous lesions and cancer of the cervix are associated with human papillomavirus (HPV), a sexually transmitted virus. Carcinogenic strains of HPV, in conjunction with other factors, may cause dysplasia and cancer not only of the cervix, but also of the vulva, vagina, anus, and oropharynx. HIV-infected women have a higher prevalence of HPV infection than do HIV-uninfected women, and a higher prevalence of oncogenic HPV types. They are about 10 times more likely to develop cervical dysplasia, or intraepithelial neoplasia (CIN), precursors to cervical cancer. Unfortunately, they also have a higher risk of invasive cervical cancer and tend to have more aggressive forms of cervical cancer and poorer responses to treatment. Invasive cervical cancer is an AIDS-defining illness.

The risk of high-grade cervical lesions and cervical cancer appears to be higher for women with advanced immunodeficiency than for women with preserved CD4 cell counts. Other risk factors for dysplasia and cervical cancer include African-American ethnicity, a history of smoking, younger age at onset of sexual intercourse, and multiple sex partners. Effective antiretroviral therapy (ART) with immune reconstitution has not been shown to prevent the progression of CIN.

Screening for cervical cancer and appropriate intervention in women with high-grade CIN (CIN 3) are effective in preventing cervical cancer. Frequent monitoring and careful follow-up in women with low-grade lesions are essential for preventing progression to invasive disease. For all HIV-infected women (if they have had sex partners), including adolescents and young women, Papanicolaou (Pap) testing should be performed routinely. An initial test should be done at the time of HIV diagnosis, repeated 6 months after the first test, then performed annually thereafter if the results are normal. (See chapter *Initial and Interim Laboratory and Other Tests*.)

Because the risk of anal dysplasia also is increased among HIV-infected women (in some studies, rates of anal dysplasia were higher than rates of cervical dysplasia), many experts and some guidelines recommend concurrent screening for anal dysplasia. For further information, see chapter *Anal Dysplasia*.

For information on prevention of HPV infection, see “Prevention,” below.

HRSA HAB Performance Measures

Percentage of female patients with a diagnosis of HIV who have a **Pap screening** in the measurement year

(Adult and Adolescent measure)

S: Subjective

Patients with CIN or early cervical cancer usually are asymptomatic, and disease will not be diagnosed unless screening is performed. Genital condylomata (warts) indicate infection with HPV and typically are associated with low-risk types of HPV; however, a mixture of HPV types may be present, and women with genital warts may have concurrent dysplasia.

The classic symptom of early invasive cervical neoplasia is intermittent, painless bleeding between menstrual periods, which may present initially as postcoital spotting. Late symptoms of invasive cervical carcinoma include flank and leg pain, dysuria, hematuria, rectal bleeding, and obstipation.

Ask all female patients about risk factors for, previous history of, and preventive measures against cervical dysplasia and cancer, including the following:

- Genital warts; previous or current HPV infection
- Previous abnormal cervical Pap test result
- Previous abnormal anal Pap test result
- Previous cervical cancer; when and how treated
- Sexual activity before age 20
- History of multiple sex partners
- Cigarette smoking
- CD4 count of <200 cells/ μ L
- Pregnancy
- Oral contraceptive use
- History of HPV vaccination

O: Objective

Perform a focused examination of the abdomen and pelvis. Examine the external genital and perianal region. Perform speculum and bimanual examinations to evaluate the vagina and cervix. Look for lesions, masses, warts, and cervical inflammation or discharge, as well as exophytic or ulcerative cervical lesions with or without bleeding. Note that simple visual examination may not reveal abnormalities.

A: Assessment

HIV-infected women have an increased risk of cervical dysplasia with progression to cervical cancer. If abnormalities of cervical disease are suspected, an appropriate evaluation should be performed. Because most women with CIN have no symptoms, routine screening should be performed for all women.

P: Plan

Screening

Perform Pap screening for all HIV-infected women. The initial test should be conducted at the time of HIV diagnosis, a second (if the first is normal) should be performed 6 months later. Screening should be repeated annually thereafter throughout life if all results are normal. (For HIV-uninfected adolescents and young women, recent guidelines recommend beginning cervical screening at age 21; for HIV-infected young women, guidelines suggest screening beginning within 1 year of first sexual activity, given the risk of progression of cervical abnormalities.) If a Pap result is abnormal, see below. Also consider screening for anal dysplasia with an anal Pap test (see chapter *Anal Dysplasia*).

Cervical (and anal) cytology usually is graded using the Bethesda 2001 system (see “References,” below), which categorizes disease in increasing order of severity as follows:

- Negative for intraepithelial lesion or malignancy
- Atypical squamous cells of undetermined significance (ASCUS)
- Atypical squamous cells, cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL)
- High-grade squamous intraepithelial lesion (HSIL)
- Squamous cell carcinoma (SCC)

Other abnormalities may be noted, including the following:

- Atypical glandular cells (AGCs), including the following subcategories:
 - AGC not otherwise specified (AGC NOS) (includes endocervical, endometrial, or glandular cells)
 - AGC, favor neoplasia (includes endometrial or glandular cells)
 - AIS (endocervical adenocarcinoma in situ)
- Infectious organisms such as *Trichomonas*

Evaluation of Cytologic Abnormalities

Atypical squamous cells of undetermined significance

If ASCUS is present without inflammation or suspected neoplastic process, several options for management exist.

- Most experts recommend that all women with ASCUS be referred for colposcopy and directed biopsy, regardless of their degree of immunodeficiency. If the biopsy result shows no dysplasia (and the examination is adequate), the patient should be monitored by annual Pap tests.
- As an alternative, patients who are considered reliable for follow-up may repeat the Pap test in 6-12 months. If repeat Pap is reported at greater than ASCUS, the woman should be referred for colposcopy.
- There are limited and conflicting data to support the use of HPV DNA testing as part of the management of HIV-infected women with ASCUS. Current OI guidelines (see “References,” below) emphasize that HPV testing alone is not recommended.

Atypical squamous cells, cannot exclude HSIL

Women with abnormalities suggestive of high-grade dysplasia should be referred for colposcopy.

Low-grade squamous intraepithelial lesion

Women with LSIL should be referred for colposcopy and directed biopsy.

High-grade squamous intraepithelial lesion or squamous cell carcinoma

Women with HSIL are at high risk of high-grade intraepithelial neoplasia or cervical cancer and should undergo colposcopy with endocervical assessment and directed biopsy as soon as possible. Refer to an oncology specialist for treatment.

Atypical glandular cells

Because of the high rate of significant lesions in patients with AGS, colposcopy with endocervical sampling is recommended for all subcategories, including AIS. In women over age 35, endometrial sampling is recommended in addition to colposcopy and endocervical sampling. Refer to an appropriate specialist for evaluation.

Treatment

The optimal management of precancerous cervical lesions has not been identified clearly for all classes of CIN. Consult with an HIV-experienced gynecologist, oncologist, or other dysplasia specialist. High-grade lesions in women with satisfactory colposcopy are typically treated with ablation (e.g., cryotherapy, electrocautery, laser vaporization) or excision (e.g., loop electrosurgical excision [LEEP], laser or cold-knife conization). For women with unsatisfactory colposcopy, excisional methods are recommended.

Prevention

Latex or plastic barriers may block transmission of HPV in areas covered by these barriers and have been shown to reduce the risk of infection with oncogenic HPV.

Although infection may occur through bodily contact outside the area covered by the barriers, the use of condoms is recommended to prevent transmission or acquisition of HPV (as well as HIV and other STDs).

Two vaccines have been approved by the U.S. Food and Drug Administration for the prevention of certain HPV strains; these are recommended for HIV-infected women and girls 9-26 years of age. They have been shown to reduce rates of cervical dysplasia; the quadrivalent vaccine also has been shown to protect against vulvar, vaginal, and anal dysplasia (as well as anogenital warts) related to the covered HPV types.

- **Quadrivalent** (Gardasil): includes HPV types 16 and 18 (which cause nearly 70% of cervical cancer, as well as vaginal, vulvar, and anal cancer), and types 6 and 11 (which cause most anogenital warts)
- **Bivalent** (Cervarix): includes HPV types 16 and 18

The quadrivalent vaccine also is recommended for use with males aged 9-26 for prevention of genital warts and anal intraepithelial neoplasia.

These vaccines are not effective against HPV types other than those covered by the vaccine, and they may not be protective against a covered type to which a patient has been exposed previously. For optimal protection, these vaccines should be given before the individual is exposed to HPV through sexual activity. They are likely to be less effective in older adolescents and adults who already may have been infected with one or more of the covered HPV types. There are few data on the use of the vaccines in persons older than 26, and they are not approved for this group. Importantly, women who have been vaccinated should continue to be screened for cervical cancer as described above; vaccination does not protect women perfectly from all oncogenic HPV viruses.

Patient Education

- Recommend the use of latex or polyurethane male or female condoms for vaginal or anal intercourse and plastic or latex barriers for oral sex to reduce the risk of transmitting HPV (the usual cause of cervical cancer) to partners. Barriers also reduce the risk of exposure to other sexually transmitted pathogens.
- Patients who smoke should be advised to quit. Cigarette smoking appears to heighten the risk of cervical cancer and makes HPV more difficult to treat. Discuss options for smoking cessation (see chapter *Smoking Cessation*), and refer patients to the American Lung Association if local programs are available.
- Emphasize the importance of keeping follow-up appointments for Pap screening or colposcopy to allow early detection of precancerous lesions and appropriate monitoring of abnormalities.

- For women with dysplasia who require treatment, emphasize that early treatment is essential for managing the disease and preventing the development of cancer. Advise patients to keep all medical appointments.

Cryptococcal Disease

Background

Cryptococcosis usually presents as a systemic or central nervous system (CNS) fungal infection caused by the yeast *Cryptococcus neoformans*. The organism is ubiquitous, and is particularly plentiful in soils enriched with bird droppings. It also may be present in fruit skins or juices, and in unpasteurized milk. In immunocompetent patients, cryptococcal infection usually is asymptomatic, self-limited, and confined to the lungs. In persons with advanced HIV infection (e.g., those with CD4 counts of <100 cells/ μL), *Cryptococcus* may cause life-threatening illness, either from a new exposure or through reactivation of a previously acquired latent infection.

In HIV-infected patients, *Cryptococcus* can infect almost all organs in the body, but most commonly causes meningitis or meningoencephalitis. Disseminated disease, pneumonia, and skin lesions also may be seen.

S: Subjective

Symptoms depend upon the locus of infection. In the case of meningitis, the patient typically experiences subacute onset of fever, headaches, and malaise, which worsen over the course of several weeks. These symptoms may be accompanied by nausea with or without vomiting. Classic meningeal signs, nuchal rigidity, and photophobia are present in only about 25% of cases. Cryptococcal meningitis may cause confusion, personality or behavior changes, blindness, deafness, and, if left untreated, coma and death. If the disease involves the lungs, patients may experience cough or shortness of breath, pleuritic chest pain, and fever. Skin lesions may be present.

O: Objective

Perform a thorough physical examination with particular attention to the following:

- Vital signs, hydration status
- Funduscopic findings
- Neck (for nuchal rigidity, which is uncommon)

- Lungs, especially if respiratory symptoms are present
- Neurologic evaluation, including cranial nerves, visual acuity, and mental status
- Skin

Cryptococcal Meningitis

Physical examination may reveal papilledema with loss of visual acuity and cranial nerve deficits (particularly in cranial nerves III and VI).

Cryptococcal Pulmonary Disease

Examination may reveal tachypnea or fine rales.

Cutaneous Infection

Skin lesions are variable and may appear as papules, nodules, or ulcers; they often resemble molluscum lesions.

A: Assessment

The differential diagnosis for cryptococcal meningitis or meningoencephalitis is broad and includes other infectious causes of meningitis (fungal, mycobacterial, bacterial, viral), syphilis, lymphoma, mass lesions, intoxication, HIV encephalopathy, and trauma. (See chapter *Neurologic Symptoms*.)

The differential diagnosis for cryptococcal pneumonia is broad and includes other infectious causes of pneumonia (fungal, mycobacterial, bacterial, viral), malignancy, and congestive heart failure. (See chapter *Pulmonary Symptoms*.)

P: Plan

Diagnostic Evaluation

The workup should include serum cryptococcal antigen (CrAg), which usually is very sensitive, and blood cultures, including bacterial, acid-fast bacilli (AFB), and fungal cultures. Patients with symptoms of disseminated or pulmonary infection should be evaluated by chest X-ray (which may show diffuse or focal infiltrates, sometimes appearing as nodular or miliary; intrathoracic adenopathy; or pleural effusions), sputum culture (including fungal and AFB cultures), and AFB stain. Bronchoscopy and bronchoalveolar lavage may be necessary for diagnosis. For cutaneous lesions, consider biopsy and histopathologic evaluation or culture. As part of the general fever workup, urinalysis and urine cultures should be checked.

Patients with a positive serum CrAg, another positive test for *Cryptococcus*, or signs or symptoms of meningitis should undergo analysis of the cerebrospinal fluid (CSF). If neurologic symptoms or signs are present, obtain a computed tomography (CT) scan of the brain before performing a lumbar puncture (LP) to rule out a mass lesion or increased intracranial pressure (ICP), which could cause herniation upon LP. Always measure the CSF opening pressure; a high ICP contributes to morbidity and mortality and determines the need for serial LP to manage the increased ICP. Send the CSF for the following:

- CrAg (usually positive at high titer in meningitis)
- Fungal culture
- India ink stain (less sensitive than CSF CrAg; perform if CSF CrAg is not available)

- Cell count
- Glucose
- Protein

For exclusion of other etiologies, perform CSF Venereal Disease Research Laboratory (VDRL) test, bacterial culture, AFB smear and culture, or polymerase chain reaction (PCR), if tuberculosis is suspected, and other tests as indicated by the patient's symptoms and exposures.

Treatment

Cryptococcal meningitis

Acute treatment of cryptococcal meningitis consists of two phases: induction and consolidation. Acute treatment is followed by chronic maintenance (suppressive) therapy.

Induction

Patients with cryptococcal meningitis should be hospitalized to start at least 2 weeks of induction therapy.

Preferred therapy:

- Liposomal amphotericin B 3-4 mg/kg IV QD + flucytosine 25 mg/kg PO QID

Lipid formulations of amphotericin B are less nephrotoxic than amphotericin B deoxycholate and appear to be equally effective.

Amphotericin-based therapy, in combination with flucytosine, is recommended. If these are not available, are contraindicated, or are not tolerated by the patient, the other indicated induction therapies may be considered.

Alternative therapy:

- Amphotericin B lipid complex 5 mg/kg IV QD + flucytosine 25 mg/kg PO QID
- Amphotericin B deoxycholate 0.7-1.0 mg/kg IV QD + flucytosine 25 mg/kg PO QID
- Liposomal amphotericin B 3-4 mg/kg IV QD + fluconazole 800 mg PO or IV QD
- Amphotericin B deoxycholate 0.7-1.0 mg/kg IV QD + fluconazole 800 mg PO or IV QD
- Liposomal amphotericin B 3-4 mg/kg IV QD alone
- Fluconazole 400-800 mg PO or IV QD + flucytosine 25 mg/kg PO QID
- Fluconazole 1,200 mg PO or IV QD alone

The primary alternative to amphotericin-based therapy is high-dose fluconazole (800-1,200 mg PO QD), with or without flucytosine. Among the newer antifungal agents, echinocandins have no activity against *Cryptococcus*. Voriconazole and posaconazole have good in vitro activity and may be considered for treatment of relapsed disease but not as first-line agents. The efficacy of alternative regimens is not well defined. See “Potential ARV Interactions,” below, regarding drug-drug interactions between these antifungals and ARVs.

Amphotericin B causes many adverse effects, including fever, rigors, hypotension, nausea, nephrotoxicity and electrolyte disturbances, anemia, and leukopenia. The patient’s hemoglobin, white blood cell (WBC) count, platelets, electrolytes, magnesium, and creatinine must be monitored closely during treatment. Liposomal forms of amphotericin cause fewer adverse effects. These should be used particularly for patients who have difficulty tolerating standard amphotericin B and for those who are at high risk of renal failure. Electrolytes and creatinine should be monitored. Flucytosine is associated with bone marrow and liver toxicity, and complete blood counts and liver function tests

should be monitored during induction therapy. If available, flucytosine levels can be evaluated 3-5 days after the start of therapy, with a target 2-hour post-dose level of 30-80 mg/mL; a level of >100 mg/mL should be avoided. Note that the dosage of flucytosine must be adjusted for patients with renal insufficiency.

Resistance testing may be considered for patients who have relapsed and for those for whom fluconazole failed to sterilize the CSF.

Consolidation

After clinical improvement with 2 weeks of induction therapy, and a negative CSF culture on repeat LP, treatment can be switched to fluconazole (400 mg PO QD for at least 8 weeks). Itraconazole (200 mg PO BID) is an alternative for patients who cannot take fluconazole. It should be noted that itraconazole is less effective than fluconazole and has significant drug interactions with commonly used medications.

Maintenance

After completing acute treatment, the patient should receive chronic maintenance therapy with fluconazole (200 mg PO QD) to prevent recurrence of cryptococcosis.

Maintenance therapy should be continued for life, unless the patient has completed induction and consolidation therapy followed by at least 1 year of maintenance therapy, and has sustained CD4 cell recovery in response to effective antiretroviral therapy (ART) (CD4 count ≥ 100 cells/ μ L for at least 3 months during ART). Maintenance therapy should be restarted if the CD4 count declines to <100 cells/ μ L.

Management of elevated ICP

Elevated ICP significantly increases the morbidity and mortality of cryptococcal meningitis and should be treated by the removal of CSF. The CSF opening pressure should be checked on the initial LP. If the initial opening pressure is >250 mm H₂O,

remove up to 30 mL of CSF to lower the ICP by 50%, if possible. LP and CSF removal should be repeated daily as needed for ICP reduction. A lumbar drain or ventriculoperitoneal shunt may be needed if the initial opening pressure is >400 mm H₂O, or in refractory cases. There is no role for acetazolamide, mannitol, or steroids in the treatment of elevated ICP.

A repeat LP is not required for patients who did not have elevated ICP at baseline and are responding to treatment. If new symptoms develop, a repeat LP is indicated. Serum CrAg titers are not useful in monitoring response to treatment.

Cryptococcal pulmonary disease, with negative CSF CrAg and culture results

After CSF cryptococcal disease has been excluded, treat with fluconazole if symptoms are mild or moderate and chest imaging shows focal infiltrates: 400 mg PO QD for 12 months, then 200 mg QD for maintenance. Otherwise, consider amphotericin induction, as described above with CNS disease. Maintenance therapy should be continued for life, unless the patient has sustained CD4 cell recovery in response to effective ART (CD4 count of ≥ 100 cells/ μ L for at least 6 months during ART) and with a minimum of 12 months of antifungal therapy. Therapy should be restarted if the CD4 count declines to <100 cells/ μ L.

Cutaneous infection, with negative CSF CrAg and culture results

Treat with fluconazole 400 mg PO QD for 6-12 months, then continue with 200 mg QD for chronic maintenance therapy, as discussed above.

Asymptomatic antigenemia

Data are limited for management of asymptomatic antigenemia, which can be associated with development of subsequent disease. Fungal cultures of CSF and blood should be obtained; if either result is positive for cryptococcal growth, treatment should be initiated for symptomatic meningoencephalitis or disseminated disease. If no

meningoencephalitis is found, fluconazole 400 mg PO QD should be given until immune reconstitution occurs; treatment may be discontinued per maintenance guidelines described above.

Cryptococcus IRIS

Immune reconstitution through ART is effective for preventing recurrence of cryptococcal infections. However, initiating ART within the first 1-2 months after starting treatment for cryptococcal infection may result in worsening or recurrence of symptoms because of immune reconstitution inflammatory syndrome (IRIS). IRIS can be life-threatening in cryptococcal meningeal disease. IRIS and relapse of cryptococcal disease (e.g., treatment failure) must be differentiated; in IRIS, the serum and CSF cultures are negative. (See chapter *Immune Reconstitution Inflammatory Syndrome*.)

Optimal timing of ART initiation in cryptococcal CNS disease is not known. Some experts recommend treating severe cryptococcosis with effective antifungal therapy for 2-10 weeks before starting ART, to decrease the risk of IRIS. On the other hand, if the CD4 count is very low (e.g., <50 copies/ μ L), it is important to initiate ART as soon as possible.

Other treatment notes

Pregnancy

Fluconazole and other azole drugs should be avoided during the first trimester of pregnancy, and voriconazole and posaconazole should be avoided throughout pregnancy. During the first and second trimesters, pregnant women should be treated with amphotericin for both induction and consolidation therapy. Flucytosine is teratogenic at high doses in rats and is classified as a pregnancy class C drug; it should be used during pregnancy only if the benefits clearly outweigh the risks.

Preventive therapy

Studies have suggested that routine primary prophylaxis for cryptococcal disease in patients with CD4 counts of <100 cells/ μ L is effective at preventing cryptococcal infection but is not cost efficient. Therefore, it is not routinely recommended.

Potential ARV Interactions

There may be significant drug-drug interactions between certain systemic antifungals, (particularly itraconazole, voriconazole, and posaconazole) and ritonavir-boosted protease inhibitors (PIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), elvitegravir/cobicistat, or maraviroc. Some combinations are contraindicated and others require dosage adjustment of the ARV, the antifungal, or both. Check for adverse drug interactions before prescribing. For example, voriconazole use is not recommended for patients taking ritonavir-boosted PIs, and dosage adjustment of both voriconazole and NNRTIs may be required when voriconazole is used concurrently with NNRTIs. See relevant tables in the U.S. Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, or consult with an expert.

Patient Education

- Cryptococcosis is not curable in persons with low CD4 cell counts and may require lifelong treatment. Patients should be instructed to take their treatment without interruptions.
- Even with therapy, disease may recur. Patients should report fevers or recurrence of other symptoms immediately.
- Antiretroviral therapy and improvement in immune system health are essential for prevention of recurrence.
- Patients should avoid pregnancy while taking any oral antifungal drug. Fetal craniofacial and skeletal abnormalities have been reported.

Cryptosporidiosis

Background

Cryptosporidiosis is caused by a species of protozoan parasite that typically infects the mucosa of the small intestine, causing watery diarrhea. Diarrhea may be accompanied by nausea, vomiting, abdominal cramping, and occasionally fever. The infection is spread by the fecal-oral route, usually via contaminated water, and is highly contagious. The course of infection depends on the immune status of the host. In immunocompetent individuals, cryptosporidiosis usually is self-limited and can cause a mild diarrheal illness. However, in HIV-infected patients with advanced immunosuppression, cryptosporidiosis can cause severe chronic diarrhea, electrolyte disturbances, malabsorption, and profound weight loss. Infection also can occur outside the intestinal tract and can cause cholangitis, pancreatitis, and hepatitis. In severe cases, cryptosporidiosis can be life-threatening without aggressive fluid, electrolyte, and nutritional support. Patients at greatest risk of acquiring cryptosporidiosis are those with CD4 counts of <100 cells/ μL . Immune reconstitution inflammatory syndrome (IRIS) has not been described in association with cryptosporidiosis.

S: Subjective

The patient may complain of some or all of the following: watery diarrhea (can be profuse), abdominal pain or cramping, flatulence, nausea, vomiting, anorexia, fever, and weight loss.

The history should include questions about the presence and characteristics of the symptoms listed above, as well as the following:

- Stool frequency (typically 6-26 bowel movements daily)
- Stool volume (up to 10 liters per day and can be described as “cholera-like” in some patients with AIDS)
- Duration of symptoms (subacute or acute onset)
- Associated symptoms
- Exposures: recent travel to areas with unsafe water supply; ingestion of possibly contaminated water while swimming, boating, or camping; oral-anal contact, fecal exposures during sexual contact
- Recent CD4 cell count (highest risk is in patients with CD4 counts of <100 cells/ μL)

O: Objective

Perform a thorough physical examination with particular attention to the following:

- Vital signs
- Hydration status (e.g., orthostatic vital signs, mucous membrane moistness, skin turgor)
- Weight (compare with previous values; document weight loss)
- Signs of malnourishment (e.g., cachexia, wasting, thinning hair, pallor)
- Abdominal examination for bowel sounds (usually hyperactive), tenderness (can be diffuse), rebound
- Recent CD4 count

A: Assessment

In HIV-infected patients with advanced immunosuppression, the differential diagnosis includes other infectious causes of subacute or chronic diarrhea or cholangitis, such as microsporidia, *Isospora*, *Giardia*, cytomegalovirus (CMV), and *Mycobacterium avium* complex (MAC), as well as lymphoma.

P: Plan**Diagnostic Evaluation**

- Test the stool for ova and parasites, including *Cryptosporidium*. Diagnosis is made by microscopic identification of the *Cryptosporidium* oocysts in stool.
- Be sure to ask the laboratory to look for *Cryptosporidium*; certain labs do not look for these parasites or their precursor, the oocyst, unless requested.
- Test for fecal leukocytes. The result usually is negative in cryptosporidiosis; if positive, consider the possibility of a second enteric infection, especially if the CD4 count is low, or a different infection.
- Among persons with profuse diarrhea, a single stool specimen usually is adequate for diagnosis. For patients with milder disease, repeat stool sampling may be needed.
- If stool is negative for ova and parasites, consider a referral for biopsy of the gastrointestinal mucosa or flexible sigmoidoscopy.
- If cholangitis is suspected, consider abdominal ultrasound to look for biliary ductal dilatation, and endoscopic retrograde cholangiopancreatography (ERCP).
- Check electrolytes; conduct liver function studies including alkaline phosphatase and bilirubin to check for possible biliary or hepatic infection.
- If fever is present, obtain blood cultures.
- Conduct other diagnostic testing as indicated by the history and physical examination (e.g., evaluation for CMV, MAC, and other infectious causes of diarrhea or cholangitis) (see chapter *Diarrhea*).

Treatment**Preferred Strategy:**

- Effective antiretroviral therapy (ART) with immune reconstitution (and CD4 count of >100 cells/ μ L) can resolve cryptosporidiosis, and it is the primary treatment. All patients with cryptosporidiosis should be initiated on ART (see chapter *Antiretroviral Therapy*). Patients who are on incompletely suppressive ART should have their regimens optimized.
- Provide supportive care and symptomatic relief (this may require hospitalization in cases of severe dehydration), including the following:
 - Aggressive fluid and electrolyte replacement as needed
 - Oral rehydration (solutions containing glucose, sodium bicarbonate, potassium, magnesium, and phosphorus); in severe cases, IV hydration may be required
 - Antidiarrheal agents: atropine/diphenoxylate (Lomotil), loperamide (Imodium), tincture of opium (Paregoric)
 - Antispasmodics
 - Antiemetics
 - Topical treatment for the anorectal area, as needed (witch hazel pads [e.g., Tucks]), sitz baths)

Alternative Management Strategies:

No antiparasitic therapy has been proven to consistently and effectively cure cryptosporidiosis if used without ART. Use of nitazoxanide and paromomycin can be considered. They should be given in conjunction with ART, but never instead of ART; symptomatic treatment and hydration also should be given, as above.

- Nitazoxanide is approved for treatment of diarrhea caused by *Cryptosporidium parvum*, the most common strain of *Cryptosporidium*. It may increase the likelihood of clinical response.

- Usual adult dosage: 500-1,000 mg PO BID for 14 days
- Adverse events associated with nitazoxanide are limited and typically mild; there are no important drug-drug interactions
- Paromomycin 50 mg QID for 14-21 days

For patients with weight loss, nutritional supplementation is a critical aspect of treatment. In some cases, partial or total parenteral nutrition may be necessary while patients are awaiting clinical improvement in response to ART or other therapies. Consult or refer to a dietitian or nutritionist, if available. If not, assess food intake and counsel the patient about increasing caloric and nutritional intake.

Cryptosporidiosis in Resource-Limited Settings

Cryptosporidium infection in HIV-uninfected populations is more common in countries with overcrowding and poor sanitary conditions. The disease also is associated with rainy seasons and is frequent among children <2 years of age.

The prognosis for HIV-infected patients with cryptosporidiosis who lack access to ART is poor. In one study, the mean survival time of coinfecting patients was 25 weeks.

Prevention of Disease and Exposure

- Effective ART with maintenance or restoration of adequate immune function will prevent severe cryptosporidiosis.
- Scrupulous handwashing can prevent the spread of cryptosporidiosis, and HIV-infected patients should be advised to wash their hands after potential contact with human feces (diapering small children, handling pets, gardening, and before and after sex).
- HIV-infected patients should avoid sexual practices that could lead to direct (e.g., oral-anal) or indirect (e.g., penile-anal) contact with feces and should be advised to use barrier methods during sex (e.g., condoms

and dental dams).

- HIV-infected persons should avoid drinking water from lakes or rivers. Waterborne infection also can result from recreational activities such as boating, fishing, and swimming.
- HIV-infected patients should avoid raw oysters as the cryptosporidial oocysts can survive in oysters for >2 months.
- Rifabutin and clarithromycin, when taken for MAC prophylaxis, appear to reduce the risk of cryptosporidiosis. However, current data are insufficient to recommend their use as prophylaxis against cryptosporidiosis.

Patient Education

- Recommend scrupulous handwashing for the patient and all contacts, especially household members and sex partners.
- Explain that effective ART is the best treatment for alleviating symptoms and helping the immune system eradicate the parasite.
- Advise the patient to increase fluid intake (not alcohol), and avoid foods that aggravate diarrhea. A lactose-free diet may improve symptoms.
- Educate the patient about healthful food choices that increase caloric intake and nutrition.
- Provide supportive counseling; discuss how to manage symptoms and the isolation that may accompany chronic diarrhea.

Cytomegalovirus Disease

Background

Although chronic infection with cytomegalovirus (CMV) rarely causes disease among immunocompetent persons, it is a major cause of morbidity and mortality in HIV-infected patients with CD4 counts of <50 cells/ μ L. CMV infection causes disease in several organ systems, including the central nervous system (CNS) (chorioretinitis, encephalitis, polyradiculopathy, myelopathy) and the gastrointestinal (GI) tract (oral ulcers, esophagitis, hepatitis, colitis, intestinal perforation), as well as life-threatening adrenalitis and pneumonitis. The prevalence of chronic infection with CMV, a member of the human herpesvirus family, is high among sexually active adults (40-60% in resource-rich countries and 80-90% in resource-poor countries). CMV is spread by sexual or other types of close personal contact, blood-to-blood contact (via transfusion or needle sharing), organ transplantation, and perinatal transmission. As with other herpesviruses, CMV is not cleared from the body, but is kept in a state of latency by an intact immune system. Symptomatic disease represents either primary infection or reactivation of latent infection that has escaped immunologic control. Effective antiretroviral therapy (ART) greatly reduces the risk of CMV reactivation and disease.

Immune reconstitution inflammatory syndrome

Although effective ART greatly reduces the risk of CMV reactivation and disease, patients on effective ART may experience CMV-related visual changes.

- Patients without a previous history of CMV disease will occasionally present with full-blown CMV retinitis after starting ART. This is thought to reflect delayed restoration of CMV-specific immunity. It is diagnosed and treated in an identical manner as for patients diagnosed with CMV disease who are not taking effective ART.
- Approximately 20% of patients with previously treated CMV retinitis may experience CMV-related immune reconstitution uveitis (IRU) after starting successful ART. Symptoms include floaters and moderate, occasionally severe, vision loss. The most common causes of vision loss are posterior disease, specifically cystoid macular edema (CME) and epiretinal membrane (ERM) formation, although inflammation of the anterior region and cataract formation also can occur. It is not clear whether treatment with steroids or anti-CMV antivirals is effective. (See chapter *Immune Reconstitution Inflammatory Syndrome*.)

S: Subjective

The patient may present with symptoms involving various organ systems, including the following:

• CNS, including the eye:

- Floaters, scotomata (blind spots), “flashing lights,” loss of peripheral or field vision (chorioretinitis)
- Headache, difficulty concentrating, sleepiness, personality changes (encephalitis, dementia)

- Bilateral lower extremity weakness, urinary retention, incontinence, spasticity (polyradiculopathy)
- Low-back pain, especially radiating to the perianal area (polyradiculopathy, myelitis)
- Family members or caregivers may report confusion, apathy, lethargy, somnolence, withdrawal, or personality changes in the patient (CMV encephalitis, dementia)

• GI tract disease:

- Mouth ulcerations
- Dysphagia or odynophagia (esophagitis)
- Abdominal pain and bloody diarrhea, weight loss, rectal ulcers, fever (colitis)

• Disease outside the CNS or GI tract:

- Persistent fever, fatigue, weight loss (adrenitis)
- Shortness of breath, dyspnea on exertion, dry cough (pneumonia; rare in patients with advanced HIV infection)
- Pancytopenia (bone marrow infection)

The history should include questions about the presence and characteristics of the symptoms listed above, as well as the following:

- Duration of symptoms
- Associated symptoms
- Recent CD4 count; nadir CD4 count (risk is highest when count is <50 cells/ μ L)
- Whether the patient is taking ART; if so, date initiated, specific medications, and CD4 and HIV RNA responses

O: Objective

Perform a thorough physical examination with particular attention to the following:

- **Vital signs:** Document fever.
- **Weight:** Compare with previous values; document weight loss.
- **Eyes:** Funduscopic examination in patients with CMV retinitis may show pathognomonic “cottage cheese in ketchup” yellow-white lesions, representing vascular hemorrhages and exudates.
- **Nervous system:** Evaluate mental status and perform a complete neurologic examination, including cranial nerves, sensation (sensory deficits may occur with preserved vibratory sense and proprioception), motor, deep tendon reflexes, coordination, and gait.

A: Assessment

For HIV-infected patients with advanced immunosuppression, the differential diagnosis includes the following:

- For suspected CMV retinitis: consider cotton-wool spots, HIV retinopathy, and progressive outer or acute retinal necrosis.
- For suspected CMV encephalitis: consider other causes of neurologic deterioration such as progressive multifocal leukoencephalopathy, toxoplasmosis, CNS lymphoma, and other mass lesions.
- For suspected CMV enteritis: consider gastrointestinal pathogens such as *Mycobacterium avium* complex, *Cryptosporidium*, other parasites, and lymphoma.
- For suspected CMV pneumonitis: consider *Pneumocystis jiroveci* and other respiratory pathogens.

P: Plan

Diagnostic Evaluation

CMV can be detected by serology, culture, antigen testing, nucleic acid amplification, or examination of tissue samples. However, serologic tests are not reliable for diagnosing CMV disease because most adults are seropositive and because patients with advanced AIDS may serorevert while remaining infected. Furthermore, for HIV-infected patients, demonstration of CMV in the blood, urine, semen, cervical secretions, or bronchoalveolar lavage (BAL) fluid does not necessarily indicate active disease, although patients with end-organ disease usually are viremic.

Diagnosis of end-organ disease generally requires demonstration of tissue invasion. The recommended evaluation is as follows:

CMV retinitis

Dilated retinal examination should be performed emergently by an ophthalmologist experienced in the diagnosis of CMV retinitis. The diagnosis usually is based on the identification of typical lesions. Diagnosis and monitoring should include serial examinations with photography to assess and follow response to treatment and to detect failure to respond early enough to change therapy. If the diagnosis is uncertain, aqueous or vitreous fluid samples can be sent for polymerase chain reaction (PCR) evaluation for CMV and other possible infectious agents.

Other sites

Detection of CMV at other sites requires visualization of typical lesions (e.g., on endoscopy or BAL) and tissue biopsy. Viral inclusions (“owl’s eye cells”) in tissue biopsy samples demonstrate invasive disease (as opposed to colonization). **Because retinitis is the most common manifestation of CMV disease, patients with CNS, gastrointestinal, or pulmonary disease should undergo ophthalmologic evaluation to detect subclinical retinal disease.**

Neurologic CMV disease

- **Encephalitis:** Magnetic resonance imaging (MRI) of the brain should be done to rule out mass lesions. CMV effects may appear as periventricular or meningeal enhancement. Lumbar puncture should be performed; cerebrospinal fluid (CSF) should be analyzed for CMV (by PCR, which is sensitive and specific), cell count (may show lymphocytic or mixed lymphocytic or polymorphonuclear pleocytosis), glucose (may be low), and protein (may be high). A brain biopsy may be performed if the diagnosis is uncertain after imaging and CSF evaluation.

- **Polyradiculopathy:** Spinal MRI should be done to rule out mass lesions. In CMV disease, nerve root thickening may be present. Lumbar puncture with CSF analysis should be performed, as described above.
- **Myelitis:** Spinal MRI should be done to rule out mass lesions. Cord enhancement may be present. Lumbar puncture with CSF analysis should be performed, as described above.

Gastrointestinal CMV disease (esophagitis or colitis)

- Perform endoscopy with visualization of ulcers and obtain tissue biopsy to look for inclusion bodies.

Pulmonary CMV disease

- Perform chest radiography showing interstitial pneumonia and obtain lung biopsy to look for inclusion bodies.

Treatment

Valganciclovir, ganciclovir, foscarnet, and cidofovir may be effective for treating CMV end-organ disease. The choice of therapy depends on the site and severity of the infection, the level of underlying immunosuppression, the patient’s ability to tolerate the medications and adhere to the treatment regimen, and the potential medication interactions.

Immune reconstitution through ART is a key component of CMV treatment and relapse prevention. CMV flares may occur if patients develop immune reconstitution inflammatory syndrome (see chapter *Immune Reconstitution Inflammatory Syndrome*). Although decisions about the timing of ART should be individualized, in most cases of CMV end-organ disease, ART probably should not be delayed for more than 2 weeks after starting treatment for CMV.

CMV retinitis

Treatment consists of two phases: initial therapy and chronic maintenance therapy.

Initial therapy

For patients with sight-threatening (zone 1) disease, the preferred treatment strategy is a combination of intravitreal and systemic therapy. Intravitreal therapy delivers high doses of drug to the retina immediately. Ganciclovir intraocular implants are no longer available, but patients may be treated with intravitreal injections of ganciclovir or foscarnet.

In the past, about half of patients treated with only local therapy (specifically, ganciclovir implants) developed disease in the contralateral eye, and one third experienced systemic disease within 3 months of implantation. Therefore, patients who receive intravitreal therapy also should be treated systemically with valganciclovir or an alternative therapy as below.

For patients with peripheral retinitis (beyond zone 1), systemic therapy alone may be given. Oral valganciclovir (see below) is the preferred treatment because it is easy to administer and is not associated with the surgery- or catheter-related complications seen with intraocular treatments and IV therapies. This formulation quickly converts to ganciclovir in the body and has good bioavailability. Valganciclovir should be used only if the patient is thought to be capable of strict adherence. Other possible IV treatments include ganciclovir, ganciclovir followed by oral valganciclovir, foscarnet, and cidofovir. See below for dosing recommendations.

For sight-threatening disease:

- Intravitreal injection of ganciclovir (2 mg/injection or foscarnet (2.4 mg/injection) 1-4 doses over the course of 7-10 days **plus** systemic therapy as below

Preferred systemic therapy:

- Valganciclovir 900 mg PO BID for 14-21 days, then QD

Alternative systemic therapy:

- Ganciclovir 5 mg/kg IV Q12H for 14-21 days, then QD
- Ganciclovir 5 mg/kg IV Q12H for 14-21 days, then valganciclovir 900 mg PO QD
- Foscarnet 60 mg/kg IV Q8H or 90 mg/kg Q12H for 14-21 days, then 90 mg/kg Q24H
- Cidofovir IV 5 mg/kg weekly for 2 weeks, then every other week (must be given with probenecid [2 g PO 3 hours before, 1 g PO 2 hours after, and 1 g PO 8 hours after the cidofovir infusion] and IV saline to decrease the risk of renal toxicity)

For peripheral lesions:

- Systemic therapy as above

Note: Valganciclovir, ganciclovir, and foscarnet require dosage adjustment in patients with renal insufficiency. Cidofovir is contraindicated for use by patients with renal insufficiency or proteinuria.

Monitor patients closely to gauge the response to therapy. Repeat the dilated retinal examination after completion of induction therapy, 1 month after initiation of therapy, and monthly during anti-CMV therapy, with photography to document progression or resolution of disease. Consult with a specialist if the response to therapy is suboptimal.

Note: Retinal detachment may occur in up to 50-60% of patients in the first year after diagnosis. Regular follow-up with an ophthalmologist is required for all patients. Patients should be instructed to report any vision loss immediately.

Chronic maintenance therapy

After initial CMV treatment, lifelong maintenance therapy should be given to prevent recurrence, and patients need regular reevaluation by an ophthalmologist. Select the specific treatment in consultation with an ophthalmologist.

Preferred therapy:

- Valganciclovir 900 mg PO QD

Alternative therapy:

- Ganciclovir 5 mg/kg IV 5-7 times per week
- Foscarnet 90-120 mg/kg IV QD
- Cidofovir 5 mg/kg IV every other week (administer with probenecid and IV hydration, as above)

Discontinuation of maintenance therapy can be considered for patients with inactive CMV and sustained immune reconstitution on ART (CD4 count of >100 cells/ μ L for at least 3-6 months). However, the decision should be guided by factors such as the extent and location of the CMV lesions and the status of the patient's vision. An ophthalmologist who is experienced in caring for HIV-infected patients with CMV should be involved in making any decision to discontinue therapy, and patients should receive regular ophthalmologic follow-up. Maintenance therapy should be resumed if the CD4 count drops to <100 cells/ μ L or the patient develops other signs of HIV progression.

Neurologic CMV disease

The optimal treatment for neurologic disease has not been determined. Prompt initiation of dual therapy with IV ganciclovir and foscarnet may be effective for some patients. Chronic maintenance therapy usually is not recommended for patients who recover and are on effective ART, unless the disease recurs.

Gastrointestinal and pulmonary CMV disease

CMV colitis and esophagitis are usually treated with IV ganciclovir or foscarnet for 21-42 days, until symptoms have resolved. Treatment should be changed to valganciclovir (900 mg QD) when the patient is able to absorb oral medications. In mild cases in which patients are able to tolerate and absorb it, valganciclovir may be used from the beginning (refer to the dosing recommendations above).

Some specialists recommend a follow-up endoscopy to verify regression of lesions before discontinuing therapy.

For pulmonary CMV infections, optimal therapy has not been defined. IV ganciclovir or foscarnet is recommended. The efficacy of valganciclovir has not been determined.

Many experts do not recommend maintenance therapy for gastrointestinal or pulmonary CMV infections for patients whose CMV symptoms resolve and who are on effective ART.

Immune reconstitution inflammatory syndrome retinitis or uveitis

Urgent consultation with experts is recommended. Corticosteroids may be beneficial.

Monitoring CMV therapies

The medications used to treat CMV have several important potential adverse effects, and monitoring for these is required. Valganciclovir and ganciclovir have been associated with bone marrow suppression, neutropenia, anemia, thrombocytopenia, and renal dysfunction. Foscarnet has been associated with cytopenia, renal insufficiency, electrolyte abnormalities, and seizures. For patients taking these medications, perform complete blood count with differential and check electrolytes and creatinine twice weekly during initial therapy and once weekly during maintenance therapy. Cidofovir has been associated with renal insufficiency and ocular hypotony. For patients taking cidofovir, check creatinine and blood urea nitrogen and perform urinalysis (for proteinuria) before each dose. Intraocular pressure must be checked at least every 6 months.

Patient Education

- Educate patients about the importance of ART in treating CMV. Urge patients to start ART if they have not done so already.
- Patients with CMV retinitis may have to remain on suppressive therapy for life to prevent blindness. Patients with CMV esophagitis or enteritis usually see improvements within 2-4 weeks after starting therapy.
- Treatment of CMV retinitis halts progression of the infection but does not reverse the damage already done to the retina. Warn patients that vision will not return to pre-CMV status.
- Advise patients to report any visual deterioration immediately. Retinal detachment or progression of CMV must be treated immediately to avoid further vision loss.
- For patients who experience significant vision loss, offer referral to education, training, and support services to help them adjust.
- With gastrointestinal disease, recurrence of symptoms warrants repeat endoscopy. Advise patients to report any recurrence of symptoms.
- Adverse reactions to current therapies are common. Educate patients about these and advise them to promptly report any adverse reactions.
- Help patients cope with the possibility of therapeutic failure, and, in the case of CMV retinitis, permanent loss of vision.
- Teach patients how to maintain indwelling venous access lines, if used. Have patients demonstrate these techniques before discharge.

Gonorrhea and Chlamydia

Background

Gonorrhea, caused by *Neisseria gonorrhoeae* (GC), and chlamydia, caused by *Chlamydia trachomatis* (CT), are sexually transmitted diseases (STDs). These infections may be transmitted during oral, vaginal, or anal sex; they also can be transmitted from a mother to her baby during delivery and cause significant illness in the infant.

Both organisms can infect the urethra, oropharynx, and rectum in women and men; the epididymis in men; and the cervix, uterus, and fallopian tubes in women. Untreated GC or CT infection in women may lead to pelvic inflammatory disease (PID), which can cause chronic pelvic pain and scarring of the fallopian tubes that results in infertility or ectopic pregnancy (tubal pregnancy). *N. gonorrhoeae* can cause disseminated infection involving the skin, joints, and other systems. Infection with GC or CT may facilitate transmission of HIV to HIV-uninfected sex partners.

Certain strains of CT can cause lymphogranuloma venereum (LGV). This infection is common in parts of Africa, India, Southeast Asia, and the Caribbean. Although relatively uncommon in the United States, outbreaks among men who have sex with men (MSM) have been reported in recent years. LGV may cause genital ulcers, followed by inguinal adenopathy; it also can cause proctocolitis with anorectal discharge, tenesmus, and pain.

Patients with symptoms of gonorrhea or chlamydia should be evaluated and treated as indicated below. Although GC or CT urethral infections in men may cause symptoms, infection in women and oral or rectal infections in men often cause no symptoms. Thus, sexually active individuals at risk of GC and CT exposure should receive regular screening for these infections as well as for syphilis and other STDs; for most patients, this should be at least annually, and every 3-6 months for persons at higher risk (see chapter *Initial and Interim Laboratory and Other Tests*).

S: Subjective

Symptoms will depend on the site of infection (e.g., oropharynx, urethra, cervix, rectum). Symptoms are not present in many patients, thus it is important to screen all patients at risk of STDs.

If symptoms are present, **women** may notice the following (depending on site of infection):

- Vaginal discharge
- Pain with sexual intercourse
- Pain or burning on urination
- Abdominal or pelvic pain
- Sore throat
- Rectal discharge
- Anal discomfort or tenesmus

If symptoms are present, **men** may notice the following (depending on site of infection):

- Pain or burning on urination
- Urethral discharge
- Testicular tenderness or pain
- Sore throat
- Rectal discharge
- Anal discomfort or tenesmus

During the history, ask the patient about the following:

- Any of the symptoms listed above, and their duration
- Previous diagnosis of GC, CT, or other STD
- New sex partner(s); number and gender of partners

- Unprotected sex (oral, vaginal, anal; receptive or insertive)
- For women: last menstrual period, and whether the patient could be pregnant; use of an intrauterine device

O: Objective

Physical Examination

During the physical examination, check for fever and document other vital signs.

For **women**, focus the physical examination on the mouth, abdomen, and pelvis. Inspect the oropharynx for discharge and lesions; check the abdomen for bowel sounds, distention, rebound, guarding, masses, and suprapubic or costovertebral angle tenderness; perform a complete genital and vaginal examination for abnormal discharge or bleeding; check for uterine, adnexal, or cervical motion tenderness; and search for pelvic masses or adnexal enlargement. Check the anus for discharge and lesions; perform anoscopy if symptoms of proctitis are present. Check for inguinal lymphadenopathy. Check the skin for rashes and lesions.

For **men**, focus the physical examination on the mouth, genitals, and anus/rectum. Check the oropharynx for lesions, the urethra for discharge, the external genitalia for tenderness, masses, or lesions, and the anus for discharge and lesions; perform anoscopy if symptoms of proctitis are present. Check for inguinal lymphadenopathy. Check the skin for rashes and lesions.

A: Assessment

A partial differential diagnosis includes the following:

- Urinary tract infection
- Dysmenorrhea
- Appendicitis
- Cystitis

- Proctitis
- PID
- Irritable bowel syndrome
- Pyelonephritis

P: Plan

Diagnostic Evaluation

Test for oral, urethral, or anorectal infection, according to symptoms and anatomic site(s) of possible exposures. Perform testing for both gonorrhea and chlamydia (testing for pharyngeal CT infection generally is not recommended although the CT pharyngeal test often accompanies the GC pharyngeal nucleic acid amplification test [NAAT]). The availability of the various testing methods varies according to the specific clinic site. Consider the following:

- NAAT: urine specimens (first stream) and urethral (men), vaginal, and endocervical swab specimens; also used with pharyngeal and rectal swab specimens (laboratory must meet Clinical Laboratory Improvement Amendments [CLIA] specifications and establish validity in nongenital specimens); recommended unless GC antibiotic resistance is suspected
- GC culture (oropharynx, endocervix, urethra, rectum) – consider especially if antibiotic resistance is suspected
- Gram stain of urethral discharge for evidence of GC
- Serologic tests (complement fixation test) if LGV is suspected

Treatment

Treatments for gonorrhea and chlamydia are indicated below. Fluoroquinolone-resistant GC is widespread in the United States and throughout the world. Thus, the U.S. Centers for Disease Control and Prevention (CDC) recommends that fluoroquinolones not be used for treatment of GC. Similarly, resistance

of GC to cephalosporins is emerging, though third-generation cephalosporins are effective against most GC strains in the United States and remain the only recommended treatment for GC. GC strains with decreased susceptibility to azithromycin also have been reported, and azithromycin should be used to treat GC only for select patients in whom treatment with a cephalosporin should be avoided.

Adherence is essential for treatment success. Single-dose treatments maximize the likelihood of adherence and are preferred. Other considerations in choosing the treatment include antibiotic resistance, cost, allergies, and pregnancy. For further information, see the CDC STD treatment guidelines (see “References,” below); treatments should be given in accordance with these guidelines.

Any sex partners within the past 60 days, or the most recent sex partner from >60 days before diagnosis, also should receive treatment. Patients should abstain from sexual activity for 7 days after a single-dose treatment or until a 7-day treatment course is completed. Reinfection with GC or CT is likely if reexposure occurs; patients with either GC or CT should be rescreened 3 months after treatment.

Treatment of Gonorrhea

Treatment options include the following (see the full CDC STD treatment guidelines, referenced below); the current guidelines emphasize that dual therapy for GC should be given, with ceftriaxone plus either azithromycin or doxycycline. Ceftriaxone is the recommended cephalosporin for GC infection at any anatomic site. Coadministration of azithromycin or doxycycline is intended to improve the likelihood of cure and may decrease the risk of emergent cephalosporin resistance; it should be given, even if test results for CT are negative.

Recommended regimen (for GC of all anatomic sites)

- Ceftriaxone 250 mg IM injection in a single dose, **plus** azithromycin 1 g PO in a single dose or doxycycline 100 mg PO BID for 7 days

Alternative regimens (for GC of pharynx, cervix, urethra, and rectum)*

- If ceftriaxone is not available: cefixime 400 mg PO in a single dose (tablet or oral suspension), plus azithromycin or doxycycline, as above
- If severe cephalosporin allergy: azithromycin 2 g PO in a single dose

* If an alternative regimen is used, a test of cure (TOC) should be done in 1 week: GC culture (preferred) or NAAT. A positive NAAT result should be followed by confirmatory culture and antimicrobial susceptibility testing. Possible cephalosporin treatment failures should be reported immediately to the local or state health department.

If penicillin or cephalosporin allergy:

- Cephalosporins are contraindicated for use only in patients with a history of severe reaction to penicillin.
- Consultation with an infectious disease specialist is recommended.
- Consider azithromycin 2 g PO, with TOC, as above.
- Consider cephalosporin treatment following desensitization.

Note: Fluoroquinolones are not recommended for treatment of gonococcal infection because of widespread resistance in the United States.

Please see full CDC STD treatment guidelines regarding treatment of PID, epididymitis, and disseminated gonococcal infection.

Treatment of Chlamydia

(See the full CDC STD treatment guidelines, referenced below.)

Recommended regimens

- Azithromycin 1 g PO in a single dose
- Doxycycline 100 mg PO BID for 7 days

Alternative regimens

- Erythromycin base 500 mg PO QID for 7 days
- Erythromycin ethylsuccinate 800 mg PO QID for 7 days
- Levofloxacin 500 mg PO QD for 7 days (see Note above)
- Ofloxacin 300 mg PO BID for 7 days (see Note above)

Treatment of LGV**Recommended regimens**

- Doxycycline 100 mg PO BID for 21 days

Alternative regimens

- Erythromycin base 500 mg PO QID for 21 days
- Azithromycin 1 g PO once weekly for 3 weeks (limited data)

For recent sex partners (within 60 days before the onset of patient's symptoms), test for urethral or cervical CT, treat with azithromycin 1 g PO in a single dose or doxycycline 100 mg PO BID for 7 days.

Treatment During Pregnancy

Use of fluoroquinolones and tetracyclines should be avoided during pregnancy.

Recommended GC regimens

- Ceftriaxone 250 mg IM + azithromycin 1 g PO in a single dose

Recommended CT regimens

- Azithromycin 1 g PO in a single dose
- Amoxicillin 500 mg PO TID for 7 days

Alternative CT regimens

- Erythromycin base 500 mg PO QID for 7 days
- Erythromycin base 250 mg PO QID for 14 days
- Erythromycin ethylsuccinate 800 mg PO QID for 7 days
- Erythromycin ethylsuccinate 400 mg PO QID for 14 days

Follow-Up

- For both GC and CT, evaluate the patient's sex partners; treat them empirically if they had sexual contact with the patient during the 60 days preceding the patient's onset of symptoms. Some clinics provide empiric treatment for partners via "partner packs," or a treatment regimen that the patient takes to the partner(s); this approach may be effective, particularly for CT, if the partner(s) is/are unlikely to come to the clinic for evaluation and treatment.
- Most recurrent infections come from sex partners who were not treated.
- The CDC recommends rescreening all patients 3 months after GC or CT treatment (for possible reinfection).
- For pregnant women with CT, retest (by NAAT) 3 weeks after completion of treatment.

- If symptoms persist, evaluate for the possibility of reinfection, treatment failure, or a different cause of symptoms. If treatment failure is suspected, perform culture and antimicrobial sensitivity testing.
- Screen for GC, CT, syphilis, and other STDs at regular intervals according to the patient's risk factors. The sites of sampling (e.g., pharynx, urethra, endocervix, anus/rectum) will be determined according to the patient's sexual exposures.
- Evaluate each patient's sexual practices with regard to the risk of acquiring STDs and of transmitting HIV; work with the patient to reduce sexual risks.

Patient Education

- Instruct patients to take all of their medications. Advise patients to take medications with food if they are nauseated and to call or return to clinic right away if they experience vomiting or are unable to take their medications.
- Sex partners from the previous 60 days need to be tested for sexually transmitted pathogens, and treated as soon as possible with a regimen effective against GC and CT, even if they have no symptoms. Advise patients to inform their partner(s) that they need to be tested and treated. Otherwise, patients may be reinfected.
- Advise patients to avoid sexual contact until the infection has been cured (in themselves and in their partners) at least 7 days.
- Provide education about sexual risk reduction. Instruct patients to use condoms with every sexual contact to prevent reinfection with GC or CT, to prevent other STDs, and to prevent transmission of HIV to sex partners.

Hepatitis B Infection

Rena K. Fox, MD

Background

Hepatitis B virus (HBV) is the most common cause of chronic liver disease worldwide. Chronic HBV can cause necroinflammation and over time can cause hepatic fibrosis and eventually cirrhosis, end-stage liver disease, and hepatocellular carcinoma (HCC). It is estimated that 350 million people have chronic HBV infection, with approximately 1.25 million of them in the United States. HBV is a DNA virus that is spread through exposure to infected blood and body fluids. It typically is transmitted by parenteral, sexual, and vertical exposures, but may be transmitted through person-to-person contacts among household members, especially because HBV can survive outside the body for long periods of time. Because HIV and HBV share transmission routes, up to 90% of HIV-infected patients have evidence of HBV exposure. In the United States, chronic HBV infection has been identified in 6-15% of HIV-infected persons.

The epidemiology of HBV infection varies by geographic region. In Southeast Asia and sub-Saharan Africa, HBV is highly prevalent and almost all infections occur perinatally or during early childhood. In the United States and Western Europe, most infections occur through sexual exposure or high-risk injection drug-use behavior.

To identify patients with HBV coinfection, and to identify and vaccinate susceptible individuals, all HIV-infected persons should be tested for HBV (see chapters *Initial and Interim Laboratory and Other Tests* and *Immunizations for HIV-Infected Adults and Adolescents*). In addition, all patients with chronic HBV infection should be tested for HIV and all patients with evidence of prior resolved HBV infection should be strongly considered for HIV testing.

It is universally recommended that HBV vaccination should be given to all HIV-infected persons who are susceptible to HBV infection (see “Interpreting HBV test results,” below, and chapter *Immunizations for HIV-Infected Adults and Adolescents*). It is recommended that the vaccine series be given when CD4 counts are >200 cells/ μ L, if possible, as doing so is associated with higher rates of vaccine response, but vaccination should not be delayed for persons with lower CD4 counts.

The natural history of HBV infection is complex and dynamic, with phases of active replication and of inactive replication, and fluctuating alanine aminotransferase (ALT) levels. The likelihood of developing chronic HBV after exposure varies with age, mode of infection, and immunocompromised status. Among newborns born to HBV-infected mothers, 90% develop chronic hepatitis B, whereas 30% of exposed infants and young children and <5% of exposed adults develop chronic infection. Most adults who become infected with HBV are able to clear the virus without treatment, and they subsequently become immune to HBV. Chronic progressive HBV can lead to cirrhosis and then to decompensated liver disease including ascites, portal hypertension, esophageal varices, coagulopathy, thrombocytopenia, and hepatic encephalopathy. HCC can develop in patients with or without cirrhosis; in fact, 30-50% of HCC cases attributable to HBV occur in the absence of cirrhosis.

HRSA HAB Performance Measures

Percentage of patients with a diagnosis of HIV who completed the vaccination series for hepatitis B

(Adult and Adolescent measure)

Factors associated with increased rates of cirrhosis include the following:

- Longer duration of infection
- HBV genotype C
- High levels of HBV DNA
- Alcohol consumption
- Smoking
- Aflatoxin exposure
- Coinfection with HIV
- Coinfection with hepatitis D virus
- Coinfection with HCV

Factors associated with increased rates of HCC include the following:

- Male gender
- Family history of HCC
- Older age
- Presence of HBV envelope antigen (HBeAg); history of reversion from anti-HBe to HBeAg
- High levels of HBV DNA
- Presence of cirrhosis
- HBV genotype C
- Core promoter mutation
- Coinfection with HCV

Among individuals who are not taking ART, HIV infection significantly modifies the natural history of HBV infection. HIV infection appears to increase the risk of developing chronic HBV infection after acute HBV, and it is associated with a higher level of HBV DNA replication and lower rates of spontaneous HBeAg seroconversion. In patients with chronic HBV, HIV coinfection is associated with faster progression of liver disease and cirrhosis and increased rates of liver-related deaths. Although HIV coinfection itself is not known to increase the risk of HCC development, it does increase the risk of cirrhosis, which in turn increases the risk of HCC.

Treatment of HIV infection with effective ART has increased the life expectancy of HIV-infected patients in recent years, and paradoxically has given HIV/HBV-coinfected patients a longer lifespan during which cirrhosis may develop. Partly for this reason, the relative proportion of deaths attributable to liver disease among HIV-infected patients is rising. On the other hand, ART can positively impact the natural history of HBV infection. Effective ART can improve patients' immune responses against HBV. ART also may be used to cotreat HBV in coinfecting patients. Several of the nucleoside analogues (NRTIs) used against HIV also are active against HBV, and these should be included in an ART regimen to treat both HIV and HBV for coinfecting persons (see "Antiviral Treatment of Chronic HBV Infection," below). Withdrawal of NRTIs with anti-HBV activity can precipitate a reactivation of HBV. ART that contains anti-HBV NRTIs also may prevent acute infections in patients who are receiving them. Current U.S. Department of Health and Human Services (HHS) guidelines recommend initiation of ART (and cotreatment of HBV) for all persons with HIV/HBV coinfection.

S: Subjective

Persons with acute HBV infection may have symptoms including fatigue, nausea, vomiting, arthralgias, fever, right upper quadrant pain, jaundice, dark urine, and clay-colored stools. Some patients may have no symptoms at all.

Persons with chronic HBV, even with early cirrhosis, may be asymptomatic or may experience only fatigue or mild right upper quadrant tenderness. Patients with decompensated cirrhosis may experience increased abdominal girth, easy bruising, telangiectasis, pruritus, gastrointestinal bleeding, or altered mentation. Patients with early or small HCC may have no additional symptoms or may develop significant abdominal pain, weight loss, nausea, or bone pain.

Ask patients with known HBV infection about symptoms that suggest complications of HBV such as cirrhosis, decompensation, risk factors for worsening liver disease, and hepatotoxins. Questions should address the symptoms listed above, and the following:

- Fatigue
- Weight loss
- Impaired concentration
- Chronic HCV
- Alcohol intake
- Substance use
- Antiretroviral (ARV) medications that may cause hepatotoxicity (e.g., didanosine, protease inhibitors, nevirapine, maraviroc)
- Medications with potential for hepatotoxicity or accumulation in persons with liver disease (e.g., acetaminophen, benzodiazepines, opiates)

O: Objective

Measure vital signs.

Perform a physical examination to include evaluation of the following:

- Head, ears, eyes, nose, throat (HEENT): temporal wasting, icterus, gum bleeding
- Heart and lungs: signs of congestive heart failure
- Chest: gynecomastia
- Abdomen: caput medusa, venous prominence, distention, signs of ascites, hepatomegaly, splenomegaly
- Extremities: edema
- Neurologic: alertness, mental status, asterixis
- Skin: jaundice, palmar erythema, petechiae, ecchymoses, spider angiomas

P: Plan

HBV Testing

As discussed above, all HIV-infected persons should be screened for HBV surface antigen (HBsAg), HBs antibody (HBsAb), and HBV core antibody (total) (HBcAb-total) and be vaccinated if not immune (see chapter *Immunizations for HIV-Infected Adults and Adolescents*).

Nonimmune persons with elevated transaminases or signs or symptoms of acute or chronic liver disease should be retested for HBV and HCV infection.

Interpreting HBV test results

Routine baseline HBV serologic screening tests for HIV-infected individuals are outlined in Table 1.

Markers of chronic hepatitis B can manifest in a number of patterns (see Table 1).

Table 1. Interpreting HBV Laboratory Tests

	Acute Hepatitis B	Recovery from Acute Hepatitis B	Chronic HBeAg+ Disease	Chronic HBeAg- Disease	Occult Hepatitis B	Successful Vaccination	Isolated HBeAb
HBsAg	X (may clear)		X	X			
Anti-HBs		X				X	
Anti-HBc IgM	X (may be the only marker during window period)						
Anti-HBc	X	X	X	X	X		X
HBeAg	X		X		X		
Anti-HBe		X (in some cases)		X			X (in some cases)
DNA* (PCR if required)	X		X	X	X		(in rare cases, may be +)

* Absence of detectable HBV DNA does not rule out chronic HBV infection in patients who are on ARVs with anti-HBV activity.

Because of the complexity of HBV diagnosis and test interpretation, it is important to test for HBsAg, HBeAb, and HBsAb. If the result for either HBsAg or HBeAb is positive, then test for HBV DNA. The presence of HBsAg for >6 months indicates chronic HBV infection, but detectable HBV DNA is required for the diagnosis. HBV DNA should be tested before initiation of ART, if possible, as NRTIs with anti-HBV activity may suppress HBV viremia and interfere with diagnosis. Some persons with HIV infection can have chronic HBV infection with high HBV DNA levels and hepatic inflammation while testing negative for HBsAg and positive only for HBeAb. This sometimes is termed “occult hepatitis B infection.” Patients with chronic HBV may test either positive or negative for HBeAg. Patients with inactive chronic HBV are positive for HBsAg but have persistently normal ALT levels, low-level or no detectable HBV DNA, and negative HBeAg results. Ongoing viral replication and infectiousness is indicated by the presence of HBV DNA or a positive result for HBeAg.

Markers of immunity or previous exposure to HBV also can manifest in a number of patterns (see Table 1). Successful vaccination to HBV (in someone who has never been infected) will result in positive HBsAb but negative HBeAb results. Prior exposure to HBV may result in positive HBeAb and HBsAb findings, indicating the development of immunity. However, prior exposure may present as positive HBeAb only, with negative results for HBsAb, HBeAg, and HBV DNA. This pattern shows that the patient was previously infected with hepatitis B but did not develop chronic infection, and lost the HBsAb. This sometimes is termed “isolated core Ab,” and it is seen more commonly in patients coinfecting with HIV or HCV. It is not known whether patients who display this pattern would have sufficient immunity to ward off another HBV infection if they were reexposed; current guidelines recommend the standard HBV vaccination series, followed by a check of HBsAb.

In acute HBV infection, HBV DNA will be detectable before HBsAg, if highly sensitive nucleic acid testing is used. Otherwise, HBsAg is the only marker detected during the first 3-5 weeks after infection. HBcAb develops at approximately 6 weeks after infection and both immunoglobulin M (IgM) and immunoglobulin G (IgG) will be evident. The IgM will decline within 6 months but the IgG will persist for life. Among individuals who recover from acute HBV infection, HBeAg typically seroconverts to HBeAb at approximately 3 months whereas, for those who develop chronic HBV infection, HBeAg typically persists for years.

Diagnostic Evaluation of Acute HBV Infection

When approaching the diagnosis of a patient with acute hepatitis B infection, the following steps should be taken:

1. Obtain history and perform physical examination.

Determine the time and route of infection if possible. Take a complete history, including HIV disease course and treatment, and other medical history. Perform physical examination, focusing on evidence of acute liver dysfunction.

2. Assess HBV replication serially.

As soon as acute infection is suspected, check HBsAg, HBV DNA, HBeAg, HBeAb, ALT, HBcAb-IgM, and HBsAb. HBsAg usually can be detected by 4 weeks (the range of detectability is 1-9 weeks). HBcAb-IgM is detectable at the onset of symptoms.

When ALT is abnormal and rising, additional tests of liver function should be serially evaluated until it is clear that ALT is trending back down. Tests should include albumin, total bilirubin, prothrombin time, and platelet count.

3. Determine whether HBV infection resolves or persists as chronic HBV infection.

If the HBsAg is still present at 6 months after acute infection, the HBV infection has persisted and the patient has chronic hepatitis B infection.

Initial Diagnostic Evaluation of Chronic HBV Infection

When approaching the diagnosis of a patient with chronic HBV infection, the following steps should be taken:

- Take a complete history, including family history of HBV or HCC, and HIV disease course and treatment. Perform physical examination.
- Assess HBV replication to determine HBV DNA level, HBeAg and HBeAb serostatus, and ALT level. Note that HBV DNA levels may be difficult to interpret in patients who are on ARVs that have anti-HBV activity (HBV level may be low or undetectable because of these medications).
- Assess liver disease – check complete blood cell count with platelet count, albumin, total bilirubin, transaminases (especially ALT), and prothrombin time.
- Assess for possible overlying liver diseases (e.g., HCV, alcoholic liver disease, fatty liver disease).
- Consider liver biopsy to assess histological degree of inflammation and fibrosis, especially if the result would affect the decision to use treatment.
- Screen for HCC at baseline via ultrasound.
- Test for hepatitis A antibodies (IgG) and vaccinate against hepatitis A if not immune.

Long-Term Monitoring of Chronic HBV Infection

It should be noted that current HHS guidelines strongly recommend treatment of both HIV and HBV in all coinfecting persons. Nonetheless, some patients may wish to defer treatment or may not tolerate treatment. For those patients who are not on treatment for HBV, regular monitoring of HBV replication and liver function should be performed.

For patients with the following seromarkers, recommendations are as indicated:

Negative HBeAg, low ALT, and low-level DNA (<2,000 IU/mL) (inactive HBV):

HBV DNA, HBeAg, and ALT testing should be performed every 3 months for the first year to determine whether the virus is truly inactive. If it remains inactive (with negative HBeAg, normal ALT, and low-level DNA), monitoring can continue every 6-12 months; some specialists recommend more frequent monitoring.

Negative HBeAg, elevated ALT, and high HBV DNA (>20,000 IU/mL):

Biopsy should be considered, and treatment should be considered. If treatment is not started, monitoring should occur every 3 months.

Negative HBeAg, moderately elevated ALT, and moderately elevated DNA (2,000-20,000 IU/mL):

Follow-up should be performed every 3-6 months if treatment is not started.

Positive HBeAg, moderately elevated ALT:

Monitoring should be performed every 3 months and, if ALT is persistently elevated, a biopsy should be considered to guide the decision regarding initiation of HBV treatment.

Positive HBeAg, high HBV DNA (>20,000 IU/mL) but low-level ALT:

Monitoring should be performed every 3-6 months to check for changes in ALT. If ALT rises significantly, treatment should be considered.

Cirrhosis:

Treatment should be considered. For patients who are not treated, monitoring should be performed every 3-6 months.

Antiviral Treatment of Chronic HBV Infection

HHS ARV guidelines and Centers for Disease Control and Prevention opportunistic infection guidelines recommend treatment of both HIV and HBV in all coinfecting persons. The goals and markers of HBV treatment for HIV/HBV-coinfecting patients are the same as for HBV-monoinfecting patients.

The goals of treatment are as follows:

- To decrease progression of liver disease
- To prevent development of cirrhosis
- To prevent development of HCC

Treatment endpoints for the HBV/HIV-coinfecting population are not well defined but efficacy is determined by the following measures:

- HBeAg seroconversion to HBeAb (this is harder to achieve for coinfecting patients than for HBV-monoinfecting persons)
- HBV DNA suppression
- ALT normalization, which usually follows the changes in HBV DNA

The timing of treatment and choice of treatment for HBV/HIV-coinfecting patients are important.

Treatment for HIV and HBV:

- All HIV/HBV coinfecting patients should be treated for both HIV and HBV infections, if possible.
- If treatment for HIV is to be started, HBV should be treated concurrently with the HIV by using a potent ART regimen that includes two NRTIs that are active against both viruses (tenofovir + emtricitabine or tenofovir + lamivudine), if possible. If tenofovir is contraindicated, entecavir or another anti-HBV drug should be used (with emtricitabine or lamivudine) to construct a two-drug therapy for HBV, and the HIV ART regimen should be designed for complete HIV suppression (see Table 2). In this situation, liver biopsy to stage disease is not necessary because HBV treatment will be undertaken (incorporated into the HIV regimen). Note that treatment of HBV with a single NRTI is not recommended, because of the risk of HBV resistance; if tenofovir cannot be used, entecavir (plus combination ART) is the preferred alternative (see Table 2).
- Most patients receiving ART who are treated for HBV will require HBV treatment indefinitely (lifelong).

Treatment for HBV alone:

- If HBV treatment is indicated, HIV infection should be treated concurrently, if possible, as stated above. If treatment for HIV is deferred, the hepatitis B should be treated if the patient otherwise meets criteria for HBV treatment (see below).
- Inactive chronic hepatitis B (HBV DNA is <2,000 IU/mL, HBeAg is negative, and ALT is not elevated): the HBV can be monitored and does not require treatment.
- HBeAg positive, ALT is more than two times the upper limit of normal (ULN), and HBV DNA >20,000 IU/mL: consider HBV treatment.

- HBeAg negative, ALT is more than two times the ULN and HBV DNA >2,000 IU/mL: consider HBV treatment.
- HBeAg positive, HBV DNA >20,000 IU/mL, but ALT is less than two times the ULN: can use a biopsy to determine the need for HBV treatment.
- HBeAg negative, DNA >2,000 IU/mL, but ALT is less than two times the ULN: can use a biopsy to determine the need for HBV treatment.
- Any patient with cirrhosis (if not decompensated) and a detectable DNA level: should be considered for HBV treatment, regardless of HBeAg status and regardless of ALT level.
- Patients with decompensated cirrhosis should not be treated for HBV but should be referred for transplant.
- Some specialists recommend HBV treatment for all patients with detectable HBV DNA, particularly if ALT is elevated or inflammation or fibrosis is seen on liver biopsy.
- If a decision is made to treat HBV but not HIV, HBV treatment should not include agents that are dually active, as that could lead to early HIV resistance. This limits choices to pegylated interferon alfa-2a (although it has not been studied in HIV/HBV-coinfecting patients) or adefovir dipivoxil. Tenofovir, lamivudine, emtricitabine, entecavir, and telbivudine should not be used as monotherapy for HIV/HBV-coinfecting patients, because HIV (and HBV) resistance may develop (see Table 2).

Table 2. Antiviral Therapies for Chronic HBV Infection

	Lamivudine	Emtricitabine	Tenofovir	Adefovir	Entecavir	Telbivudine	Pegylated Interferon
Dual activity against HBV and HIV	Yes	Yes	Yes	No (at the low HBV treatment dosage), but theoretical concern remains	Yes	Possibly	No
Recommended for use in HIV/HBV coinfection	With tenofovir, as part of fully suppressive ART	With tenofovir, as part of fully suppressive ART	With lamivudine or emtricitabine, as part of fully suppressive ART	If HIV is not being treated, or in combination with a lamivudine- or emtricitabine-containing ART regimen, if tenofovir is not used	With fully suppressive ART	With fully suppressive ART	If HIV is not being treated
Loss of HBV DNA	40-44%		76%	21%	67%	60%	25%
HBsAg seroconversion	16-21%		21%	12%	21%	22%	27-32%
Class	Nucleoside analogue	Nucleoside analogue	Nucleotide analogue	Nucleotide analogue	Nucleoside analogue	Nucleotide analogue	Interferon

Additional points about treatment for HIV/ HBV-coinfected patients:

- When lamivudine is used as a single agent, HBV resistance develops in many patients by 1-2 years. Although combination therapy has not been well studied, specialists recommend using dual-NRTI combinations that have activity against HBV (lamivudine + tenofovir, or emtricitabine + tenofovir [Truvada]) as part of the ARV regimen, to treat HBV and to prevent HBV resistance.
- Some patients treated with ART may experience worsening of HBV symptoms

and laboratory markers in the weeks after ART initiation, because of immune reconstitution inflammatory reactions. Hepatic decompensation owing to immune reconstitution must be distinguished from other causes, such as medication toxicity, or other infection. Liver function tests should be monitored closely for patients starting ART.

- Some ARV medications are hepatotoxic and should be avoided or used cautiously. These include nevirapine, tipranavir, and high-dose ritonavir. Numerous other medications (e.g., fluconazole, isoniazid) are hepatotoxic

and can pose problems for patients with impaired liver function.

- Discontinuation of HBV medications in patients with HIV/HBV coinfection may cause a flare of liver disease. Be very cautious when discontinuing HBV-active medications from an anti-HIV ART regimen. If the HBV DNA is suppressed, options include continuing the HBV-active ARVs, even if there is HIV resistance (modify the other parts of the ART regimen for maximal HIV suppression) or substituting other HBV-active medications to avoid rebound liver inflammation and decompensation. For example, if it is decided to discontinue a lamivudine/tenofovir-containing regimen in an HIV/HBV-coinfected patient on ART, consider starting interferon or possibly adefovir to maintain activity against HBV. If HBV therapy is discontinued and a flare occurs, consider reinstating HBV therapy as soon as possible.
- Limited data exist on treatment of HBV in the setting of HIV and HCV. Consider consultation with an expert if optimal timing for treatment of the three infections is not clear.

Screening for HCC in patients with chronic HBV infection:

Persons with chronic HBV are at increased risk of developing HCC. Note that HCC may occur even in the absence of cirrhosis. HCC screening should be performed every 6-12 months using ultrasound (computed tomography [CT] is an alternative); alpha-fetoprotein should be monitored if ultrasound reliability is low.

HBV-infected patients who should be screened for HCC include the following:

- Anyone with cirrhosis
- Anyone over age 40 with elevated ALT or HBV DNA level of >2,000 copies/mL
- Asian men aged >40

- Asian women aged >50
- Persons of African descent aged >20
- Anyone with a family history of HCC

Interventions to slow progression and prevent complications

Persons with HCV infection should be counseled to avoid exposure to hepatotoxins, including alcohol and hepatotoxic medications (e.g., acetaminophen in large doses, fluconazole, isoniazid). Heavy alcohol use is a risk factor for increasing rate of fibrosis. It is not clear what degree of alcohol consumption is safe, so many experts recommend complete abstinence from alcohol.

- No specific dietary measures are recommended.
- Patients who are not already immune to hepatitis A should be vaccinated against hepatitis A.
- Patients should be counseled on ways to avoid infection with hepatitis C.

Preventing transmission

All patients with HBV infection should receive individualized counseling on ways to reduce the risk of HBV transmission (including by sexual or needle-sharing behavior, perinatal routes, or household exposure), as appropriate.

Household members and sexual contacts should be vaccinated against HBV.

Women who are pregnant or considering pregnancy should consult with a specialist in both HBV and HIV to discuss ways of decreasing the infection risk for the fetus; this may include treatment for HBV and HIV. Infants born to coinfecting women should receive HBV immune globulin and start the HBV vaccine series within 12 hours after birth (with subsequent vaccine doses per usual protocol).

Patient Education

- Advise patients that most people with HBV will remain asymptomatic for several years. However, ongoing injury to the liver occurs during this time and can culminate in liver failure. Patients can slow the progression of damage by avoiding alcohol and any medications (including over-the-counter drugs and recreational drugs) that may damage the liver. Patients should contact their pharmacist or health care provider if they have questions about a specific medication or supplement.
- Advise patients that treatment for both HIV and HBV is recommended for anyone with HIV/HBV coinfection. ART can be used to treat both infections.
- As with HIV, patients must avoid passing HBV to others. Instruct patients not to share toothbrushes, dental appliances, razors, sex toys, tattoo equipment, injection equipment, or personal care items that may have blood on them. Emphasize to patients the importance of safer sex to protect themselves and their partners.
- Tell patients to discuss HBV with their sex partners, and suggest that partners be tested for HBV.
- Nonimmune sex partners and individuals in close contact with persons with chronic hepatitis B (e.g., family and household members) should be vaccinated.
- Pregnant women have a high risk of transmitting HIV or HBV to the fetus because each virus makes it easier to transmit the other. Women who are pregnant or considering pregnancy should talk with a specialist in HIV and HBV to discuss ways of decreasing the infection risk for the fetus.

- Advise patients who are on treatment for HBV that abrupt discontinuation of HBV treatment can cause a flare of HBV; they should not stop treatment without medical supervision.
- Certain ARV drugs are more likely than others to cause hepatotoxicity. Advise patients that their liver function should be monitored carefully if they start an ARV regimen, in order to determine whether the body is able to process the medicines.

Hepatitis C Infection

Rena K. Fox, MD

Background

In the United States, an estimated 2.7-3.9 million people are living with chronic hepatitis C virus (HCV) infection. Without treatment, 15% to 40% of persons living with the virus will develop cirrhosis or cancer, and HCV is the leading cause of liver transplantation in the United States. Hepatitis C-related mortality has been steadily increasing in recent years, and as the baby boomer generation ages, the rates of cirrhosis and hepatocellular carcinoma (HCC) are expected to rise.

As antiretroviral therapy (ART) has reduced AIDS-related mortality among HIV-infected patients, liver disease owing to HCV infection has become a leading cause of death and the sequelae of chronic HCV have increased. HCV is common among persons with HIV infection in the United States. It is estimated that 20-30% of the HIV-infected population in the United States is coinfecting with HCV, but the prevalence varies with risk factor for transmission. Among HIV-infected injection drug users and hemophiliacs, 70-95% may be coinfecting with HCV; among HIV-infected men who have sex with men (MSM), 1-12% are coinfecting with HCV. The U.S. Centers for Disease Control and Prevention and the U.S. Public Health Service recommend that all HIV-infected persons receive screening for HCV.

HCV is a single-stranded RNA virus that is transmitted mainly through blood exposure and, less commonly, through perinatal or sexual exposure. HCV is more likely than HIV to be transmitted via a bloodborne route; there is an approximately 10-fold greater risk of HCV transmission after needlestick exposure compared with the risk of HIV transmission, and the concentrations of HCV in a given volume of blood are greater than those of HIV. Perinatal transmission of HIV is more likely among women who are coinfecting with HIV and HCV than among women with HIV infection alone; similarly, perinatal transmission of HCV is more likely in coinfecting women than in those with HCV monoinfection. Breast-feeding is not known to transmit HCV, although HIV-infected women are advised against breast-feeding because of the risk of transmitting HIV.

Although sexual transmission of HCV is not efficient, 10% of acutely HCV-infected persons report no risk factor other than sexual contact with an HCV-infected partner. Many centers have reported an increase in acute HCV in MSM, and rates of sexual transmission of HCV appear to be higher in MSM than in the general population, especially among persons who are coinfecting with HIV. In HIV-infected MSM, outbreaks of acute HCV have been reported, with sexual activity as the risk factor for transmission. Risk factors associated with sexual transmission of HCV include the presence of coexisting sexually transmitted diseases, unprotected anal receptive sex, and use of recreational drugs.

The natural history of HCV infection is variable. Approximately 20% of monoinfected patients ultimately develop cirrhosis, whereas approximately 80% of patients develop some degree of fibrosis (without progression to cirrhosis); patients without cirrhosis typically remain asymptomatic. HCV can affect organ systems outside the liver, such as dermatological and renal systems, but its effects most commonly are limited to the liver. Coinfection with HIV adversely impacts the natural history of HCV infection. HIV/HCV-coinfecting patients have lower rates of spontaneous HCV clearance, higher HCV viral loads, lower rates of successful HCV treatment with interferon and ribavirin, faster progression to cirrhosis, and greater risk of developing liver decompensation, end-stage liver disease, and hepatocellular carcinoma (HCC). On the other hand, HCV coinfection does not appear to increase HIV- and AIDS-related complications or the success of HIV antiretroviral (ARV) treatment.

Acute HCV Infection

Persons with acute HCV infection typically are asymptomatic or have only mild symptoms. Patients who do present with new onset of jaundice, weakness, anorexia, abdominal pain, or malaise without a known cause should be tested for acute HCV infection. Symptoms usually subside after several weeks. Patients who present after a potential exposure, such as a needlestick injury, should be tested for acute infection whether or not they are symptomatic. Overall, approximately 15-30% of patients acutely infected with HCV will clear the virus spontaneously, and 70-85% of patients will develop chronic infection. However, there are few prospective studies on the natural history of acute HCV infection with preexisting HIV infection. Because it is difficult to establish the precise timing of HCV infection, prospective natural history studies are difficult to perform.

Chronic HCV Infection

For the majority of HCV patients, other than laboratory abnormalities, there are no clinical manifestations of infection until the late stages of cirrhosis. Cirrhosis develops in approximately 20% of HCV-monoinfected patients, usually 20 years or more from the time of infection. A higher proportion of HIV/HCV-coinfected patients are thought to develop cirrhosis, and at a faster rate. Once patients have developed cirrhosis, approximately 50% will decompensate within the first 5 years. Typically, the first sign of decompensation is the development of ascites. Of patients with cirrhosis, approximately 1-4% per year will develop HCC, or approximately 20% of cirrhotic patients in total. The median survival time from the onset of HCC is approximately 5 months, and the 1-year survival rate is 29%.

S: Subjective

Patients with HCV infection, whether acute or chronic, often have no symptoms, and the infection is discovered via screening tests or on workup of an abnormal liver test result. Patients with acute HCV infection typically are asymptomatic but may present with symptoms such as jaundice, abdominal pain, and malaise. If symptoms from acute infection develop, they usually do so within 4 weeks after infection has occurred. Most patients with chronic HCV cannot recall a time when they were acutely symptomatic, and HCV is detected because of an incidental finding of abnormal transaminases or through a screening test.

Ask patients with known chronic HCV infection about symptoms that suggest complications of HCV, such as cirrhosis, decompensated cirrhosis, or hepatocellular carcinoma. Additionally, ask patients about any risk factors for other liver injury, such as alcohol and hepatotoxic drugs, and about drugs whose metabolism may be affected by liver disease.

- Fatigue
- Weight loss
- Impaired concentration
- Chronic hepatitis B
- Alcohol intake
- Substance use
- ARVs that may cause hepatotoxicity (e.g., didanosine, protease inhibitors, nevirapine, maraviroc)
- Medications with potential for hepatotoxicity, or accumulation in persons with liver disease (e.g., acetaminophen, benzodiazepines, opiates)

O: Objective

Measure vital signs. Calculate body mass index (see chapter *Initial Physical Examination*).

Perform physical examination to include evaluation of the following:

- Head, eyes, ears, nose, and throat (HEENT): temporal wasting, icterus
- Heart and lungs: signs of congestive heart failure

- Chest: gynecomastia
- Abdomen: caput medusa, venous prominence, distention, signs of ascites, hepatomegaly, splenomegaly
- Extremities: edema
- Neurologic: alertness, mental status, asterixis
- Skin: jaundice, palmar erythema, petechiae, ecchymoses, spider angiomas

P: Plan

Diagnostic Evaluation

Acute HCV infection

After initial exposure, HCV RNA can be detected in blood within 1-3 weeks and is present at the onset of symptoms. Antibodies to HCV can be detected in only 50-70% of patients at the onset of symptoms, but in >90% after 3 months. Within an average of 4-12 weeks, liver cell injury is manifested by elevation of serum alanine aminotransferase (ALT). It is important to understand the timeline of these diagnostic tests in order to appropriately diagnose acute infection and follow for potential resolution versus persistent infection.

In patients with suspected acute HCV infection, check HCV antibody (IgG), HCV RNA, and ALT immediately and then weekly until the ALT has begun to decline and HCV antibody has seroconverted to positive status; consider checking interleukin-28B (IL28B) (see below). The seroconversion of HCV antibody establishes the diagnosis of acute infection. At that point, check the HCV RNA every 2-4 weeks for the following 3 months. If HCV RNA is still present at 3 months, strongly consider prompt initiation of treatment for acute HCV. If treatment is not initiated and RNA is still present at 6 months after infection, the likelihood of spontaneous clearance is extremely low, and the patient is diagnosed with chronic infection.

Chronic HCV Infection

The following tests are part of the evaluation of HCV infection.

HCV antibodies

All HIV-infected patients should be tested for HCV infection with the HCV antibody test. Patients with risk factors for HCV infection who test negative should be retested at regular intervals. A positive HCV antibody test result does not establish the diagnosis of active HCV infection but is evidence of exposure; HCV RNA must be checked (see below). In HIV-infected patients, the HCV antibody test result can be falsely negative, although this is rare. Therefore, if HCV infection is suspected in spite of a negative HCV antibody finding (e.g., because of a history of high-risk behavior, unexplained elevated ALT, or evidence of cirrhosis), the HCV RNA should be tested even if the HCV antibody result is negative.

HCV RNA

All patients who test positive for HCV antibody should have HCV RNA testing performed. As noted above, if patients have negative results on HCV antibody tests but persistently abnormal transaminases or suspected acute or chronic infection, HCV RNA testing should be performed.

The definition of chronic HCV infection is the presence of HCV RNA 6 months after the estimated time of infection. If a patient is HCV antibody positive but HCV RNA negative, the patient has cleared the HCV and does not have chronic HCV infection. False-positive HCV antibody results are possible but rare; they are more likely to occur in the setting of autoimmune disease.

There are quantitative RNA tests and qualitative RNA tests. Although both types of RNA tests are highly sensitive and specific, the qualitative tests can detect lower levels of viremia than the quantitative tests. The choice of RNA test can be important. The quantitative RNA tests will be reported as a value, with a measured

number of international units per milliliter (IU/mL). Quantitative tests are useful for determining the prognosis of HCV treatment and then monitoring while on HCV treatment. Qualitative RNA tests will be reported as a present or absent value, but without a numerical value. They are useful for serial testing during suspected acute infection and for determining whether spontaneous viral clearance has occurred, a sustained virological response has occurred during treatment, or a relapse has occurred after treatment.

Genotyping

There are six main HCV genotypes, numbered 1-6. Genotype 1 infections account for approximately 75% of HCV infections in the United States. In the absence of treatment, HCV genotypes are not associated with prognosis or progression of liver disease. However, the HCV genotype is one of the strongest predictors of response to HCV treatment and is a major factor in determining the appropriate treatment regimen for a patient. HCV genotyping should be performed once for all patients with detectable HCV RNA; it does not need to be repeated.

Subtyping

HCV genotypes are further divided by subtypes. Subtypes are termed 1a, 1b, 2a, 2b, among others. Subtypes are newly being recognized as predictors of treatment response, particularly with genotypes 1a and 1b. Additionally, a polymorphism, Q80K, in genotype 1a patients may become clinically significant in determining treatment regimens using some of the new HCV drugs.

IL28B testing

IL28B is a host genetic polymorphism on chromosome 19. Three different IL28B polymorphisms exist: C/C, C/T, and T/T. Patients with C/C type have higher rates of spontaneous clearance after acute HCV

infection, and much higher response rates to interferon-based HCV treatment, whereas patients with the C/T or T/T genotype have lower rates of spontaneous clearance and much lower response rates to treatment with interferon. With non-interferon-based regimens, the role of IL28B has not yet been determined. In regimens containing either sofosbuvir (with or without pegylated interferon) or simeprevir (with interferon), better response rates were seen in patients with IL28B CC than in those with non-CC types, but the differences were much less dramatic than in older regimens.

Alanine aminotransferase

Monitoring of ALT can be useful to assess acute infection, chronic liver inflammation, and response to HCV treatment. However, ALT does not always correlate with the degree of fibrosis; in addition, ALT can be persistently normal in 25% of HCV patients, including patients with cirrhosis or advanced liver disease. Small fluctuations in ALT usually are not clinically significant in HCV, though trends can be significant during or following HCV treatment.

Additional tests

Check complete blood cell count with platelet count, albumin, total bilirubin, and prothrombin time.

Test all patients for hepatitis B (HBsAg, anti-HBsAb, and anti-HBcAb). For patients with a positive HBsAg or a positive anti-HBcAb result (absent anti-HBsAb), test for active HBV infection (HBV DNA and HBeAg) (see chapter *Hepatitis B Infection*). Patients with a negative HBsAg and negative anti-HBsAb result should be vaccinated against HBV.

Test for hepatitis A virus (HAV) anti-bodies (IgG or total). All patients with a negative HAV antibody result should be vaccinated against HAV.

Imaging

Ultrasonography can be performed to screen for indications of cirrhosis or focal hepatic masses. Repeated ultrasound every 6 months to screen for HCC is recommended for patients with known cirrhosis or advanced fibrosis (stage 3). For noncirrhotic patients, regular repeated ultrasound is not recommended. Computed tomography (CT), magnetic resonance imaging (MRI), and single-photon emission computed tomography (SPECT) are more expensive and generally are reserved for further evaluation of liver masses detected by ultrasound.

Fibrosis staging

For any patient with HCV, it is useful to determine the degree of fibrosis (scarring) in the liver. Fibrosis stage is one of the most important pieces of information in determining a patient's need for HCV treatment. Fibrosis is scored from F0 to F4, with 0 indicating no fibrosis and F4 indicating cirrhosis.

Tools that may be used to determine the severity of chronic liver disease include biopsy, imaging, and serologic tests.

For HIV/HCV-coinfected patients, liver disease may progress quickly. A biopsy or other fibrosis test may be useful in determining the stage of disease and in planning whether or when to initiate HCV treatment. If the test reveals more advanced fibrosis or cirrhosis, treatment should be considered relatively urgently, using currently available therapeutics. Conversely, if the test reveals only mild-to-moderate fibrosis, it may be preferable to defer treatment and monitor the patient, particularly as more effective and more tolerable therapies are anticipated to become available within the next few years.

Liver biopsy

Liver biopsy is used to define the degree of inflammation (the grade) and degree of fibrosis (the stage) to determine the need for HCV treatment. Biopsy has been the gold

standard method, and is the main technique used in the United States. Liver biopsy carries some risk, primarily from bleeding (the risk of significant bleeding or fatality is approximately 1/10,000). Patients with severe thrombocytopenia or coagulopathy should not undergo liver biopsy.

As HCV therapies evolve and demonstrate higher response rates, a biopsy may prove less of a determinant of when to initiate treatment than in years past. At this time, with few directly acting agents (DAA) available, biopsy may still be useful for determining whether a patient can safely wait for more effective regimens.

Fibroscan

Several noninvasive tests to determine fibrosis have been developed. Fibroscan (elastography) is a radiology test used to assesses liver shear wave speed (expressed in meters per second) and equivalent stiffness (expressed in kilopascal) in a rapid, simple, noninvasive, and painless way. The FDA approved the Fibroscan in 2013. For diagnosing cirrhosis (stage F4), the sensitivity and specificity were 87% and 91%, respectively, whereas for diagnosing moderate stages of fibrosis (F2-F3), the sensitivity and specificity were 70% and 84%, respectively.

Serologic tests

Several different scoring systems have been developed to estimate the degree of liver fibrosis based on serum biomarkers and other patient factors. For example, the Fibrosure test uses the measurements of alpha-2-macroglobulin, alpha-2-globulin (haptoglobin), gammaglobulin, apolipoprotein A1, GGT, and total bilirubin, as well as the age and sex of the patient. The currently available serologic tests are not as accurate as liver biopsy in distinguishing different stages of fibrosis, and none of these have been FDA approved.

Treatment

Overview of the Treatment of HCV

The goal of HCV treatment is to clear the HCV RNA from the bloodstream – making the virus undetectable – in order to slow or halt inflammation, fibrosis, and progression of liver disease, and to reduce risk of cirrhosis and HCC. Treatment success is defined as a sustained virological response (SVR). SVR is achieved when the HCV RNA becomes undetectable during treatment and remains undetectable after the completion of treatment. Originally, SVR was defined as the absence of HCV RNA 24 weeks (“SVR24”) after the completion of treatment. SVR12 (12 weeks after the end of treatment) is 99% predictive of SVR24, so recent studies often report this as the outcome measure. SVR correlates with clinical outcomes such as decreased risk of decompensation, decreased risk of HCC, and decreased risk of liver-related death. Most experts consider SVR to represent “cure” of HCV. It is important, however, to remember that this is a cure of the chronic viral hepatitis infection, but it is not the same as “curing” the damage to the liver.

Pegylated interferon and ribavirin

The standard of care in the treatment of chronic HCV from 2001 to 2011 was the combination of pegylated interferon (PEG-IFN) alfa-2a and ribavirin, for both HCV-monoinfected and HIV/HCV-coinfected patients. Response rates varied by host and viral factors, among them HIV coinfection, HCV genotype, stage of liver disease, HCV viral load, race/ethnicity, and IL28B type. Overall, HCV-monoinfected genotype 1 patients have had SVR rates of 42-46% and monoinfected genotype 2/3 patients have had SVR rates of 70-80% with PEG-IFN + ribavirin. HIV/HCV-coinfected patients have had much lower response rates, in the range of 14-38%. Treatment was limited by these poor response rates as well as by multiple complete

and relative contraindications to interferon or ribavirin, multiple side effects of both drugs but especially interferon, and the cost and complexity of care for both patients and providers.

Telaprevir and Boceprevir

In 2011, the HCV protease inhibitors boceprevir and telaprevir were approved for genotype 1 HCV. These were the first direct acting antivirals (DAAs) available for treatment of HCV. With use of these agents in combination with PEG-IFN and ribavirin, treatment response rates in HCV-monoinfected genotype 1 patients were much higher than with PEG-IFN + ribavirin alone. In HIV/HCV-coinfected patients, smaller studies of boceprevir and telaprevir (plus PEG-IFN and ribavirin) have shown SVRs in the range of 60-75%, substantially higher than with standard therapy. These triple-therapy regimens, however, are complex and burdened with adverse effects and drug interactions.

Sofosbuvir

Sofosbuvir is an HCV polymerase inhibitor that was FDA approved in late 2013 for treatment of HCV in both HIV-coinfected and HCV-monoinfected patients with genotypes 1-4. It is approved for use with ribavirin alone (for genotypes 2 and 3) or with PEG-IFN + ribavirin (for most patients with genotypes 1 and 4), using specific protocols. It also is being studied in combination with other HCV medications, including in several interferon-free regimens. Use of sofosbuvir-containing regimens has resulted in very high SVR rates (80% to >90%) with 12 or 24 weeks of therapy, in both treatment-experienced and treatment-naive patients and in cirrhotic patients. Few significant drug-drug interactions with ARVs have been identified.

Simeprevir

Simeprevir is a HCV protease inhibitor that was FDA approved in late 2013 for treatment of genotype 1 HCV, in combination with PEG-IFN and ribavirin. Study data have shown SVR rates of 82% in treatment-naïve genotype 1 noncirrhotic patients and 58-65% in cirrhotic individuals treated with simeprevir + PEG-IFN + ribavirin. Among patients with the IL28B CC type, 95% achieved SVR. Simeprevir also is being studied in interferon-free regimens.

Simeprevir has markedly reduced efficacy in patients with the Q80K polymorphism, and screening for this is recommended before treatment. Simeprevir also has significant drug-drug interactions with some ARVs, in particular many protease inhibitors, nonnucleoside reverse transcriptase inhibitors, and the pharmacokinetic enhancer cobicistat.

Expansion of DAAs

In 2014-15, several additional HCV DAAs and combinations of DAAs are expected to be considered for FDA approval; many have the potential to be used in regimens that do not include interferon.

Treatment of acute HCV

As mentioned above, in the setting of acute HCV infection, RNA should be tested repeatedly for 12 weeks from the time of infection to ascertain whether spontaneous clearance will occur. If RNA is still present at 12 weeks, treatment should be offered.

With HIV/HCV-coinfected patients, as with HCV-monoinfected patients, early treatment of acute HCV infection yields a much higher rate of SVR than does treatment of chronic HCV infection. In three prospective trials of treatment for acute HCV in HIV-coinfected patients, using PEG-IFN + ribavirin for 24 or 48 weeks, the SVR for genotype 1 HCV was 55-75%, and 100% for genotype 3. By contrast, in the largest study of the same regimen for

chronic HCV treatment in HIV-coinfected patients (n = 868), the SVR was about 29% for genotype 1 and 62% for genotype 2 or 3. Currently, there are no data on the efficacy of DAAs to treat acute HCV infection in HIV-coinfected patients. Given the relatively high SVR rates that result from treatment of acute HCV with pegylated interferon and ribavirin, and the absence of data in this setting, it is not routinely recommended to use DAAs in acute coinfection at this time.

Treatment of chronic HCV

HIV coinfection is a strong indication for treatment of chronic HCV infection, because the risk of accelerated fibrosis and cirrhosis is higher for coinfecting patients. HIV-infected patients with low CD4 cell counts should not be excluded from HCV treatment on the basis of CD4 count alone; this is true particularly for patients already on ART. For timing of HCV treatment, see “Timing of HCV treatment and HIV treatment,” below. Traditional treatment of chronic HCV infection in HIV/HCV-coinfected patients with PEG-IFN + ribavirin yields lower rates of SVR than does treatment of monoinfected patients (see above), but use of newer anti-HCV medications has improved the treatment outcomes in coinfecting patients.

Patients with a high risk of progression to cirrhosis, including coinfecting patients, should receive higher priority for treatment. Patients who have developed cirrhosis but remain compensated should be treated as soon as possible if they otherwise are candidates. Patients with decompensated liver disease should not receive HCV treatment (the likely risks of treatment outweigh potential benefits); appropriate candidates can be considered for liver transplantation. Many patients with minimal fibrosis may be best served by deferring treatment, pending availability of more effective and tolerable therapy options.

Current guidelines recommend treatment of HCV genotype-1-coinfected patients with PEG-IFN + ribavirin + an HCV protease

inhibitor for 48 weeks; because of potential drug interactions between HCV protease inhibitors and antiretroviral medications, the selection of HCV protease inhibitor and ARV drugs must be made with great care (see “Drug Interactions,” below). HCV genotypes 2-6 should be treated with PEG-IFN + ribavirin. However, as discussed above, the recent FDA approval of new DAA agents and the anticipated approval of others means that the paradigm for HCV treatment is in flux. It is anticipated that currently available and anticipated HCV drugs will be combined to construct a number of effective regimens (including all-oral and “interferon-free” regimens) that can be tailored to the treatment needs of particular patients. Based on current data, the emerging era of HCV treatment is expected to be one of higher response rates, lower side-effect profiles, and perhaps shorter courses of treatment.

To determine an appropriate treatment regimen, consultation with a specialist is recommended.

HCV Directly Acting Antivirals: Classes and Agents

FDA approved:

Protease Inhibitors (NS3/4a)

- Boceprevir
- Telaprevir
- Simeprevir

Nucleoside Polymerase Inhibitors:

- Sofosbuvir

Classes with Agents under Investigation

- Protease Inhibitors (NS3/4a)
- Nucleoside Polymerase Inhibitors
- NS5A Inhibitors
- Nonnucleoside Polymerase Inhibitors

Drug Interactions

HCV protease inhibitors and other DAAs may have significant interactions with certain HIV ARVs, particularly with protease inhibitors, nonnucleoside reverse transcriptase inhibitors, and the pharmacokinetic booster cobicistat. Interactions between many DAAs and ARVs have not been studied. Known and expected drug-drug interactions need to be carefully considered before selecting an HCV treatment regimen. Consult with HIV, HCV, and clinical pharmacy specialists. Table 2 shows potential DAA-ARV interactions, based on currently available data.

Table 2. Characteristics of Directly Acting Agents and Potential Interactions with ARVs

DAA	Mechanism	Activity Against HCV Genotype	Barrier to Resistance	Potential ARV Interactions
Telaprevir	NS3/4A protease inhibitor	1	Low	- Contraindicated with all protease inhibitors except atazanavir/ritonavir - Contraindicated with elvitegravir/cobicistat - Requires increased dosage when administered with efavirenz - No dosage adjustment when used with raltegravir
Boceprevir	NS3/4A protease inhibitor	1	Low	Contraindicated with all protease inhibitors, and with efavirenz and elvitegravir/cobicistat
Simeprevir	NS3/4A protease inhibitor	1, 2, 4, 5, 6	Low	- Concentrations decreased by efavirenz, and may be decreased by etravirine and nevirapine; should not be given with these NNRTIs - Concentrations increased by darunavir/ritonavir, ritonavir, and cobicistat; should not be given with any PI or cobicistat - No clinically significant interactions with raltegravir, rilpivirine, tenofovir
Sofosbuvir	NS5B RNA polymerase inhibitor	1-6	High	- Concentrations decreased by tipranavir/ritonavir - No known clinically significant interactions with other ARVs

Adverse effects of treatment

IFN can cause fatigue, flulike symptoms, thrombocytopenia, nausea, depression, hair loss, weight changes, and many other potential side effects. IFN reduces total white blood cell counts, and can cause neutropenia. It also decreases CD4 cell counts, although the CD4 percentage usually does not change. IFN can reduce HIV RNA somewhat (by approximately 0.5 log₁₀ copies/mL).

Ribavirin can cause a hemolytic anemia, sore throat, cough, and other side effects. Zidovudine and didanosine should be avoided with patients taking ribavirin, because of the risk of compounded toxicities (anemia with zidovudine, neuropathy, lactic acidosis, liver toxicity, and pancreatitis with didanosine).

The side effects of boceprevir and telaprevir can include anemia, rash, and altered taste; telaprevir also can cause anorectal discomfort. The most commonly reported adverse effects of sofosbuvir + ribavirin regimens were fatigue, headache, insomnia, and nausea. In treatment arms containing sofosbuvir + PEG-IFN + ribavirin, side effects were similar to those reported with PEG-IFN + ribavirin, with the exception of increased rates of fatigue and nausea. The addition of simeprevir to PEG-IFN + ribavirin resulted in an increased incidence of rash including photosensitivity, pruritus, nausea, dyspnea, and hyperbilirubinemia.

HCV treatment should not be given during pregnancy, and women receiving HCV treatment should avoid pregnancy. IFN may cause fetal growth abnormalities, and

it is abortifacient in animals. Ribavirin is teratogenic, and both women and men must use two forms of contraception consistently during treatment with ribavirin and for 6 months after discontinuation of treatment. Boceprevir and telaprevir are FDA Pregnancy Category B drugs but must be used with PEG-IFN and ribavirin, which are not recommended.

Timing of HCV treatment and HIV treatment

The decision of whether and when to treat HCV among people infected with HIV must be made on an individual basis. When coinfecting patients require treatment for both infections, some experts begin with HIV treatment based on limited data that improved CD4 cell counts will enhance the response to HCV therapy, and this generally is recommended for patients with CD4 counts of <350 cells/ μ L. With patients who do not require ART urgently (e.g., because their CD4 counts are very high), consideration could be given to treating HCV first, with ART delayed until after completion of HCV treatment. This strategy is intended to simplify treatment and improve the tolerability of both therapies, though it brings the risk of HIV disease progression during HCV treatment. Patients already on ART generally should remain on ART throughout the course of HCV treatment, though regimens should be evaluated for adverse drug interactions with HCV drugs (e.g., with boceprevir and telaprevir). Consult with an HCV treatment expert to determine the appropriateness and timing of HCV treatment.

Some patients with HCV will experience worsening of hepatic function during ART, and liver function should be monitored closely. Some ARV medications are hepatotoxic and should be avoided or used cautiously; these include nevirapine, tipranavir, and high-dose ritonavir. Numerous other medications (e.g., fluconazole and isoniazid) are hepatotoxic and can pose problems for patients with impaired liver function.

Other care issues

Acute HAV or HBV infection in persons with chronic HCV can cause fulminant liver disease. All patients with HCV infection should be tested for immunity to HAV and HBV; patients who are not immune should be vaccinated.

Persons with HCV infection should be counseled to avoid exposure to hepatotoxins, including alcohol and hepatotoxic medications (e.g., acetaminophen in dosages >2 g per day, fluconazole, and isoniazid).

As appropriate, all persons with hepatitis C should receive individualized counseling on ways to reduce the risk of infecting others with HCV (including by unprotected sex, by sharing of injection drug equipment, other blood exposures [e.g., from sharing razors or tattoo equipment], and perinatal exposure).

Patient Education

- Advise patients that most people with HCV will be asymptomatic for many years and may never develop symptoms. However, slow progression of fibrosis can be happening in the absence of symptoms and can progress to cirrhosis, so ongoing monitoring is important.
- Patients can slow the development of fibrosis by avoiding alcohol and obesity, as fat in the liver can add to the liver damage.
- As with HIV, patients must avoid passing HCV to others. Emphasize the importance of safer sex to protect themselves as well as their partners. Instruct patients not to share toothbrushes, dental appliances, razors, sex toys, tattoo equipment, injection equipment, or personal care items that may have blood on them.
- Tell patients to discuss HCV with their sex partners and suggest that partners be tested for HCV.
- Women who are pregnant or considering pregnancy should talk with a specialist in HIV and HCV to discuss ways of decreasing the risk of perinatal transmission.
- HCV is not spread by coughing, sneezing, hugging, sharing food and water, or other casual contact.
- HAV can cause severe illness, liver damage, or even death in people with HCV. Patients who are not immune to HAV need to receive the two-part hepatitis A vaccination series.
- HBV can worsen liver function greatly if it is acquired in addition to HCV. Patients who are not immune to HBV need to receive the three-part hepatitis B vaccination series. If patients have been vaccinated in the past, they should have a blood test to confirm immunity.
- HCV treatment aims to clear the HCV virus from the body. That reduces risk of cirrhosis, end-stage liver disease, hepatocellular carcinoma, and liver-related death.
- HCV treatment is rapidly evolving and it is anticipated that several new regimens will be available over the next few years (2014-15). Each patient should talk to his or her health care provider about whether treatment is appropriate.
- Standard HCV treatment until 2011 included two drugs used together, pegylated interferon-alfa and ribavirin, for all patients being treated. In 2011, for genotype 1 patients, boceprevir or telaprevir became available to be used to create a triple-therapy regimen.
- In late 2013, simeprevir was FDA approved for use in combination with pegylated interferon and ribavirin for genotype 1 and 4 patients and sofosbuvir was approved for use in combination with pegylated interferon and ribavirin for genotype 1 patients and for use with ribavirin alone (interferon-free) in genotype 2 or 3 patients and some genotype 1 and 4 patients.
- Pegylated interferon can cause many side effects, including flulike symptoms, body aches, fevers, leukopenia, neuropathy, and depression. Most of these adverse effects are treatable with medications and resolve after therapy is completed.
- Ribavirin can cause side effects including rash, sore throat, and anemia.
- Multiple drug interactions are a concern for direct acting antivirals, including HIV medications. Drug-drug interactions need to be carefully considered before starting HCV treatment and choosing which HCV treatment is right for each patient.
- It is essential that both men and women who are taking ribavirin should use two forms of contraception consistently during ribavirin therapy and for 6 months after completion of treatment.

Herpes Simplex, Mucocutaneous

Background

Herpes simplex virus (HSV) types 1 and 2 cause both primary and recurrent oral and genital disease. HSV usually appears as a vesicular eruption of the mucous membranes of the oral or perioral area, vulva, perianal skin, rectum, and occasionally the inguinal or buttock areas. The eruption develops into tender or painful ulcerated lesions that frequently are covered with a clear yellow crust. In some patients, however, the typical painful vesicular or ulcerative lesions may be absent. Persons with HIV disease and low CD4 cell counts have more frequent recurrences of HSV and more extensive ulcerations than do HIV-uninfected people. Persistent HSV eruption (lasting >1 month) is an AIDS-indicator diagnosis. HSV facilitates HIV transmission.

S: Subjective

The patient may complain of eruption of red, painful vesicles or ulcers (“fever blisters”) with or without an exudate in the mouth, on the lips (and occasionally in nares), on the genitals, or in the perianal area. The patient may complain of burning, tingling, or itching before eruption of the lesions. In the genital area, symptoms may be nonspecific without any eruption of lesions; most HSV type 1 and 2 infections are asymptomatic, yet virus still can be shed.

The vesicles will rupture and ulcerate, generally crusting over and healing in approximately 7-14 days. The lesions may be pruritic and are often painful. As immunosuppression progresses, the lesions may recur more frequently, grow larger or coalesce, and become chronic and nonhealing.

Perform a history, asking the patient about the symptoms described above, duration, associated symptoms, and history of oral or genital HSV infection.

O: Objective

Look for grouped vesicular or ulcerative lesions on an erythematous base on the mouth, anus, or external genitals, or ones that are visible on speculum or anoscopic examination. When immunosuppression is severe, lesions may coalesce into large, painful, and nonhealing

ulcerations that spread to the skin of the thighs, lips, face, or perirectal region. These chronic erosive lesions may be confused with a chronic bacterial infection or decubitus ulcer, and should prompt consideration of acyclovir-resistant HSV infection. Recurrent lesions may start atypically, first appearing as a fissure, pustule, or abrasion.

A: Assessment

A partial differential diagnosis includes the following:

- Oral: Oral aphthous ulcers
- Genital: Chancroid, syphilis, cytomegalovirus, candidiasis, drug-related eruption, trauma

P: Plan

Diagnostic Evaluation

A clinical diagnosis of HSV can be made on the basis of the patient’s symptoms and clinical appearance only if vesicles and constitutional symptoms are present, but symptoms and signs may be variable, and primary syphilis always must be ruled out. Also, HSV-1 (rather than HSV-2) is increasingly the cause of initial episodes of anogenital herpes. For these reasons, current guidelines recommend laboratory testing to establish the diagnosis of HSV and to determine its type.

For cell culture or polymerase chain reaction (PCR), obtain a specimen from a freshly opened vesicle or the base of an ulcer for culture confirmation. Note that lesions that are >72 hours old or are beginning to resolve may not show HSV in culture. Tzanck smears are not sensitive or specific.

PCR is more sensitive for detection of herpes DNA in ulcerative lesions, but is more expensive to perform and is less widely available than viral culture. If virologic test results are positive, typing should be performed to determine the type of HSV. Negative results do not rule out the possibility of HSV infection.

If cultures are negative, a sample can be taken from a fresh lesion for another culture or for PCR. In addition, type-specific serologic tests may be useful in the evaluation of symptomatic patients in whom a diagnosis of genital HSV is not clear. Current sexually transmitted disease (STD) guidelines also recommend that serologic testing be considered for HIV-infected individuals, for MSM at risk of HIV infection, and for those who present for STD evaluation if there is no history of past genital HSV diagnosis. Glycoprotein G (gG)-based serologic assays are recommended, as older assays do not reliably differentiate HSV-1 antibody from HSV-2 antibody.

In any patient who presents with genital, anal, or oral ulceration, even if the suspicion of HSV is high, syphilis serologic testing (rapid plasma reagin [RPR], Venereal Disease Research Laboratory [VDRL], enzyme immunoassay [EIA], or chemiluminescent immunoassay [CIA]) should be done (see chapter *Syphilis*).

Treatment

Empiric antiviral treatment for new-onset suspicious lesions may be initiated in the absence of laboratory confirmation, especially if symptoms are significant. Dosage reduction of the antivirals is required for patients with renal impairment.

Note: treatment recommendations reflect current CDC/NIH/IDSA opportunistic infections guidelines; the CDC STD guideline recommendations are slightly different (see “References,” below).

Orolabial lesions (5-10 days) or genital lesions (5-14 days)

- Valacyclovir 1,000 mg PO BID
- Famciclovir 500 mg PO BID
- Acyclovir 400 mg PO TID

Severe mucocutaneous HSV disease

Treat initially with acyclovir 5 mg/kg IV Q8H until the lesions have started to regress, then an oral HSV antiviral agent (as above) until all lesions have healed.

Suppressive therapy

Consider suppressive therapy for patients with frequent or severe recurrences and those with HSV-2. Treatment may be continued indefinitely. If acyclovir is used, its dosage may need to be increased to 800 mg BID or TID for individuals whose HSV episodes are not adequately suppressed by 400 mg BID. Suppressive therapy using valacyclovir reduces the risk of HSV transmission between HIV-uninfected heterosexual partners but the extent to which this is true in HIV-infected persons is unknown. Effective antiretroviral therapy (ART) also may reduce the frequency of HSV outbreaks.

- Valacyclovir 500 mg PO BID
- Famciclovir 500 mg PO BID
- Acyclovir 400 mg PO BID

Acyclovir-resistant HSV

The diagnosis of acyclovir-resistant HSV should be suspected if lesions fail to respond to 7-10 days of standard therapy and should be confirmed with culture and sensitivities. Cross-resistance to valacyclovir and ganciclovir will be present, and cross-resistance to famciclovir is likely. The usual alternative treatment is foscarnet (40 mg/kg IV Q8H); other possibilities include IV cidofovir, topical imiquimod, topical trifluridine, and topical cidofovir. An infectious disease or HIV specialist should be consulted.

HSV During Pregnancy

Acyclovir appears to be safe and effective for use by pregnant women and remains the drug of choice. Few data are available on the use of valacyclovir and famciclovir during pregnancy but they appear to be safe.

It is important to avoid peripartum transmission of HSV. For women with recurrent or new genital HSV late in pregnancy, obstetric or infectious disease specialists should be consulted, and suppressive therapy with valacyclovir or acyclovir is recommended. All women should be evaluated carefully for symptoms and signs of genital HSV at delivery.

Patient Education

- Patients should be told that HSV has no cure, but treatment can decrease symptoms and recurrences. Treatment also has been shown to decrease shedding and HSV transmission in HIV-uninfected discordant couples, but it has not been studied in HIV-infected couples. Outbreaks and viral shedding may occur at intervals for the rest of their lives but frequency generally decreases with age of infection.
- HSV may be spread through kissing (if mouth or lips are infected) and sexual contact (oral, anal, or vaginal). Most HSV is transmitted when no genital lesions are present, so it is important that patients inform their sex partners of their herpes infection before sexual activity. Patients must avoid all sexual contact when lesions are visible, because a high volume of virus is present at those times. Correct use of condoms at each sexual encounter reduces the risk of HSV transmission.
- All patients with genital HSV should be encouraged to inform their partners.
- Episodic treatment is most effective when taken early in the outbreak, so patients not taking suppressive therapy should keep medication on hand and start treatment at the first signs of a prodrome or eruption.
- Genital HSV in a pregnant woman around the time of delivery can cause severe illness in the newborn. Women should inform their obstetrician and pediatrician if they have a history of HSV or are exposed to or infected with HSV during pregnancy. Pregnant women who do not have HSV should avoid sexual practices that facilitate HSV transmission in the third trimester with partners who have HSV, and men who have HSV should avoid sexual practices that facilitate HSV transmission with pregnant women in their third trimester who do not have HSV.

Herpes Zoster/Shingles

Background

Shingles is a skin or mucosal infection caused by the varicella-zoster virus (VZV) that occurs along a dermatome and represents a reactivation of varicella (chickenpox). Zoster is common in patients with HIV infection, including apparently healthy individuals before the onset of other HIV-related symptoms. The incidence may be higher among patients with low CD4 cell counts and during the 4 months after initiating potent antiretroviral therapy.

Zoster may be particularly painful or necrotic in HIV-infected individuals. Disseminated infection, defined as outbreaks with >20 vesicles outside the primary and immediately adjacent dermatomes, usually involves the skin and the visceral organs. Neurologic complications of zoster include encephalitis, aseptic meningitis, cranial nerve palsies, optic neuritis, transverse myelitis, and vasculitic stroke.

S: Subjective

The patient complains of painful skin blisters or ulcerations along one side of the face or body. Loss of vision may accompany the appearance of facial lesions. Pain in a dermatomal distribution may precede the appearance of lesions by many days (prodrome).

Assess the following during the history:

- Duration of pain or blisters (average of 2-3 weeks if untreated)
- Location of pain or blisters; severity of pain
- History of chickenpox (usually in childhood)

O: Objective

Perform a skin and neurologic examination to include the following:

- Vesicular lesions with erythematous bases in a dermatomal distribution; may be bullous or hemorrhagic
- Necrotic lesions; may persist for as long as 6 weeks
- Dermatomal scarring (particularly in dark-skinned individuals)
- Lesions in the eye area or tip of nose,

along the trigeminal nerve; these represent ophthalmic nerve involvement, which requires immediate evaluation and IV treatment (see below)

A: Assessment

- Rule out other causes of vesicular skin eruptions (e.g., herpes simplex virus, severe drug reactions).
- Assess contact exposures (see below).

P: Plan

Diagnostic Evaluation

The diagnosis usually is clinical and is based on the characteristic appearance and distribution of lesions. If the diagnosis is uncertain, perform viral cultures or direct fluorescent antigen or polymerase chain reaction test of samples from a freshly opened vesicle or biopsy from the border of a lesion.

Treatment

- Treatment ideally should begin within 72 hours of an outbreak or while lesions are not yet fully crusted and should be continued for 7-10 days. Early treatment may attenuate a herpes zoster attack.

Localized dermatomal zoster**• Preferred therapy**

- Valacyclovir 1 g PO TID
- Famciclovir 500 mg PO TID

• Alternative therapy

- Acyclovir 800 mg PO 5 times daily
- Dosage reductions of these drugs are required for patients with renal impairment.
- If new blisters are still appearing at the end of treatment, repeat course of PO therapy or consider IV treatment. Adjunctive corticosteroids aimed at preventing postherpetic neuralgia are not recommended.
- Consult an ophthalmologist immediately if lesions appear in the eye area or on the tip of the nose, or if the patient complains of visual disturbances, because VZV-related retinal necrosis can cause blindness. Because of the rapid progression associated with this diagnosis, hospitalization for administration of IV acyclovir and possibly foscarnet is recommended.
- VZV from zoster lesions is contagious, and contact or airborne spread from vesicle fluid may cause chickenpox in nonimmune people. If a zoster patient's household includes a pregnant woman (HIV infected or uninfected) or an HIV-infected child, consult with a specialist immediately for advice on management of exposed household members. (See "Postcontact Chickenpox Prevention," below.)
- Give analgesics for pain; narcotics may be required.
- Postherpetic neuralgia (PHN) is a common sequela of zoster. Antiviral therapy may reduce the risk of PHN, but PHN often requires special treatment for pain control. Treatment options include:
 - Nortriptyline 10-25 mg. To be taken at bedtime and increased by 25 mg every 3-5 days to a maximum dosage of 150 mg QD

until pain is controlled, assuming adverse effects remain tolerable. Other tricyclics may be used.

- Gabapentin 100-300 mg PO BID; this may be increased by 300 mg every 3 days until reaching 3,600 mg total daily dosage. Adjust gabapentin dosage in patients with kidney disease.
- Pregabalin 75 mg BID (or 50 mg TID) in patients with estimated creatinine clearance of >60 mL/minute; this may be increased to 300 mg total daily dosage over the course of a week as needed.
- Lidocaine 5% patches provide good local relief with minimal systemic absorption. Up to 3 patches may be applied simultaneously to the affected area for up to 12 hours in a 24-hour period.
- Capsaicin cream may be applied to the affected area TID or QID. Patients should wear gloves to apply the cream and wash their hands with soap and water afterward.
- Sustained-release opiates may be required.

(See chapter *Pain Syndrome and Peripheral Neuropathy* for more options and specific recommendations.)

Severe or unresponsive cases

- IV acyclovir may be indicated if:
 - The patient is severely immunocompromised
 - The ophthalmic branch of the trigeminal nerve is affected (as noted above)
 - Dissemination has occurred; visceral disease is suspected
 - Lesions are extensive
 - Lesions are not responsive to oral therapy
 - Pain is intractable in the setting of active skin lesions
- The usual adult dosage is 10-15 mg/kg Q8H for 7-14 days based on clinical response; can switch to oral therapy when signs/symptoms are improving. Dosage reduction is required

for patients with renal impairment. Refer to an infectious disease specialist.

- Acyclovir resistance may occur in patients previously treated with acyclovir or related drugs, and foscarnet may be required for effective treatment. Resistance should be suspected if lesions are not resolving after 10 days of therapy or if they develop an atypical appearance. Such lesions should be cultured and drug sensitivities should be obtained.

Prevention

The vaccine for prevention of herpes zoster (Zostavax) has not been recommended by national guidelines for use in persons with HIV infection. Limited data in HIV-infected individuals with CD4 counts of >200 cells/ μL show safety and immunogenicity. The zoster vaccination may be considered for select patients >50 years of age with CD4 counts of >200 cells/ μL who have evidence of varicella immunity (if they have no evidence of varicella immunity, give the primary varicella vaccination). The vaccine is contraindicated in persons with AIDS or clinical manifestations of HIV.

Postcontact Chickenpox Prevention

All HIV-infected susceptible persons, including pregnant women, who have close contact with a patient who has chickenpox or zoster must be treated to prevent chickenpox. Exposed individuals who have no history of chickenpox or shingles or no detectable antibody against VZV should be administered varicella-zoster immune globulin (VariZIG) as soon as possible, but at least within 10 days after contact. Some experts also would

recommend varicella vaccination for exposed patients with CD4 counts of ≥ 200 cells/ μL , or preemptive treatment with acyclovir or valacyclovir; these approaches have not been studied in HIV-infected persons. Even immunocompetent adults with primary VZV (chickenpox) can develop viral dissemination to the visceral organs. HIV-infected patients may develop encephalitis, pneumonia, or polyradiculopathy during primary varicella (chickenpox) or reactivated zoster (shingles).

Patient Education

- Patients should bathe the skin lesions in mild soap and water. For necrotic lesions, use warm, moist compresses 2-3 times a day to remove debris.
- Antibiotic ointments may help prevent secondary infection and keep dressings from sticking.
- Advise patients to take their medications as directed, and to contact the clinic if symptoms worsen.

Histoplasmosis

Background

Histoplasmosis is caused by *Histoplasma capsulatum*, a fungus that thrives in soil contaminated by droppings from birds and bats. In the United States, *H. capsulatum* is found most often along the Ohio and Mississippi River Valleys, in the central, mid-Atlantic, and south-central states, and from Alabama to southwest Texas. In highly prevalent areas, such as Indianapolis and Kansas City, more than 80% of the population has been exposed to *Histoplasma* through inhalation of airborne infectious elements. Histoplasmosis also is found in the Canadian provinces of Quebec and Ontario, Puerto Rico, Mexico, Central and South America, Africa, East Asia, and Australia.

The initial infection in most cases either produces no symptoms or manifests only as a mild flulike illness. However, immunosuppressed individuals may develop disseminated disease. Progressive disseminated histoplasmosis often represents a reactivation of latent infection, occurs late in the course of HIV disease (the CD4 count usually is <150 cells/ μ L), and is an AIDS-defining illness. Pulmonary histoplasmosis (without dissemination) may occur in people with higher CD4 counts. Within endemic areas, histoplasmosis accounts for 5% of opportunistic infections among patients with AIDS. In hyperendemic areas, the prevalence of histoplasmosis may reach 25% among AIDS patients. The incidence of histoplasmosis in the United States has declined with the use of effective antiretroviral therapy (ART).

Common clinical features that may be associated with histoplasmosis are shown in Table 1.

S: Subjective

Histoplasmosis may be difficult to diagnose because the symptoms are nonspecific. In addition, clinicians may not consider this diagnosis in low-prevalence areas.

Patients may experience fever, weight loss, fatigue, cough, and shortness of breath. They also may develop skin lesions, adenopathy, central nervous system (CNS) changes, oropharyngeal ulcers, nausea, diarrhea, and abdominal pain. Symptoms usually begin several weeks before patients present for care. On occasion, histoplasmosis presents abruptly as a sepsis-like syndrome.

Ask the patient about possible exposures, but note that absence of reported exposures does not rule out histoplasmosis. The following are associated with significant risk of exposure:

- Residence or travel in endemic areas (see above); in the United States, particularly the Ohio and Mississippi River Valleys
- Occupational history of farming or construction/remodeling
- Hobbies that involve contact with caves, bird roosts or nests, or farm areas
- Contact with soil having a high organic content and undisturbed bird droppings, such as that found around old chicken coops and bird roosts

Table 1. Common Clinical Manifestations of Histoplasmosis

Symptom Group	Percentage of Cases	Examples
Constitutional	95%	- Weight loss - Fatigue - Fever
Gastrointestinal	>10%	- Splenomegaly - Diarrhea - Hepatomegaly - Abdominal pain
Respiratory	50-60%	- Pneumonia - Pneumonitis
Hematologic	>50%	- Anemia - Thrombocytopenia - Leukopenia
Neurologic	15-20%	- Meningitis, cerebritis - Focal parenchymal lesions - Encephalopathy
Septic	10-20%	- Hypotension - Disseminated intravascular coagulopathy - Respiratory insufficiency - High fever - Renal or hepatic failure
Dermatologic	<10%	Follicular, pustular, maculopapular, or erythematous lesions

O: Objective

Measure vital signs and document fever.

Perform a complete physical examination, with special attention to the lymph nodes, lungs, abdomen, skin, and neurologic system.

Common findings include enlargement of the liver, spleen, and lymph nodes. Skin lesions and oropharyngeal ulcers may be seen.

A: Assessment

A partial differential diagnosis includes the following:

- Other deep-seated fungal infections, such as cryptococcosis and coccidioidomycosis
- Mycobacterial disease (*Mycobacterium tuberculosis* or *Mycobacterium avium* complex)
- *Pneumocystis* pneumonia
- Lymphoma

P: Plan

Diagnostic Evaluation

- The *H. capsulatum* antigen test is sensitive and specific. The test is most sensitive for urine samples (>95% in disseminated disease), but can be used on serum (>85% sensitive in disseminated disease), bronchial fluids, or cerebrospinal fluid (CSF) specimens. Results may be obtained in a few days' time. Urine antigen levels can be used to monitor the response to therapy.
- Cultures of blood, bone marrow, and specimens from other sources have reasonable sensitivity (about 85%), but obtaining results may take several weeks.
- Wright stain of the buffy coat of a blood specimen may reveal intracellular organisms.
- Biopsies of lymph nodes, liver, cutaneous lesions, and lungs may be diagnostic in up to 50% of cases; bone marrow can be stained with methenamine silver to show the organism within macrophages.

- Meningitis can be challenging to diagnose. Diagnostically, *Histoplasma* antigen or anti-*Histoplasma* antibodies can be detected in CSF in up to 70% of cases, whereas results for cultures are often negative. Nonspecific findings in the CSF include elevated protein and low glucose as well as a lymphocytic pleocytosis. A diagnosis of *Histoplasma* meningitis should be considered if the patient has known disseminated disease and other more common etiologies of meningitis have been ruled out.
- Lactate dehydrogenase (LDH) and ferritin, although not specific, may be markedly elevated in disseminated disease.
- Complete blood count and chemistry panels may show pancytopenia, elevated creatinine, or abnormal liver function.

Treatment

Treatment consists of two phases: induction and chronic maintenance. Treatment should be continued for at least 12 months.

Severe disseminated histoplasmosis

Severe infection requires IV induction therapy with a lipid formulation of amphotericin; standard amphotericin is less effective and is associated with more adverse effects, but may be used as an alternative.

- **Induction therapy (≥2 weeks or clinically improved):**
 - **Preferred:** Liposomal amphotericin B lipid formulation 3 mg/kg IV QD
 - **Alternatives:** Amphotericin B lipid complex or amphotericin B cholesteryl sulfate complex 3 mg/kg IV QD
- **Maintenance therapy:** After ≥2 weeks of therapy or improvement of the patient's clinical status, therapy may be switched to itraconazole 200 mg PO TID for 3 days, then BID for at least 12 months of therapy. Liquid formulation of itraconazole is preferred.

Histoplasma meningitis

Amphotericin B must be used because itraconazole has poor penetration into the CNS:

- **Induction therapy:** Liposomal amphotericin B 5 mg/kg QD for 4-6 weeks
- **Maintenance therapy:** Itraconazole 200 mg PO BID or TID for ≥12 months and until abnormal CSF findings resolve

Mild to moderate disseminated histoplasmosis without CNS involvement

- **Induction and maintenance therapy:** Itraconazole 200 mg PO TID for 3 days followed by itraconazole 200 mg BID for ≥12 months; liquid formulation of itraconazole is preferred

Pulmonary histoplasmosis in patients with CD4 counts of >300 cells/μL

Manage as for non-immunocompromised patients.

See “Potential ARV Interactions,” below, regarding azoles.

Long-term suppressive therapy

Long-term therapy must be given to prevent relapse after 12 months of initial treatment; preferred therapy consists of itraconazole 200 mg PO QD. Fluconazole 800 mg QD is less effective but can be used as an alternative for patients who cannot tolerate or cannot obtain itraconazole. Voriconazole and posaconazole appear to be effective. (See “Potential ARV Interactions,” below, regarding azoles.)

Few data support the discontinuation of chronic maintenance therapy. One small study sponsored by the AIDS Clinical Trials Group demonstrated safety in discontinuing suppressive itraconazole therapy for patients who met the following criteria: had completed >1 year of itraconazole therapy, negative blood cultures, *Histoplasma* serum antigen <2 units, CD4 counts >150 cells/μL, and had been on ART for ≥6 months. Therefore, per U.S. Centers for Disease Control and Prevention guidelines, discontinuing

suppressive therapy for any patient who meets these criteria can be considered. Suppressive therapy should be restarted if the CD4 count drops to <150 cells/ μL .

Monitoring and relapse

Monitor either serum or urine *Histoplasma* antigen, as well as clinical status, to evaluate response to therapy; a rise in the antigen level suggests relapse of histoplasmosis. A drug level of itraconazole should be measured at least once after 2 weeks of therapy as absorption of this drug can be erratic and interactions are expected between itraconazole and some ARVs.

In cases of treatment failure, both voriconazole and posaconazole have been successful in a few case reports; if treatment failure is suspected, an infectious disease specialist should be consulted.

Primary Prophylaxis

Currently, there are no studies that prove any survival benefit in using primary prophylaxis; however, prophylaxis with itraconazole 200 mg PO QD can be considered for high-risk patients whose CD4 counts are <150 cells/ μL (e.g., those with occupational exposure and those who reside in hyperendemic regions). HIV-infected patients with CD4 counts of <150 cells/ μL should be educated about avoiding exposure.

Primary prophylaxis can be discontinued if the CD4 count remains ≥ 150 cells/ μL for 6 months on effective ART; prophylaxis should be restarted if the CD4 count drops to <150 cells/ μL .

Potential ARV Interactions

There may be significant drug-drug interactions between certain systemic antifungals, (particularly itraconazole, voriconazole, and posaconazole) and ritonavir-boosted protease inhibitors (PIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), elvitegravir/cobicistat, or maraviroc. Some combinations are contraindicated and others require dosage adjustment of the ARV, the antifungal, or both, and/or monitoring of drug levels. Check for adverse drug interactions before prescribing. See relevant tables in the U.S. Department of Health and Human Services *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, or consult with an expert.

Patient Education

- Histoplasmosis is not transmitted from person to person, so isolation is not necessary.
- Patients should take all their medications exactly as prescribed by their health care provider.
- Even with maintenance therapy, relapses can occur. Patients should contact their provider immediately if symptoms worsen.
- Persons with histoplasmosis should be treated with antiretroviral therapy.
- The azoles may cause birth defects. Women who are taking azole medications should avoid pregnancy. In addition, itraconazole and other azoles interact with some antiretrovirals and other medications; patients should tell their provider if they begin taking any new medications while receiving itraconazole.

Kaposi Sarcoma

Background

Kaposi sarcoma (KS) is an endothelial neoplasm that usually occurs as skin or oral lesions but may involve the internal organs. It is the most common AIDS-associated neoplasm and is an AIDS-defining disease. AIDS-associated KS is one of four types of KS, along with classic, endemic, and organ transplant-associated KS. Although the types vary in epidemiology and clinical presentation, all are associated with human herpesvirus type 8 (HHV-8), also known as KS-associated herpesvirus. The clinical manifestations of AIDS-associated KS (sometimes called epidemic KS) range in severity from mild to life-threatening. The progression of disease may be rapid or slow, but the overall prognosis is poor in the absence of treatment. The skin lesions of KS, even when they do not cause medical morbidity, may cause significant disfigurement and emotional distress.

AIDS-associated KS usually occurs in HIV-infected persons with advanced immunosuppression (CD4 count of <200 cells/ μ L), but may occur at any CD4 count. In the United States and Europe, KS occurs in all HIV risk groups, but most frequently among men who have sex with men (MSM). Risk factors for MSM include multiple sexual partners and a history of sexually transmitted diseases (STDs); risk factors for other groups have not been clearly identified. The transmission of HHV-8 is not well understood. Although experts believe HHV-8 is transmitted sexually, it apparently also passes from person to person by other routes.

The incidence of KS in resource-abundant countries has declined markedly since the early 1990s, in part because of the widespread availability of effective combination antiretroviral therapy (ART). In parts of sub-Saharan Africa, where endemic KS has long existed in people with normal immune function, the incidence of KS has risen sharply in people with HIV. ART appears to be effective in reducing the risk of AIDS-associated KS, particularly when initiated before the development of advanced immunosuppression.

S: Subjective

Skin Lesions

The cutaneous presentation of KS is the most common, occurring in 95% of cases. Lesions may occur anywhere on the skin. Common sites include the face (particularly under the eyes and on the tip of the nose), behind the ears, and on the extremities and torso. Lesions may be macules, papules, plaques, or nodules. At first, the lesions are small and may be flat. Their color may vary from pink or red to purple or brown-black (the latter particularly in dark-skinned individuals), and they are nonblanching, nonpruritic, and painless (lesions may become painful in the setting of immune reconstitution inflammatory

syndrome [IRIS] associated with KS). Over time, the lesions often increase in size and number, darken, and rise from the surface; they may progress to tumor plaques (e.g., on the thighs or soles of the feet), or to exophytic tumor masses, which can cause bleeding, necrosis, and extreme pain.

Oral Lesions

Oral lesions may be flat or nodular and are red or purplish. They usually appear on the hard palate, but may develop on the soft palate, gums, tongue, and elsewhere. Oral lesions, if extensive, may cause tooth loss, pain, and ulceration.

Lymphedema

Lymphedema associated with KS usually appears in patients with visible cutaneous lesions, and edema may be out of proportion to the extent of visible lesions. Lymphedema also may occur in patients with no visible skin lesions. Common sites include the face, neck, external genitals, and lower extremities. A contiguous area of skin usually is involved. Lymph nodes may be enlarged.

Pulmonary KS

Pulmonary KS may be asymptomatic or cause intractable cough, bronchospasm, hemoptysis, chest pain, and dyspnea. The patient may exhibit difficulty breathing, bronchospasm, cough (sometimes with hemoptysis), and hypoxemia.

Gastrointestinal KS

Gastrointestinal KS may arise anywhere in the gastrointestinal tract. Patients usually are asymptomatic except in cases of intestinal obstruction or bleeding. KS may cause protein-losing enteropathy. Visceral disease is uncommon in the absence of extensive cutaneous disease.

During the history, ask about the symptoms noted above and associated characteristics, including the following:

- Duration of lesions
- Pain
- Frequency of new lesions
- Respiratory or gastrointestinal symptoms
- Edema or swelling

O: Objective**Physical Examination**

Perform a careful physical examination, with particular attention to the following:

- Vital signs
- Skin (examine the entire skin surface including the scalp and conjunctiva)
- Oropharynx
- Extremities and external genitals (look for lesions, edema)
- Lymph nodes

Examine the lungs, abdomen, rectum, and other systems as indicated.

A: Assessment

The partial differential diagnosis depends on the type of symptoms present.

For cutaneous, oral, and lymph node presentations, consider the following:

- Bacillary angiomatosis
- Lymphoma
- Dermatofibromas
- Bacterial or fungal skin infections
- Venous stasis

For pulmonary symptoms, consider the following:

- *Pneumocystis jiroveci* pneumonia (PCP)
- Cytomegalovirus (CMV) pneumonia
- Pulmonary lymphoma (rare)

P: Plan**Diagnostic Evaluation**

For cutaneous or oral KS, the diagnosis often is suggested by the appearance of skin or mucous membrane lesions. Biopsy of a lesion (or a suspect lymph node) is required to verify the diagnosis and rule out infectious or other neoplastic causes. Biopsy is particularly

important if the lesions are unusual in appearance or if the patient has systemic or atypical symptoms.

If respiratory symptoms are present, obtain chest X-rays or computed tomography (CT) studies. The chest X-ray typically shows diffuse interstitial infiltrates, often accompanied by nodules or pleural effusion. Radiographic findings may be suggestive of KS, but cannot provide a definitive diagnosis. Bronchoscopy with visualization of characteristic endobronchial lesions usually is adequate for diagnosis.

For patients with gastrointestinal symptoms and suspected KS, perform endoscopy.

If the patient has fever or respiratory, gastrointestinal, or constitutional symptoms, evaluate for other infectious and malignant causes (e.g., by culture or biopsy) as suggested by the history and physical examination.

Treatment

Treatment of KS is not considered curative, and no single therapy is completely efficacious. ART is a key component of the treatment of KS and should be initiated promptly (or optimized to achieve complete HIV RNA suppression) for all persons with KS (for further information, see chapter *Antiretroviral Therapy*). KS often regresses and sometimes resolves in patients treated with effective ART. Some data suggest that protease inhibitors may have an anti-KS effect; however, non-PI-containing regimens also lead to KS regression; the role of specific antiretroviral agents beyond HIV control in KS remains unclear.

KS-associated IRIS has been described, and patients may experience painful enlarged lesions or progression of KS lesions during the first months of ART; they should be advised of this possibility.

Specific treatment of KS depends on various factors such as the number, extent, severity, and location of lesions; cosmetic considerations; and presence of visceral

involvement. The goals of therapy may vary according to the clinical presentation and may include controlling symptoms, improving cosmetic appearance, reducing edema, eliminating pain, and clearing lesions. ART alone may be effective in mild-to-moderate KS. Local treatment (in conjunction with ART) may be given to patients who have bothersome symptoms from a few small lesions. Systemic therapy (in conjunction with ART) is needed for more extensive or more severe disease, including symptomatic visceral disease, widespread skin involvement, significant edema, and rapidly progressive KS. Consultation with a KS-experienced oncologist or dermatologist is recommended.

Local treatment of limited disease

Options for local treatment of limited disease include the following:

- ART with observation for response (limited, stable cutaneous disease may require no specific treatment)
- Intralesional chemotherapy (e.g., vinblastine)
- Radiation therapy, for localized or facial lesions (may cause mucositis when used for oropharyngeal lesions)
- Cryotherapy
- Laser therapy

Treatment of extensive or rapidly progressing disease

Extensive or rapidly progressing disease may include lymphedema, intraoral or pharyngeal disease that interferes with eating, painful or bulky lesions, and symptomatic pulmonary or visceral disease. Options for treatment include the following:

- Intralesional chemotherapy (e.g., vinblastine)
- Systemic chemotherapy (e.g., liposomal formulations of doxorubicin or daunorubicin, or paclitaxel)

- Numerous experimental agents are under evaluation
- Consultation with an oncologist is recommended for optimal treatment of extensive disease

Patient Education

- KS often responds to treatment. Educate patients that ART is a cornerstone of treatment; encourage them to start and adhere to ART.
- Swollen or edematous lesions increase the risk of cellulitis, whereupon lesions can become infected and progress rapidly. Advise patients to avoid injuring swollen or edematous lesions, to keep them clean, and to call their health care provider if lesions appear to be spreading or if swelling worsens.
- Advise patients to return to the clinic if respiratory or gastrointestinal symptoms develop.
- Patients may use cosmetic preparations to cover facial lesions. Refer patients to support groups or counseling services if they are having difficulty coping with their physical appearance.

Molluscum Contagiosum

Background

Molluscum contagiosum is a viral infection of human epidermal keratinocytes, caused by a double-stranded DNA virus of the Poxviridae family. Molluscum appears as papules or nodules and sometimes is called “molluscum warts.” It is seen most frequently in HIV-uninfected children (up to 5% of children in the United States), in sexually active young adults, and in immunocompromised persons. It occurs in 5-18% of HIV-infected persons. Molluscum is benign but may cause extensive and cosmetically bothersome lesions, particularly in persons with advanced HIV infection.

Transmission occurs by person-to-person skin-to-skin contact (e.g., sexual activity, contact sports [especially wrestling], or simply touching) or via fomites (towels, bedclothes, clothing [including underwear], soft toys, shaving utensils, electrolysis equipment, tattooing tools, and sponges). The virus may be spread to other areas via self-inoculation (e.g., scratching, shaving, or touching a lesion).

In immunocompetent persons, the infection usually resolves spontaneously after 6-12 months, though genital lesions may remain longer. In HIV-infected persons, the lesions may be more extensive and persistent. There is a strong correlation between the degree of immunosuppression and the risk of molluscum infection, the number of lesions, and the ability of lesions to resist treatment.

S: Subjective

Patients complain of new papules on the trunk, axillae, antecubital and popliteal fossae, face, or genital/crural area. Papules of molluscum contagiosum may cause no symptoms but also can be intensely pruritic or tender to the touch. Ask patients whether others in the home (especially children and adolescents) or their sex partners have similar papules. Genital lesions are transmitted sexually; patients may recall seeing such lesions on the genitals of a previous partner.

Ask about fever or other systemic symptoms to evaluate for other causes of the papules.

O: Objective

Perform a thorough evaluation of the skin, genitals, and mouth. Molluscum commonly presents as multiple grouped lesions. The lesions are white, pink, or flesh colored; shiny, smooth surfaced, firm, pearly, and spherical (dome-shaped) papules (2-5 mm) or nodules (6-10 mm), with umbilicated, or dimpled, centers. Patients with HIV infection may develop giant lesions (>1 cm) or clusters of hundreds of small lesions. Occasionally, molluscum will have a polyp-like appearance. Lesions are usually found on the head, face, or neck or in the genital area, but may affect every part of the body except the palms and soles. Molluscum may occur inside the mouth, vagina, and rectum, and around the eyes. Lesions on the eyelids can cause conjunctivitis.

A: Assessment

A partial differential diagnosis includes the following:

- Disseminated cryptococcosis
- Histoplasmosis skin lesions
- *Penicillium marneffei*
- Other fungal skin lesions
- Folliculitis
- Syphilis, condyloma acuminata, vulvar syringoma for multiple small molluscum genital lesions
- Squamous or basal cell carcinoma

P: Plan**Diagnostic Evaluation**

The diagnosis of molluscum usually is based on the characteristic appearance of the lesions. Perform histologic or other laboratory testing to confirm the diagnosis or to exclude other infections or malignancies. Special staining will show keratinocytes containing eosinophilic cytoplasmic inclusion bodies. Electron microscopy will show poxvirus particles.

Treatment

Because molluscum does not cause illness and rarely causes symptoms, the treatment usually is undertaken primarily for cosmetic purposes. For individuals with large or extensive lesions, molluscum may be disfiguring or stigmatizing, and treatment may be important for their well-being. Treatment (particularly of genital lesions) can be considered in order to prevent transmission to others.

In HIV-infected patients, molluscum is difficult to eradicate and lesions often recur, particularly if immune suppression persists. Effective antiretroviral therapy may achieve resolution of lesions or significant improvement in the extent or appearance of molluscum and should be recommended for all.

Lesions that remain after weeks of antiretroviral therapy should be treated to prevent further spread. Refer complex cases to a dermatologist.

Choice of treatment modality is based on age, likelihood of compliance, number and size of lesions, and potential adverse effects of treatment. Therapeutic options include the following:

- **Local excision:** May be done by curettage, cryotherapy, electrocautery, or visceration. Adverse effects include pain, irritation, soreness, and mild scarring. Repeated treatments are necessary. Curettage appears to be most efficacious (even for children) but is painful and requires anesthesia and a large time commitment over the course of several visits; it also has a risk of scarring. Relapse is common.
- **Imiquimod 5% (Aldara):** An immune response modifier; stimulates production of interferon-alfa and other proinflammatory cytokines, inducing a tissue reaction associated with viral clearance from the skin. Apply TIW for up to 16 weeks or QPM for 4 weeks. Clearing can take up to 3 months. Limited studies; painless.
- **Podophyllotoxin:** Can be administered by a health care provider and washed off after 1-4 hours. This treatment is caustic, may cause significant irritation, and has limited effectiveness. It is contraindicated for use during pregnancy. Patient-administered podophyllotoxin (Podofilox) may be a safer alternative to podophyllum. Adverse effects include burning, pain, inflammation, erosion, and itching.
- **Cantharidin 0.7%:** Can be applied by a health care provider. One study of 300 children found that lesions cleared after two visits. This treatment may cause allergic reactions, stinging, and blistering. Do not use cantharidin around the eyes.

- **Tretinoin (Retin-A) 0.1% cream:** Can be applied to lesions BID. Adverse effects include drying, peeling, irritation, and soreness.
- **Trichloroacetic acid:** Can be administered by a health care provider. Controlling the depth of acid penetration is difficult. Adverse effects include pain and irritation; mild scarring is common.
- **A combination of salicylic and lactic acid:** Response is highly variable and recurrence is common.
- **Laser therapy:** Safe, efficient, tolerable, and efficacious.
- **Cidofovir 1-3% topical cream:** Applied BID for 2 weeks, followed by a 30-day rest period and then two additional cycles. This treatment has been shown to be effective in several small studies and case reports, but it is expensive and difficult to compound. No systemic adverse effects are noted.
- **Silver nitrate paste:** May be used to burn each lesion individually.

Patient Education

- Molluscum infection is benign but may be distressing.
- Molluscum infection may be transmitted both sexually and nonsexually, through direct contact with lesions. Molluscum also can be transmitted indirectly by contact with infected objects.
- Latex condoms or barriers may not prevent transmission of genital molluscum.
- To prevent the spread of molluscum, instruct patients to take the following precautions:
 - Avoid close contact between their molluscum lesions and the skin, mouth, and genitals of other people.
 - Avoid picking at, squeezing, or puncturing the lesions, as a lesion's central plug is full of viral particles that can be spread easily by coming into contact with other parts of the body. In addition, lesions may become secondarily infected.
 - Wash hands frequently.
 - Keep fingernails short.
 - Avoid shaving in areas with lesions because shaving could result in lesions spreading to other areas.
 - Avoid sharing towels, bedclothes, clothing, shaving utensils, bathing equipment, or other objects that have been in contact with molluscum lesions.
 - Wash all contaminated items in very hot, but not scalding, water.
 - Cover lesions with clothing, if possible.

Mycobacterium avium Complex Disease

Background

Mycobacterium avium complex (MAC) disease is an opportunistic infection caused by species of *Mycobacterium* that can produce severe illness in people with advanced AIDS but rarely affects others. The risk of disseminated MAC (DMAC) is directly related to the severity of immunosuppression. DMAC typically occurs in persons with CD4 counts of <50 cells/μL, and its frequency increases as the CD4 count declines. In the absence of antibiotic prophylaxis, DMAC occurs in up to 40% of AIDS patients with CD4 counts of <50 cells/μL. Antimicrobial therapy, especially if given in conjunction with antiretroviral therapy (ART) that achieves immune reconstitution, can be successful in treating MAC disease. Specific antimicrobial prophylaxis and effective ART also may be used to prevent MAC in patients with advanced AIDS (see chapter *Opportunistic Infection Prophylaxis*).

MAC organisms are common in the environment. They are found worldwide and have been isolated from soil, water, animals, birds, and foods. They usually enter the body through the respiratory or gastrointestinal tract and disseminate to cause multisystem infection, typically manifested by nonspecific symptoms and signs such as fever, sweats, weight loss, abdominal pain, fatigue, chronic diarrhea, and anemia and other cytopenias. MAC also can cause local disease such as central nervous system infection, lymphadenitis, soft-tissue or bone infections, and rarely, isolated pulmonary disease. Focal MAC disease is more common among patients on ART, whereas DMAC is the more common manifestation among those with low CD4 cell counts who are not on ART. Unlike *Mycobacterium tuberculosis*, *Mycobacterium avium* is not thought to be transmitted via person-to-person contact. In patients with subclinical or incompletely treated MAC who have recently started ART, an immune reconstitution inflammatory syndrome (IRIS) may occur with localized lymphadenitis or paradoxically worsening symptoms (see chapter *Immune Reconstitution Inflammatory Syndrome*).

S: Subjective

The patient complains of one or more of the following symptoms:

- Persistent or cyclic fever
- Night sweats
- Unintentional weight loss
- Anorexia
- Chronic diarrhea
- Weakness
- Fatigue
- Abdominal pain
- Lymph node enlargement

When taking the history, ask about the following:

- Any symptoms as described above, including duration and intensity; other symptoms of infection
- Whether the patient is taking MAC prophylaxis or ART

O: Objective

Perform a full physical examination with particular attention to the following:

- Vital signs (temperature, heart rate, blood pressure, respiratory rate)
- Weight (compare with previous measurements)

- General appearance (cachexia, wasting, signs of chronic illness, jaundice, pallor)
- Lymph nodes (lymphadenopathy)
- Abdomen (hepatosplenomegaly, tenderness)

Review previous laboratory values, particularly the CD4 count (usually <50 cells/ μ L).

A: Assessment

Rule out other infectious or neoplastic causes of constitutional symptoms, anemia, or organomegaly. A partial differential diagnosis would include the following:

- *M. tuberculosis* infection
- Cytomegalovirus infection
- Lymphoma
- Bartonellosis
- Disseminated fungal infection
- Pyogenic abscess
- Other septicemia

P: Plan

Diagnostic Evaluation

Definitive diagnosis requires identification of MAC in blood or other normally sterile body fluids or tissues (*M. avium* cultured from sputum, bronchial washing, or stool may represent colonization rather than infection). Send blood for acid-fast bacilli (AFB) culture (sensitivity of a single blood culture for MAC bacteremia is 91%, sensitivity increases to 98% if two samples [drawn at different times] are sent). Because MAC may take weeks to grow in culture, ancillary studies should be performed. The following are not specific, but may be helpful in reaching a presumptive diagnosis:

- AFB smear
- Complete blood count (CBC) for anemia, lymphopenia, and thrombocytopenia
- Serum alkaline phosphatase (often elevated in DMAC)

- Computed tomography (CT) scan of the chest and abdomen (intraabdominal and mediastinal lymphadenopathy or hepatosplenomegaly often are present)

If blood cultures are negative and MAC is suspected (or if results of blood cultures are pending), consider biopsy of the lymph nodes, bone marrow, liver, or bowel (via endoscopy) to detect DMAC by microscopic examination for AFB and culture. If the evidence suggests pulmonary MAC, consider bronchoscopy and bronchoalveolar lavage. Note that in MAC IRIS, MAC bacteremia usually is absent and a tissue-based diagnosis is required.

Perform additional studies as indicated to rule out other causes of the patient's symptoms, including bacterial blood cultures, sputum for *M. tuberculosis*, *Bartonella* studies, lymph node cytology for lymphoma, and stool cultures, as appropriate.

Treatment

Because antimicrobial resistance develops quickly with single-drug therapy, multidrug regimens must be administered for DMAC.

Preferred regimens:

- Clarithromycin 500 mg BID + ethambutol 15 mg/kg QD
- Azithromycin 500-600 mg QD + ethambutol 15 mg/kg QD (see below)

Clarithromycin is the preferred cornerstone of MAC therapy, as it has been studied more extensively and is associated with more rapid clearance of MAC bacteremia. If clarithromycin cannot be tolerated or if there is concern regarding drug interactions, azithromycin may be substituted for clarithromycin, as above. Clarithromycin dosages should not exceed 1 g per day, as high-dose clarithromycin has been associated with excess mortality.

Some experts recommend including a third agent for patients with more advanced HIV disease or higher MAC burden in blood cultures, and for those who are not receiving

effective ART. The addition of rifabutin (300 mg QD) has been associated with a mortality benefit in one study and with reduced emergence of mycobacterial resistance in two other trials; however, these studies were done before potent ART was available; the possible benefit of rifabutin in patients treated with effective ART has not been established. A fluoroquinolone (e.g., levofloxacin, moxifloxacin), amikacin, or streptomycin may be used instead of rifabutin as a third agent, or in addition to rifabutin as a fourth agent; however, studies have not confirmed the

clinical benefit of these medications.

Because immune reconstitution is essential for controlling MAC, all patients who are not already receiving ART should begin ART, if possible. Current guidelines recommend initiation of ART after 2 weeks of MAC treatment, for patients who are not already on ART. This strategy may decrease the risk IRIS and it serves to forestall interactions between DMAC and ARV drugs and the additive toxicities of those medications. Patients who are receiving suboptimal ART should be changed to suppressive regimens, if possible.

Potential ARV Interactions

Clarithromycin and rifabutin have a number of significant drug interactions, including interactions with some commonly prescribed ARVs. These interactions should be reviewed prior to initiation of MAC therapy. Dosage adjustments or alternative medications may be required. Azithromycin does not have significant interactions with ARVs.

Interactions of concern include the following:

Clarithromycin:

- **Atazanavir** may raise clarithromycin levels by 90%; some experts recommend using azithromycin in place of clarithromycin, or dosage reduction of clarithromycin by 50%.
- **Darunavir** increases clarithromycin levels; alternative agent (azithromycin) or dosage reduction of clarithromycin is recommended for patients with renal impairment.
- **Lopinavir/ritonavir and other protease inhibitors** may increase clarithromycin levels; alternative agent (azithromycin) or dosage reduction of clarithromycin is recommended for patients with renal impairment.
- **Efavirenz** may lower clarithromycin levels; avoid this combination if possible.
- **Etravirine** may lower clarithromycin levels, while clarithromycin may in turn increase etravirine levels. Avoid this combination, if possible.
- **Nevirapine** may decrease clarithromycin levels and increase levels of its active metabolite. Avoid this combination, if possible.
- **Elvitegravir/cobicistat** may increase clarithromycin levels. Dosage reduction of clarithromycin is required for patients with renal insufficiency.

Protease inhibitor-based ART (e.g., lopinavir or darunavir) or integrase inhibitor-based ART may be the preferred HIV treatment for patients on MAC therapy, because of limited drug interactions associated with those ARV classes.

Rifabutin has significant interactions with many drugs, including nonnucleoside reverse transcriptase inhibitors, protease inhibitors, and elvitegravir/cobicistat; therefore, dosage adjustments or alternative agents may be needed (for further information, see chapter *Mycobacterium tuberculosis*).

The patient should show clinical improvement within the first weeks of treatment. If there is not a response to treatment after 2-4 weeks, assess adherence, consider adding one or more drugs, and consider evaluation for other or additional causes of the patient's symptoms. Repeat a blood culture with antimicrobial sensitivities for patients whose clinical status has not improved after 4-8 weeks of treatment. Interpretation of MAC drug susceptibility testing should be undertaken in consultation with an infectious disease or HIV specialist, because laboratory evidence of drug resistance does not always correlate with clinical drug resistance.

If immune reconstitution inflammatory reactions are suspected, consider adding antiinflammatory medications, including corticosteroids if moderate to severe MAC IRIS symptoms do not improve with NSAIDs (see chapter *Immune Reconstitution Inflammatory Syndrome*).

Treatment of MAC generally is required for the remainder of the patient's life in the absence of immune reconstitution with effective ART. It may be reasonable to discontinue MAC therapy if patients complete at least 12 months of MAC treatment, have no further symptoms, and demonstrate immune restoration in response to ART (an increase in CD4 counts to >100 cells/ μ L for at least 6 months). If MAC treatment is discontinued, the patient must be monitored carefully for any decrease in CD4 cell count or recurrence of MAC symptoms. Treatment should be resumed if the CD4 count drops to <100 cells/ μ L or if symptoms recur.

Prevention

Primary prevention using azithromycin or clarithromycin should be initiated in persons with CD4 cell counts of <50 cells/ μ L. See chapter *Opportunistic Infection Prophylaxis*.

Patient Education

- Advise patients that antimycobacterial therapy alone will not eradicate MAC infection, but should decrease symptoms and improve quality of life. A response to treatment may take up to 4 weeks. If medications are discontinued, the disease almost always recurs, unless the CD4 count has increased to >50-100 cells/ μ L in response to ART.
- Patients must take all medicines exactly as prescribed. If doses are missed, or if the medication is stopped and restarted, MAC can develop resistance to the medications. If patients are having trouble taking the medications on schedule, they should contact their health care provider promptly.
- Advise patients that MAC IRIS is a common complication of effective ART and MAC therapy, and its occurrence in the course of treatment should be anticipated.
- Urge patients to contact the clinic immediately if they notice worsening of existing symptoms or the development of new symptoms.
- DMAC is an opportunistic infection of late-stage HIV and it is indicative of profound immunosuppression. Some patients may not respond to MAC treatment or to ART. Because this is a life-threatening disease, clinicians should discuss advance directives and durable power of attorney with patients. Referral to a social worker, mental health clinician, or chaplain experienced in such issues may facilitate the discussion.

Mycobacterium tuberculosis

Background

In HIV-infected individuals, tuberculosis (TB) causes more deaths worldwide than any other condition. A biologic synergy exists between HIV and TB such that HIV-induced immunosuppression increases susceptibility to active TB infection, whereas active TB infection increases HIV progression and risk of death. The populations infected by these two pathogens overlap in many respects, creating epidemiologic synergy. Poverty, crowded living conditions, and inadequate interventions to reduce transmission and treat latent TB infection (LTBI) combine to enhance the transmission of both organisms.

In the United States, more than 60% of TB cases occur in foreign-born individuals, with the majority of these cases attributed to reactivation of LTBI. In 2010, only 8% of active TB cases occurred in patients known to be infected with HIV, and TB is a relatively infrequent AIDS-defining illness. Nevertheless, TB remains important to HIV clinicians in the United States because it can be highly infectious and challenging to diagnose, and because improper treatment may lead to drug resistance both in the infected patient and in individuals to whom that patient transmits. Although other conditions increase the risk of TB disease (e.g., malnutrition, diabetes, end-stage renal disease, pulmonary silicosis, and iatrogenic immunosuppressive drugs [especially inhibitors of tumor necrosis factor]), HIV infection remains an important risk factor.

TB is an infection caused by *Mycobacterium tuberculosis* (MTB) complex. These organisms grow slowly and can be identified only with special staining techniques, a trait that led to the name “acid-fast bacteria.” This chapter focuses on disease caused by *M. tuberculosis*; other chapters describe diagnosis and management of latent MTB infection (see chapter *Latent Tuberculosis Infection*) and diagnosis and management of disease caused by *Mycobacterium avium* (see chapter *Mycobacterium avium Complex Disease*).

MTB most often causes a chronic pneumonia, but it can affect organs other than the lungs as well. The lung destruction caused by MTB may create cavities, similar to abscesses; these contain huge numbers of organisms. TB is transmitted almost always by persons with active pulmonary TB who release large numbers of organisms in their sputum. Patients with smear-positive sputum are the most infectious; however, transmission from patients with AFB smear-negative, culture-positive sputum has been well documented. Extrapulmonary tuberculosis generally is not considered contagious.

MTB organisms are inhaled and infect the lung. In most people, the initial lung infection is contained by an effective immune response. It usually is asymptomatic but leads to foci in the lung (and sometimes in other organs) of latent TB, which may reactivate and cause active TB disease years later. Shortly after the onset of infection with MTB, before its containment in the lung by the immune system, organisms can spread to other organs and establish latent infection in those areas as well. Reactivation in these other organs can lead to local disease (e.g., in the lymph nodes, meninges, bone, pericardium, peritoneum or intestine, and urogenital tract).

Persons with impaired immunity, such as persons with HIV-associated immunosuppression and very young children, are at high risk of developing progressive primary TB at the time of initial MTB infection. Primary progressive MTB usually causes pulmonary disease, but also can

cause meningitis or disseminated disease (blood, liver, spleen, lung, and other organs). Persons who have latent TB infection and then develop immunodeficiency are at high risk of developing reactivation disease. For example, compared with the <10% lifetime risk of developing active TB in immunologically normal persons, an HIV-infected person with latent TB has about a 10% chance each year of developing active disease. Even with immune reconstitution through antiretroviral therapy (ART) and a normalized CD4 cell count, HIV-infected patients remain at elevated risk of reactivation TB, compared with the background community risk of TB.

Classical pulmonary tuberculosis, with upper-lobe infiltrates and cavitary lesions, may occur in HIV-infected persons with relatively intact immunity. As the CD4 count decreases (particularly to <200 cells/ μ L), TB is more likely to manifest atypically in the chest (without cavitary disease) or with lower-lobe disease, adenopathy, pleural effusions, or interstitial or military infiltrates), and as extrapulmonary or multiorgan disease (particularly in lymph nodes, peritoneum, pericardium, and meninges). Granulomas may be seen in the tissues; in persons with advanced immunodeficiency, these may be poorly formed and non-caseating. Bone, joint, and urogenital TB are less-commonly associated with HIV-induced immunosuppression. Symptoms and signs in HIV-infected persons therefore can vary widely and can be difficult to distinguish from HIV-related opportunistic infections and malignancies.

Appropriate use of modern chemotherapy with rifampin-containing TB treatment applied to drug-susceptible MTB disease cures at least 95% of these patients, including those with HIV coinfection. However, drug resistance seriously reduces the cure rate. Drug resistance usually is caused by improper or erratic treatment. It is spreading rapidly and becoming more severe. Effective diagnosis and cure of drug-susceptible TB not only reduces the disease burden in the individual and reduces further transmission, it also is crucial to avoiding drug resistance.

MTB resistance to a single drug may extend or complicate treatment but usually does not prevent successful treatment of TB. Resistance to both isoniazid and rifampin, with or without resistance to other first-line drugs, is called **multidrug resistance (MDR)**, and it makes treatment especially difficult. **Extreme drug resistance (XDR)** occurs when, in addition to isoniazid and rifampin resistance, there is resistance to specific second-line drugs: a fluoroquinolone plus an injectable agent (kanamycin, amikacin, or capreomycin). Treatment of drug-resistant TB should be managed by experts or in consultation with experts. MDR TB is uncommon in the United States; it occurred in 1.3% of cases in 2010, and the great majority of these were foreign-born patients (82.6%). XDR is very rare in the United States, with only 4 cases reported in 2010.

Effective antiretroviral treatment (ART) is a critical component of the care of persons with TB, and ART should be initiated or optimized in all persons with active TB, regardless of their current CD4 cell count.

This chapter will discuss the evaluation and management of TB in the United States and other high-income settings. For management of TB in resource-limited settings, see the relevant World Health Organization guidelines and other resources.

S: Subjective

Persons with TB generally describe an illness lasting several weeks to months, associated with systemic features such as high fevers, night sweats, loss of appetite, and weight loss. These symptoms are nonspecific, but should raise the possibility of TB.

- Pulmonary TB presents with a chronic productive cough and sometimes with hemoptysis; shortness of breath occurs late in the disease course.
- TB adenitis presents with enlarged lymph nodes (usually asymmetric involvement in one region) that may suppurate and drain but usually are not painful, hot, or erythematous.
- TB meningitis presents with headache, gradual change in mental status, and at times with cranial nerve abnormalities such as double vision or decreased hearing.
- Disseminated TB may occur with systemic manifestations such as fever, sweats, and weight loss, with no localizing features.

Risk factors for TB infection include known prior contact with an active case, exposure in congregate settings (such as homeless shelters and prisons, but also in health care facilities), travel or residence in countries with high rates of endemic TB, and birth in a TB-endemic country (more than half of foreign-born individuals diagnosed with TB in the United States originated from one of the following five countries: Mexico, the Philippines, Vietnam, India, or China). In the United States, persons with active or past substance-use disorders and persons of color are more likely than others to have had exposure to TB. History of a prior positive tuberculin skin test (TST) or interferon-gamma release assay (IGRA) result provides evidence of previous TB exposure; however, up to 35% of patients with active TB will have a negative TST or IGRA result (see chapter *Latent Tuberculosis Infection*). Risks for active TB disease include any degree of HIV-associated immunosuppression, immunosuppression

associated with other diseases (e.g., leukemia, lymphoma) or caused by medical therapies (e.g., tumor necrosis factor-alpha blockers such as etanercept), and malnutrition.

O: Objective

- Measure vital signs, including oxygen saturation.
- Measure weight; compare with previous values.
- Perform thorough physical examination with particular attention to the lungs, heart, abdomen, lymph nodes, skin, and neurologic system.

Systemic signs of chronic disease and inflammation are common, including cough, fever, night sweats (which may occur without awareness of the high fever that precedes them), and weight loss.

In patients with pulmonary TB, the breath sounds may be normal or focally abnormal; tachypnea and hypoxia occur only with extensive lung damage.

Extrapulmonary TB may present with focal adenopathy without local signs of inflammation, but perhaps with a draining sinus.

TB meningitis presents as subacute or chronic meningitis, with neck stiffness and changes in mental status. Symptoms may include cranial nerve palsies owing to inflammation at the base of the brain or increased intracranial pressure.

Pericardial disease can cause the pain and friction rub of pericarditis or signs of pericardial tamponade.

Infiltration of the bone marrow can produce pancytopenia.

Disseminated TB may cause diffuse adenopathy, hepatic or splenic enlargement, and abnormal liver function, although hepatic failure is rarely attributable to TB alone. Infection of the adrenal glands can cause adrenal insufficiency.

A: Assessment

Note: If pulmonary TB is suspected, the patient should wear a mask while in the medical facility and the care provider should wear an N95 respirator during the examination to reduce transmission risk.

The differential diagnosis of TB is extensive and depends in part on the degree of immunosuppression (as indicated by the CD4 cell count) of the individual. It includes a broad range of bacterial, mycobacterial, viral, and fungal infections in addition to noninfectious causes. A partial differential diagnosis of pulmonary TB includes the following:

- Bacterial pneumonia
- Pulmonary *Mycobacterium* pneumonia (nontuberculous)
- *Pneumocystis jiroveci* pneumonia (PCP)
- *Cryptococcus neoformans* pneumonia/pneumonitis
- Pulmonary Kaposi sarcoma
- *Toxoplasma* pneumonitis
- Disseminated histoplasmosis
- Disseminated coccidioidomycosis
- Cytomegalovirus pneumonia
- Bronchogenic carcinoma
- Non-Hodgkin lymphoma
- Influenza
- Pulmonary embolus
- Chronic obstructive pulmonary disease
- Reactive airway disease
- Congestive heart failure
- Lactic acidosis

P: Plan

Diagnostic Evaluation

Initial evaluation

Suspected TB should be evaluated aggressively.

- During the initial evaluation, check complete blood count (CBC) and differential, sputum gram stain, sputum acid-fast bacilli (AFB) stain, culture, and nucleic acid amplification (NAA) test (see below), blood cultures, and chest X-ray.
- For patients with lymphadenopathy, consider fine-needle aspiration biopsy for bacterial and AFB stains and culture, and cytologic evaluation.
- For patients with meningitis or central nervous system (CNS) abnormalities, perform lumbar puncture (LP) and cerebral spinal fluid (CSF) analysis including cell count, protein, glucose, AFB smear and culture, and bacterial and fungal cultures.
- Computed tomography (CT) is recommended for all patients with HIV prior to LP, particularly if focal neurologic abnormalities are present.
- Perform other diagnostic tests as suggested by the clinical presentation.

Imaging

Pulmonary TB can be associated with any chest X-ray appearance, including a normal X-ray image. However, the chest X-ray classically demonstrates upper-lobe infiltrates with or without cavities. Patients with HIV infection (especially advanced HIV and low CD4 cell counts) are more likely to have atypical chest X-ray presentations, including absence of cavities, presence of lower-lobe disease, hilar or mediastinal adenopathy, and pleural effusions.

In disseminated TB, the chest X-ray may show a miliary pattern with small nodules (“millet seeds”) scattered throughout both lungs.

AFB testing

TB should be diagnosed by identification of the organism in stained sputum smears or stains of tissue and confirmed by culture or NAA test. All positive cultures should undergo drug susceptibility testing. Proof of the diagnosis is important because other opportunistic diseases can mimic TB, and mycobacterial infections other than TB (e.g., MAC) can occur; these require different treatment. TB drug susceptibility testing is necessary to ensure appropriate treatment, to reduce the risk of developing further TB drug resistance, and to decrease the risk of transmission of drug-resistant TB. Three specimens of expectorated sputum should be sent for acid-fast staining and mycobacterial culture. A presumptive diagnosis of pulmonary TB can be made if AFB are seen, but confirmation is

required. Sputum induction with nebulized saline (e.g., by respiratory therapists) can be used for patients who do not have spontaneous sputum production. (Sputum induction has been successful in children, but for young children who cannot produce sputum, gastric lavage on three successive mornings can be performed to obtain swallowed sputum for smear [although false-positive results can occur] and culture.)

Current U.S. guidelines for treatment of opportunistic infections recommend NAA testing on at least one respiratory specimen (regardless of smear status) from each patient with signs and symptoms of pulmonary TB. The algorithm in Table 1 is recommended by the U.S. Centers for Disease Control and Prevention (CDC) for interpretation of NAA test results.

Table 1. Nucleic Acid Amplification Testing and Interpretation Algorithm

1. If the NAA result is positive and the AFB smear result is positive, presume the patient has TB and begin anti-TB treatment while awaiting culture results. The positive predictive value of FDA-approved NAA tests for TB is >95% in AFB smear-positive cases.
2. If the NAA result is positive and the AFB smear result is negative, use clinical judgment in deciding whether to begin anti-TB treatment while awaiting culture results and determine whether additional diagnostic testing is needed. Consider testing an additional specimen using NAA to confirm the NAA result. A patient can be presumed to have TB, pending culture results, if two or more specimens are NAA positive.
3. If the NAA result is negative and the AFB smear result is positive, a test for inhibitors should be performed and an additional specimen should be tested with NAA. Sputum specimens (3-7%) might contain inhibitors that prevent or reduce amplification and cause false-negative NAA results.
 - a. If inhibitors are detected, the NAA test is of no diagnostic help for this specimen. Use clinical judgment to determine whether to begin anti-TB treatment while awaiting results of culture and additional diagnostic testing.
 - b. If inhibitors are not detected, use clinical judgment to determine whether to begin anti-TB treatment while awaiting culture results and determine whether additional diagnostic testing is needed. A patient can be presumed to have an infection with non-TB mycobacteria if a second specimen is smear positive and NAA negative and has no inhibitors detected.
4. If the NAA result is negative and the AFB smear result is negative, use clinical judgment to determine whether to begin anti-TB treatment while awaiting results of culture and additional diagnostic tests. Currently available NAA tests are not sufficiently sensitive (detecting 50-80% of AFB smear-negative, culture-positive pulmonary TB cases) to exclude the diagnosis of TB in AFB smear-negative patients suspected of having TB.

Adapted from U.S. Centers for Disease Control and Prevention. *Updated Guidelines for the Use of Nucleic Acid Amplification Tests in the Diagnosis of Tuberculosis*. MMWR Morb Mortal Wkly Rep. 2009 Jan 16;58(1):7-10. Available at www.cdc.gov/mmwr/preview/mmwrhtml/mm5801a3.htm. Accessed December 1, 2013.

Sensitivity of the NAA tests in smear-positive specimens is high but decreases to 50-80% in smear-negative, culture-positive specimens. The rapid identification of MTB facilitates appropriate respiratory infection control precautions, contact tracing, and immediate treatment of MTB. NAA tests also are useful in making a presumptive diagnosis in smear-negative patients who are suspected to have active pulmonary TB, pending culture results. However, these tests can yield false-positive results, particularly with persons in whom pulmonary TB is unlikely. Also, false negatives can occur in both smear-positive and smear-negative patients. NAA testing is not available in all laboratories and in some it is restricted to AFB smear-positive specimens.

The Xpert MTB/RIF is a rapid NAA test that was recently reviewed by the FDA and allowed to be marketed the United States. This assay identifies TB and at the same time identifies rifampicin (RIF) resistance from a direct sputum sample. Data from high-prevalence TB settings show a sensitivity of >98% for TB in smear-positive specimens. Sensitivity in smear-negative specimens is 70% with a single test, and up to 90% with three tests, with a specificity of 99%. Other NAA tests can be used to rapidly identify clinically significant non-TB mycobacteria such as MAC and *Mycobacterium kansasii*. If a non-TB mycobacteria is diagnosed, respiratory precautions can be discontinued, and treatment for the specific or suspected organism can be started.

In patients with suspected pulmonary TB, negative sputum microscopy or NAA results do not rule out TB; and consideration should be given to starting empiric TB treatment while further evaluation is undertaken.

A diagnosis of extrapulmonary TB generally requires an examination of infected tissue or body fluid by microscopy and culture. NAA tests are approved for testing of sputum

samples, but have been used on tissue and body fluids (such as CSF); specimens that are fresh or frozen generally are preferable to specimens preserved in formalin or a similar chemical. Specimens of organs with suspected TB can be obtained by peripheral lymph node aspiration, CT-guided or other guided aspiration and biopsy, liver biopsy, bone marrow biopsy, or thoracoscopy- or laparoscopy-guided biopsies of pleura or peritoneum. In some cases, surgery is required to obtain appropriate specimens. Blood cultures for mycobacteria (using appropriate mycobacterial media rather than standard blood culture media) may be positive in disseminated TB, particularly with advanced HIV disease; the technique is the same as in culturing blood for MAC organisms. Urine culture is used to diagnose renal TB, although this condition is rare among HIV-infected persons.

Initial growth of MTB on culture may occur within 3-8 weeks. A nucleic acid probe can confirm a positive culture as MTB within few days of culture growth; otherwise, speciation may take several weeks. Susceptibility testing generally takes 3-4 weeks after the initial culture growth, depending on what laboratory procedures are used. Rapid tests for diagnosis of drug resistance allow early identification of resistance and optimization of treatment. The Xpert MTB/RIF assay is available in the United States, and others (including line probe assays, nitrate reductase assay, and phage-based assays) are available in other countries. Some health departments have in-house assays for rifampin resistance. NAA tests for TB drug resistance are efficient at screening for resistance against drugs for which a single mutation (e.g., rifampin) or a few mutations (e.g., isoniazid) are responsible. Rapid assays to detect mutations that confer resistance to other first- and second-line drugs are in development.

Note that a positive TST or IGRA result confirms TB infection but does not prove active disease (see chapter *Latent Tuberculosis*).

Similarly, a negative result may occur in up to 35% of HIV-infected persons with active TB and does not rule out TB disease. When a specific microbiologic diagnosis cannot be made or may be delayed (as with TB meningitis testing, for which CSF culture results may take weeks to obtain or may be negative), a positive TST or IGRA result can help support the diagnosis and implementation of therapy; however, a negative result on these tests does not rule out active TB.

Respiratory Precautions

Respiratory infection control precautions should be implemented for HIV-infected patients with an undiagnosed chronic cough or undiagnosed inflammatory infiltrate on chest X-ray. Individual institutions have specific guidelines that should be followed; patients usually are housed in single negative-pressure rooms and persons entering the rooms are required to wear protective respirators. Patients seen in the outpatient setting should wear a mask while in the medical facility, and providers should wear an N95 respirator when evaluating the patient. If three sputum smears yield negative results on AFB staining, or if a single deep specimen (bronchial lavage or tracheal aspirate) is smear negative, infectious TB is unlikely and respiratory precautions can be discontinued. Patients who are highly suspect for MTB and lack an alternative diagnosis may be kept on precautions and empiric treatment may be started, as transmission of TB from AFB smear-negative, culture-positive TB patients is well documented. Persons who have responded to treatment for an alternative diagnosis (e.g., bacterial pneumonia), and those who cannot produce the requisite three sputum samples, may be released from the TB precautions.

The impact of TB transmission is greater in a health care setting, where immunosuppressed persons may be exposed, than at home, where exposure has occurred prior to the TB evaluation. Of course, children younger than age 5 and immunosuppressed persons in the home are at increased risk.

Treatment

Treatment for TB should be instituted promptly when TB is considered likely and the proper specimens to prove the diagnosis have been obtained. It is ideal to have a positive smear result (and confirmation by NAA testing) prior to initiating treatment, but empiric treatment should be started while the initial specimens are collected from patients in whom the suspicion of TB is high, in severely ill persons, or in circumstances in which positive smear results are unlikely (e.g., suspected TB meningitis with AFB smear-negative CSF).

Randomized trials have demonstrated that ART decreases mortality in HIV-infected persons with active TB regardless of initial CD4 cell count; thus, effective ART should be initiated or optimized in everyone with TB/HIV coinfection; see “Coordinating with antiretroviral therapy,” below.

Adherence is the most important treatment issue once the decision to treat is made and an appropriate regimen is selected. *It is the responsibility of the treating clinician to ensure that the patient completes a full course of therapy.* Therefore, it is strongly recommended that patients be referred to public health departments for TB treatment. Health departments usually can provide free TB treatment and have specific resources and systems to promote adherence. It is recommended that all patients receive directly observed therapy (DOT), an approach by which the taking of every dose of anti-TB medication is observed and documented. Clinical trials have documented that DOT with enhancements to maximize adherence not only improves the rate of completion of therapy but also reduces mortality among HIV-infected TB patients. If a health department manages the TB treatment, the HIV clinician must coordinate with the health department for the following reasons: 1) to coordinate TB and HIV treatment regimens; 2) to avoid or adjust for drug interactions; 3)

to assist the health department in avoiding diagnostic or treatment confusion in the event of immune reconstitution inflammatory syndrome (IRIS) or incident opportunistic diseases; and 4) to maximize adherence with the TB medications, ART, opportunistic infection treatment or prophylaxis, and any other medications.

Treatment consists of two phases: intensive and continuation. Several intermittent therapy regimens have been designed to simplify DOT; however, use of TIW and BIW regimens during the intensive phase of treatment have led to higher rates of treatment failure and resistance, as have weekly or BIW continuation

phase regimens. **Thus, daily (or 5-7 days per week) dosing by DOT is recommended during the intensive phase of treatment,** and 5-7 days per week or TIW dosing is recommended during the continuation phase.

Preferred therapy (drug-susceptible pulmonary TB)

- **Intensive Phase:** Isoniazid + rifampin (or rifabutin) + pyrazinamide + ethambutol QD (5-7 days per week) for 8 weeks, by DOT
- **Continuation Phase:** isoniazid + rifampin or rifabutin 5-7 days per week or TIW

Table 2. Recommended Dosages of First-Line Antituberculosis Drugs for Adults

Drug	Daily	3 Times Weekly
Isoniazid	5 mg/kg (usual dose 300 mg)	15 mg/kg (usual dose 900 mg)
Rifampin[†]	10 mg/kg (usual dose 600 mg)	10 mg/kg (usual dose 600 mg)
Rifabutin*		
without HIV protease inhibitors, efavirenz, rilpivirine, or elvitegravir/cobicistat	5 mg/kg (usual dose 300 mg)	5 mg/kg (usual dose 300 mg)
with HIV protease inhibitors	150 mg	300 mg
with efavirenz	450-600 mg	450-600 mg
with elvitegravir/cobicistat*	150 mg	150 mg
Pyrazinamide		
40-55 kg body weight	1,000 mg (18.2-25.0 mg/kg)	1,500 mg (27.3-37.5 mg/kg)
56-75 kg body weight	1,500 mg (20.0-26.8 mg/kg)	2,500 mg (33.3-44.6 mg/kg)
76-90 kg body weight	2,000 mg (22.2-26.3 mg/kg)	3,000 mg (33.3-39.5 mg/kg)
>90 kg body weight	2,000 mg [#]	3,000 mg [#]
Ethambutol		
40-55 kg body weight	800 mg (14.5-20.0 mg/kg)	1,200 mg (21.8-30.0 mg/kg)
56-75 kg body weight	1,200 mg (16.0-21.4 mg/kg)	2,000 mg (26.7-35.7 mg/kg)
76-90 kg body weight	1,600 mg (17.8-21.1 mg/kg)	2,400 mg (26.7-31.6 mg/kg)
>90 kg body weight	1,600 mg [#]	2,400 mg [#]

[†] Rifampin is not recommended for patients receiving HIV protease inhibitors, efavirenz, rilpivirine, or elvitegravir/cobicistat. Dolutegravir, raltegravir, and maraviroc require dosage adjustment.

* Avoid coadministration of rifabutin with elvitegravir/cobicistat, if possible. If used together, consider therapeutic drug monitoring and dosage adjustment as indicated. Do not coadminister with rilpivirine.

[#] For patients weighing >90 kg, monitor for therapeutic response can consider therapeutic drug monitoring.

Adapted from Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents. *Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from the Centers for Disease Control and Prevention, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America*. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Four anti-TB drugs are administered for the first 2 months, then two drugs are administered for an additional 4 months (if the organism is susceptible to standard medications). The initial phase of TB treatment usually consists of isoniazid, rifampin or rifabutin (see below), pyrazinamide, and ethambutol; the continuation phase typically is simplified to isoniazid and rifampin. Pyridoxine (vitamin B6) at a dosage of 10-50 mg QD usually is included to minimize the risk of isoniazid-induced peripheral neuropathy. If drug resistance or MDR is suspected, more drugs can be used initially, and treatment should be directed by experts. Resistance may be suspected among persons exposed to TB in countries with high rates of endemic resistance, those for whom previous treatment has failed, those who have been on and off treatment erratically, those who may have had a specific exposure to drug-resistant TB, and those who have been diagnosed during an outbreak. If drug susceptibility testing shows sensitivity to isoniazid and rifampin, ethambutol can be discontinued during the intensive phase.

In certain circumstances, treatment duration is extended. In cavitary TB or TB in an HIV-infected person that remains sputum culture positive after 2 months of treatment, the two-drug continuation phase should be extended to 7 months for a total treatment course of 9 months. For extrapulmonary TB in HIV-infected persons, a 6- to 9-month course of treatment is recommended. Exceptions include meningeal TB, which is treated for 9-12 months. If cultures obtained prior to treatment demonstrate drug resistance, the regimen and the duration of therapy may need to be changed.

For TB meningitis or pericarditis, a course of corticosteroids may be given in addition to specific anti-TB therapy: dexamethasone 0.3-0.4 mg/kg/day for 2-4 weeks then tapered over

the course of 8-10 weeks or prednisone 1 mg/kg/day for 3 weeks followed by a taper over the course of 3-5 weeks. For adrenal insufficiency, replacement corticosteroids should be given.

Considerations During pregnancy

Pyrazinamide has not been formally proven safe for use during pregnancy; however, it is used during pregnancy in many countries and there have been no reports of problems. Some health departments in the United States avoid the use of pyrazinamide for pregnant women and extend the continuation phase to 7 months, whereas others prescribe the standard regimens shown in Table 2 during pregnancy. Streptomycin and certain second-line drugs should be avoided during pregnancy. HIV-infected women in the United States are instructed not to breast-feed, so there usually are no issues regarding TB treatment of HIV-infected women during breast-feeding. ART should be started as early as possible; consult with an expert.

Coordinating with Antiretroviral Therapy

ART and TB treatment must be coordinated for both to be successful. ART is strongly recommended for all adults and adolescents with active TB, and both randomized and nonrandomized trials have demonstrated reduction in mortality when ART is combined with anti-TB chemotherapy.

The optimal timing of ART initiation in relation to TB treatment has been established with several randomized controlled trials. Adults and adolescents with active TB and CD4 counts of <50 cells/ μ L should start ART within 2 weeks of starting TB treatment. All patients with CD4 counts of $\geq$ 50 cells/ μ L should start ART within 8-12 weeks of starting TB therapy, but those who have CD4 counts of 50-200 cells/ μ L and severe disease should start within 2-4 weeks, if possible. Further, current HHS ARV guidelines recommend consideration of early ART (within 2-4 weeks)

for patients with CD4 counts of >200 cells/μL and severe disease. In all cases, TB treatment should be started immediately.

Timing of ART initiation in CNS TB infection is not clear. In one randomized trial, there was not a mortality benefit to starting ART at 2 weeks after TB treatment initiation compared with starting after 2 months of TB treatment, and more severe adverse events occurred in the earlier ART arm. Given the capacity for close monitoring that exists in the United States, many experts recommend initiating ART as with non-CNS TB.

Although paradoxical immune response (i.e., IRIS, see below) appears to be more common in patients who start ART earlier in the course of TB treatment, IRIS generally is not fatal.

Drug-drug interactions

Drug interactions between TB medications and ARVs may require dosage adjustments or modifications in treatment (see Table 3). Rifampin is a potent inducer of cytochrome P450 enzymes and has many clinically important drug interactions. It reduces the blood levels of nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors, and the CCR5 antagonist maraviroc, but does not affect nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) or the fusion inhibitor enfuvirtide. Triple-nucleoside regimens can be administered safely during rifampin treatment but are less potent than first-line ARV combinations and generally are not recommended. Current guidelines recommend the use of efavirenz plus a two-drug NRTI backbone if cotreatment with rifampin is planned (see Table 3). Efavirenz blood levels may be reduced 25% by concomitant rifampin, but the majority of available clinical data suggest that the standard efavirenz dosage of 600 mg/day is appropriate for rifampin coadministration, particularly in African-American and Asian populations. Limited clinical data support

the use of nevirapine at standard dosages in combination with rifampin. This is not a favored approach because nevirapine levels are reduced up to 50% when combined with rifampin. In one study, 20% of patients on ARV and TB treatment with rifampin had trough nevirapine levels that were below target, although they achieved the same rates of HIV RNA suppression as did patients on efavirenz. Plasma levels of the integrase inhibitors raltegravir and dolutegravir also are reduced when they are given with rifampin but the interaction can be overcome by increasing the dosage of the integrase inhibitor; few clinical data are available on the use of integrase inhibitors with rifampin.

To avoid rifampin-ARV interactions, rifabutin typically is used in place of rifampin. Rifabutin has fewer marked effects on the pharmacokinetics of other drugs, although its own blood concentrations can be affected by certain ARVs. Dosing recommendations for rifabutin with ARVs are found in Table 3. Acquired rifamycin resistance has been reported with coadministration of rifabutin with protease inhibitors, leading to the recommendation that the rifabutin dosage be at least 150 mg daily when given with ritonavir-boosted PIs and that monitoring of serum rifabutin levels be considered. Rifabutin is expensive; some public health systems do not provide rifabutin as part of TB treatment and it often is not available in resource-limited countries. The FDA characterizes rifabutin in pregnancy category B: it has been safe in animal studies of pregnancy but has not been proven safe for humans. For pregnant women who require both TB and ARV therapy, the use of rifabutin rather than rifampin allows the use of non-efavirenz-based ARV regimens.

Persons who are already on ART when TB treatment is begun must have their ARV regimens reassessed; the appropriate dosages of rifampin or rifabutin must be chosen or the ARV regimen must be modified, at least until completion of TB treatment (see Table 3).

Table 3. Interactions Between Antiretroviral Medications and Rifampin or Rifabutin: Contraindicated Combinations and Dosage Adjustments*

Antiretroviral Agent	Rifampin	Rifabutin* (Preferred in combination with PIs)
Nonnucleoside Reverse Transcriptase Inhibitors		
Efavirenz**	↓ efavirenz AUC; use standard efavirenz dosage 600 mg QD with monitoring for virologic efficacy (consider 800 mg QD if weight >60 kg).	Use standard efavirenz dosage. Increase rifabutin to 450-600 mg daily.
Etravirine	↓ etravirine levels expected; do not coadminister.	Etravirine without ritonavir-boosted PI: rifabutin 300 mg QD. Etravirine with a boosted PI: avoid, or consider therapeutic drug monitoring or rifabutin.
Nevirapine	↓ nevirapine levels; avoid if possible. If used, initiate nevirapine at 200 mg BID (no lead-in dosage); do not use nevirapine extended-release formulation.	↓ nevirapine and ↑ rifabutin levels. No dosage adjustment recommended; use cautiously.
Rilpivirine	↓ rilpivirine levels; do not coadminister.	↓ rilpivirine levels; do not coadminister.
Protease Inhibitors		
All protease inhibitors	↓ protease inhibitor levels; do not coadminister.	↑ rifabutin levels; adjust rifabutin dosage to 150 mg QD. Monitor for anti-TB efficacy, consider therapeutic drug monitoring.
Integrase Inhibitors		
Dolutegravir	↓ dolutegravir levels; increase dolutegravir to 50 mg BID for integrase-naïve patients (avoid if integrase resistance).	No dosage adjustment.
Elvitegravir/cobicistat	↓ elvitegravir and cobicistat levels expected; do not coadminister	↓ elvitegravir and ↑ rifabutin levels; do not coadminister.
Raltegravir	Increase raltegravir dosage to 800 mg BID; monitor for virologic response.	No dosage adjustment.
CCR5 Receptor Antagonists		
Maraviroc	↓ maraviroc levels; coadministration not recommended. If maraviroc must be used: Without a strong CYP 3A4 inhibitor: maraviroc 600 mg BID. With a strong CYP 3A4 inhibitor: maraviroc 300 mg BID.	Possible ↓ maraviroc levels. Without a strong CYP 3A4 inhibitor: maraviroc 300 mg BID. With a strong CYP 3A4 inhibitor: maraviroc 150 mg BID.
Fusion Inhibitors		
Enfuvirtide	No dosage adjustment.	No dosage adjustment.

Note: Rifapentine should not be coadministered with NNRTIs, PIs, or maraviroc.

* If available, rifabutin may be substituted for rifampin when TB treatment and ART are combined.

** Avoid use of efavirenz during early pregnancy and with women who may become pregnant while on therapy. Both rifampin and rifabutin significantly reduce estrogen and progestin levels for women on hormonal contraceptives; efavirenz raises estrogen levels moderately. Two forms of birth control, including one barrier method and either a mid- to high-dose hormonal contraceptive or an intrauterine device, are recommended most often.

Adapted from Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents. *Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from the Centers for Disease Control and Prevention, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America*. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Monitoring for efficacy

Ideally, every dose of anti-TB therapy is observed and documented by a health care agent or responsible individual, particularly during the intensive phase. Patients' adherence should be evaluated by a health care team member at least weekly during the initial phase of treatment and at least weekly or monthly during the continuation phase. If gaps in medication use occur, the cause must be evaluated and a plan to improve adherence must be implemented.

In treatment of pulmonary TB, monthly sputum specimens should be obtained for smear and culture until two sequential specimens are sterile on culture. Patients with extrapulmonary and disseminated TB usually are monitored clinically and with imaging studies. Biopsies are not repeated but other specimens (CSF and other body fluids) may be obtained for repeat AFB smear and culture. Monitoring of patients with extrapulmonary and disseminated TB should be done in consultation with an expert.

Immune reconstitution inflammatory syndrome

Patients on treatment for active TB who begin ART may experience a paradoxical increase in signs and symptoms of TB (fever, dyspnea, increased cough, enlarging lymph nodes, worsening chest X-ray findings, increased inflammation at other involved sites, or enlargement of CNS tuberculomas). These often are attributable to an enhanced immune response against remaining MTB organisms that occurs because of immunologic improvement from ART. IRIS may occur at any point from within 2 weeks up to several months after ART is initiated. TB treatment failure (potentially owing to an inappropriate treatment regimen, inadequate adherence, or drug resistance) must be ruled out, and the possibility of drug toxicity should be considered. In addition, new presentation

of opportunistic infection or malignancies should be considered. Paradoxical IRIS is a clinical diagnosis, and it can be made only after alternative diagnoses are excluded. If IRIS is diagnosed, TB and HIV treatment should be continued and symptoms can be managed with nonsteroidal antiinflammatory drugs or, in severe cases, with corticosteroids. Many experts recommend the use of corticosteroids particularly in the case of TB IRIS involving the CNS (see chapter *Immune Reconstitution Inflammatory Syndrome*).

Adverse effects of anti-TB medications

Anti-TB medications may have significant adverse effects. The most important adverse reactions reported for the commonly used anti-TB medications are listed in Table 4. The most frequent toxicities of first-line TB medications include hepatic enzyme elevations. Before initiating TB treatment, conduct a complete blood count with platelet count, serum creatinine count, liver function tests (aspartate aminotransferase [AST], alanine aminotransferase [ALT], bilirubin, alkaline phosphatase), and hepatitis B and C serology. Newly diagnosed TB patients with unknown HIV status should be tested for HIV infection.

Patients should be monitored monthly with a symptom review to assess possible toxicity, and laboratory tests should be performed if symptoms suggest adverse effects. For patients with liver disease, it may be prudent to perform routine laboratory monitoring after 1 month on treatment and every 3 months thereafter. Persons with symptoms and aminotransferase elevations ≥ 3 times the upper limit of normal, and asymptomatic persons with aminotransferase elevations ≥ 5 times the upper limit of normal, should have therapy interrupted and should be managed thereafter in consultation with an expert.

Patients should be monitored for isoniazid-induced peripheral neuropathy; this adverse

effect is rare if pyridoxine is administered with isoniazid, as recommended. Testing of visual acuity and red-green color vision is recommended at the start of therapy with ethambutol. Persons on standard ethambutol dosages with normal baseline examinations

should be asked monthly about visual disturbances. Patients on higher ethambutol dosages and those who have been on ethambutol for more than 2 months should have periodic eye examinations for acuity and color discrimination.

Table 4. Adverse Events Associated with Common Anti-TB Medications

Medication	Common Toxicity	Rare Toxicity
First-Line Agents		
Isoniazid	Transient transaminase elevation, hepatitis, positive antinuclear antibody (ANA)	Peripheral neurotoxicity, lupus-like syndrome, CNS effects, hypersensitivity, rash, monoamine poisoning
Rifampin	Transient bilirubin elevation, transaminase elevations, anorexia, nausea, vomiting, hepatitis, red-orange discoloration of urine and tears	Acute renal failure, shock, thrombocytopenia, rash, “flu” syndrome from intermittent doses, pseudomembranous colitis, pseudoadrenal crisis, osteomalacia, hemolytic anemia
Rifabutin	Elevated liver function tests, nausea, red-orange discoloration of urine and tears	Cytopenias, uveitis, rash
Ethambutol	Optic neuritis	Skin rash, joint pains, peripheral neuropathy
Pyrazinamide	Joint pains, gout, hepatitis	Gastrointestinal symptoms, skin rash, sideroblastic anemia
Streptomycin	Auditory and vestibular nerve damage, renal injury	Rash
Second-Line Agents		
Moxifloxacin	Nausea, diarrhea, dizziness	Tendon rupture, hepatotoxicity, renal damage, prolonged QT interval, skin reactions
Amikacin/ Kanamycin	Auditory, vestibular, renal injury

Patient Education

- All patients with TB-positive sputum or bronchoscopy specimens can infect others with TB. All close contacts, especially children, should be screened for TB as soon as possible and given medication to prevent (or treat) active disease.
- The health department will be notified of each TB case and will provide the required follow-up care.
- Patients must take all medicines exactly as prescribed. If doses are missed, or if the medication is stopped and restarted, the TB bacteria can develop resistance to even the best medications and become even more dangerous. If patients are having trouble taking the medication on schedule, they should contact their health care provider immediately.
- If patients become ill, if their skin or eyes turn yellow, or if their urine darkens to a “cola” color, they should contact their health care provider immediately.
- Patients must keep all follow-up appointments. Blood tests will be done regularly to ensure that the liver is working well, and patients will be checked for medication adverse effects. They should show their health care provider all medications, vitamins, and supplements they are taking so that the provider can check for drug interactions.
- Rifampin and rifabutin will make urine, sweat, and tears turn orange; this is not harmful. They will cause staining of plastic contact lens; patients should avoid wearing contact lenses if they are taking rifamycins.
- Rifampin and rifabutin may cause birth control pills to become ineffective. An alternative method of contraception should be used when the patient is undergoing treatment.
- The use of alcohol should be avoided during treatment with TB drugs to avoid the risk of liver damage.

Pelvic Inflammatory Disease

Background

Pelvic inflammatory disease (PID) is the syndrome resulting from the ascent of microorganisms from the vagina and cervix to the uterine endometrium, fallopian tubes, ovaries, or contiguous abdominal structures. Many episodes of PID go unrecognized, because of lack of symptoms or mild, nonspecific symptoms (e.g., dyspareunia, abnormal bleeding, and vaginal discharge). Infecting organisms may include *Neisseria gonorrhoeae* (GC) and *Chlamydia trachomatis* (CT), which are sexually transmitted, as well as anaerobic bacteria (*Gardnerella vaginalis* or *Haemophilus influenzae*), gram-negative rods (*Escherichia coli*), *Streptococcus agalactiae*, gastrointestinal flora, and mycoplasmas (*Mycoplasma hominis*). It is thought that PID generally is caused by sexually transmitted diseases (STDs) and that additional organisms become involved after infection spreads and protective immunological barriers are disrupted.

Between 20% and 40% of women with cervical chlamydial infection and 10-20% of women with gonococcal infection eventually develop PID, but accurate estimates of the incidence of PID and infertility resulting from GC and CT are difficult to obtain. Hospitalizations for PID declined steadily throughout the 1980s and 1990s but remained relatively constant between 2000 and 2006, at approximately 80,000 annually.

PID is co-epidemic with HIV among some urban populations of reproductive age. Data on PID outcomes among HIV-infected women are limited. Many studies have documented no difference in length or severity of lower abdominal pain, vaginal discharge, fever, abnormal vaginal bleeding, or low back pain between HIV-infected and HIV-uninfected women with PID. However, there is a higher rate of tubo-ovarian abscesses and severe salpingitis and pyosalpinx among HIV-infected women.

Clinical presentation may include salpingitis, endometritis, tubal and ovarian abscess, and pelvic peritonitis, although PID may present with subtle or mild symptoms even in HIV-infected women. Long-term complications of PID may include infertility, ectopic pregnancy, pelvic adhesions, and chronic pain. After a single episode of PID, a woman's risk of ectopic pregnancy increases sevenfold. Approximately 13% of women are infertile after a single episode of PID, 25-35% after two episodes, and 50-75% after three or more episodes.

Diagnosis of PID usually is based on clinical findings, and providers should maintain a low threshold for diagnosing and promptly treating this disease, as it can wreak havoc on a woman's reproductive health. All women who are diagnosed with PID should be tested for GC and CT.

S: Subjective

The patient may complain of mild-to-moderate lower abdominal pain and tenderness, pain with intercourse, vaginal discharge, fever, chills, heavy menstrual bleeding, or other abnormal vaginal bleeding.

Inquire about the following during the history:

- Symptoms listed above, and duration
- Sexual history including new sex partner(s)

and episodes of unprotected sex

- Last menstrual period
- Previous diagnosis of gonorrhea or chlamydia
- Previous abdominal or gynecologic surgery
- History of recent intrauterine device (IUD) placement (the risk of PID associated with IUD use is confined primarily to the first 3 weeks after insertion)

O: Objective

Check vital signs with special attention to temperature (may be elevated or normal).

Perform a focused physical examination.

Check abdomen (bowel sounds, distention, rebound, guarding, masses, suprapubic and costovertebral angle [CVA] tenderness); perform complete pelvic examination looking for abnormal bleeding or discharge; uterine, adnexal, or cervical motion tenderness; pelvic masses or adnexal enlargement.

A: Assessment

A partial differential diagnosis includes the following:

- Pregnancy, uterine or ectopic
- Ruptured or hemorrhagic ovarian cyst
- Dysmenorrhea
- Appendicitis
- Pyelonephritis
- Diverticulitis
- Irritable bowel syndrome
- Cystitis
- Uterine fibroids/leiomyomas
- Ovarian torsion
- Mittelschmerz
- Kidney stones
- Pyelonephritis

P: Plan**Diagnostic Evaluation**

A diagnosis of PID usually is based on clinical findings; however, the following can support a diagnosis and help rule out other causes of abdominal pain:

- Pregnancy test
- Nucleic acid amplification tests (NAAT) or culture for GC and CT
- Microscopic examination of saline preparation of vaginal secretions

Often, diagnosis must be made and treatment initiated on the basis of clinical criteria. Current guidelines identify “minimal criteria” found on pelvic examination in patients with PID:

- Cervical motion tenderness, or
- Uterine tenderness, or
- Adnexal tenderness

The following signs support a diagnosis of PID:

- Oral temperature $>101^{\circ}\text{F}$ ($>38.3^{\circ}\text{C}$)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of abundant numbers of white blood cells on saline microscopy of vaginal secretions (this also can detect concomitant infections such as bacterial vaginosis and trichomoniasis)
- Elevated erythrocyte sedimentation rate (ESR)
- Elevated C-reactive protein (CRP)
- Laboratory documentation of cervical infection with GC or CT (the absence of infection from the lower genital tract, where samples are usually obtained, does not exclude PID and should not influence the decision to treat)

Definitive diagnosis may be made on the basis of:

- Endometrial biopsy with histopathologic evidence of endometritis
- Transvaginal sonogram or other imaging showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex
- Laparoscopic abnormalities consistent with PID

Treatment

Because clinical diagnostic criteria for PID are not always conclusive, presumptive diagnosis and early empiric treatment is common. The positive predictive value of a clinical diagnosis is 65-90%.

Empiric therapy for PID should be started in women who have one or more of the minimal criteria, plus pelvic or lower abdominal pain and risk factors for PID (sexually active young women, women at risk of STDs), unless another cause for the symptoms is identified.

Treatment considerations

Antimicrobial regimens must be broadly effective against likely pathogens (see below). HIV-infected women appear to respond as well to standard antibiotic regimens as do HIV-uninfected women. It is not known whether HIV-infected women with advanced immunosuppression should be treated more aggressively; decisions about whether to use oral or parenteral therapy must be individualized.

In the United States and elsewhere GC commonly is resistant to fluoroquinolone; thus, this class of antibiotics is no longer recommended for treatment of PID.

No evidence suggests that IUDs should be removed in women diagnosed with PID. However, caution should be used if the IUD remains in place, and close clinical follow-up is recommended.

The goals of treatment include the following:

- Alleviate the pain and systemic malaise associated with infection
- Achieve microbiological cure
- Prevent development of permanent tubal damage with associated problems, such as chronic pelvic pain, ectopic pregnancy, and infertility
- Prevent the transmission of infection to others

Indications for hospitalization of patients with PID include the following:

- Unsure diagnosis; surgical emergency cannot be excluded
- Pregnancy
- Patient does not respond clinically (within 72 hours) to oral antimicrobial therapy
- Tubo-ovarian abscess
- Severe illness with nausea and vomiting or high fever
- Inability to follow or tolerate outpatient regimen

Pregnancy

If the patient is pregnant, aggressive treatment is essential to prevent preterm delivery, fetal loss, and maternal morbidity. Some medications should be avoided to reduce the risk of fetal toxicity; these include doxycycline and gentamicin. Hospitalization for parenteral antibiotic therapy is recommended.

Antibiotic Regimens

Recommended Oral/Outpatient Regimens

- Ceftriaxone 250 mg IM in a single dose + doxycycline 100 mg PO BID for 14 days, with or without metronidazole 500 mg PO BID for 14 days
- Cefoxitin 2 g IM in a single dose and probenecid 1 g PO concurrently in a single dose + doxycycline 100 mg PO BID for 14 days, with or without metronidazole 500 mg PO BID for 14 days
- Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime) + doxycycline 100 mg PO BID for 14 days, with or without metronidazole 500 mg PO BID for 14 days

Alternative Oral Regimens

If parenteral cephalosporin therapy is not feasible, consult with an expert. Limited evidence supports the use of amoxicillin/clavulanic acid with doxycycline, and azithromycin with or without metronidazole or ceftriaxone. Because of the prevalence of fluoroquinolone-resistant GC, use of fluoroquinolones is no longer recommended but may be considered, with or without metronidazole, if the community prevalence is low, the patient's risk of gonorrhea is low, and follow-up can be assured if the GC test result is positive. For more information, see the *CDC Sexually Transmitted Diseases Treatment Guidelines* (see "References," below).

Recommended Parenteral Regimens

- Cefotetan 2 g IV Q12H + doxycycline 100 mg PO BID

- Cefoxitin 2 g IV Q6H + doxycycline 100 mg PO BID
- Clindamycin 900 mg IV Q8H + gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) Q8H; single daily dosing (3-5 mg/kg) may be substituted

Alternative Parenteral Regimen

- Ampicillin/sulbactam 3 g IV Q6H + doxycycline 100 mg PO BID

Women who are started on oral antibiotics but do not respond within 72 hours should be reevaluated to confirm the diagnosis of PID and should be administered parenteral therapy on either an outpatient or inpatient basis. Patients who are treated with parenteral antibiotics usually can be transitioned to oral antibiotics within 24 hours of clinical improvement.

Follow-Up

- Patients should show significant clinical improvement within 3 days of initiation of therapy (e.g., improvement in fever, abdominal tenderness, and uterine, adnexal, and cervical motion tenderness). If the patient has not improved, consider hospitalization, additional diagnostic testing, or surgical intervention. Patients who are hospitalized for treatment initially may be switched to an oral regimen and be discharged on oral therapy after they have improved clinically.
- Evaluate sex partners and offer them treatment if they had sexual contact with the patient during the 60 days preceding the patient's onset of symptoms. Treat empirically for both chlamydia and gonorrhea.
- If the GC or CT test results are positive, rescreening for GC and CT 3 months after therapy is recommended. Provide education about sexual risk reduction. Instruct patients

to use condoms with every sexual contact to prevent reinfection with GC and CT, to prevent other STDs, and to prevent passing HIV to sex partners.

- Studies of patients treated for CT infection show reinfection rates as high as 13% within 4 months of treatment, highlighting the need for follow-up and partner treatment.

Patient Education

- Instruct patients to take all of their medications. Advise patients to take medications with food if they feel nauseated, and to contact the clinic promptly if they experience vomiting or are unable to take their medications.
- Sex partners from the previous 60 days need to be tested for CT, GC, and syphilis (as well as HIV, if uninfected) and treated empirically, as soon as possible, with a regimen effective against GC and CT, even if they have no symptoms. Advise patients to inform their partners that they need to be tested and treated. Otherwise, they may be reinfected.
- Advise patients to avoid sexual contact until the infection has been cured.
- Provide education about sexual risk reduction. Instruct patients to use condoms with every sexual contact to prevent becoming reinfected, to prevent other STDs, and to prevent passing HIV to sex partners.
- Advise patients that PID can recur, and that they should contact the clinic if symptoms such as pain or fever develop.
- Patients must not drink beer, wine, or any other alcoholic beverage while taking metronidazole, and for at least 24-48 hours after the last dose. Metronidazole may cause a disulfiram-like reaction, resulting in severe nausea and vomiting. Note that patients taking ritonavir capsules may experience symptoms caused by the small amount of

alcohol in the capsules; advise patients to contact the clinic if nausea and vomiting occur.

Pneumocystis Pneumonia

Background

Pneumocystis jiroveci pneumonia (previously called *Pneumocystis carinii* pneumonia, and still abbreviated PCP), is caused by an unusual fungus, *P. jiroveci*. Many humans appear to be infected in childhood, but clinical illness occurs only in people with advanced immunosuppression, either through new infection or reactivation of latent infection. More than 90% of PCP cases occur in patients with CD4 counts of <200 cells/ μ L. Cases of PCP in otherwise healthy young men who have sex with men were among the first recognized manifestations of AIDS, in 1981. The organism can affect many organ sites, but pneumonia is by far the most common form of disease. In the United States, the incidence of PCP has declined sharply since the use of prophylaxis and effective antiretroviral therapy (ART) became widespread, but PCP is still many patients' initial presenting opportunistic infection, and it is a significant cause of morbidity and mortality among HIV-infected patients.

S: Subjective

The patient reports fever, shortness of breath, particularly with exertion, nonproductive cough, night sweats, weight loss, or fatigue. Typically, the symptoms worsen over the course of days to weeks. Pleuritic pain and retrosternal pain or burning also may be present. There may be minimal symptoms early in the disease course of PCP.

Ask the patient about fever, fatigue, and weight loss, which may be present for weeks, with gradual worsening of shortness of breath. PCP may present less commonly with acute onset symptoms of fevers, chills, sweats, dyspnea, and cough.

Note: Given the possibility of HIV-associated tuberculosis (TB), patients with cough should be kept in respiratory isolation until TB is ruled out.

O: Objective

Perform a full physical examination, with particular attention to the following:

- Vital signs, including temperature, heart rate, blood pressure, respiratory rate, oxygen saturation at rest and after exertion (there is often a sharp drop in oxygen saturation with exertion)

- Appearance
- Lung examination

Patients may appear relatively well, or acutely ill. Tachypnea may be pronounced, and patients may exhibit such a high respiratory rate (e.g., >30 breaths per minute) that they are unable to speak without stopping frequently to breathe. Chest examination may be normal, or reveal only minimal rales, although coughing is common on deep inspiration. Cyanosis may be present around the mouth, in the nail beds, and on mucous membranes. Cough is either unproductive, or productive of a thin layer of clear or whitish mucus.

A: Assessment

A partial differential diagnosis includes the following:

- Pneumococcal pneumonia
- Other bacterial pneumonias
- TB
- Influenza Lymphocytic interstitial pneumonitis
- Bronchitis
- Cytomegalovirus (CMV) pneumonitis
- Histoplasmosis

- Other fungal pneumonia, especially cryptococcosis
- Pulmonary Kaposi sarcoma
- *Mycobacterium avium* complex
- Asthma, chronic obstructive pulmonary disease
- Congestive heart failure
- Pulmonary hypertension

P: Plan

Diagnostic Evaluation

- **CD4 cell count:** Check records for a recent CD4 count (CD4 is <200 cells/ μ L in $>90\%$ of PCP cases). Note that a CD4 count obtained in the setting of acute illness (e.g., when the patient presents with pneumonia) may be substantially lower than the usual baseline, and may be difficult to interpret.
- **Pulse oximetry at rest and after exercise:** Oxygen desaturation with exercise suggests an abnormal alveolar-arterial O_2 gradient (A-a gradient).
- **Arterial blood gas (ABG):** Hypoxemia is common, as is elevation in A-a gradient. Generally, PO_2 levels and A-a gradient are associated with disease severity. Poorer outcomes are seen with $PO_2 <70$ mm Hg and A-a gradient >35 mm Hg.
- **Lactate dehydrogenase (LDH):** Elevated serum LDH (>300 – 500 IU/L) is common.
- **Chest X-ray:** Typically shows bilateral interstitial infiltrates, but atypical patterns with cavitation, lobar infiltrates, nodules, or pneumothorax may occur, and chest X-ray findings may be normal in some cases. Upper-lobe predominance is common if the patient is receiving aerosolized pentamidine for PCP prophylaxis.
- **Thin-section chest computed tomography (CT) scan:** May show patchy ground-glass opacities; in a patient with clinical signs or symptoms of PCP, these are suggestive but not diagnostic of PCP.
- **Sputum induction:** The patient inhales saline mist to mobilize sputum from the lungs. The respiratory therapist collects expectorated sputum, which is stained and examined for *P. jiroveci* organisms. This technique is useful because of its noninvasive approach, but it requires an experienced technician, and is not available at all centers. Sensitivity varies widely (10–95%), depending on the expertise level of the staff at a particular center. (If there is any chance that the patient has TB, sputum induction should be performed in a confined space in a negative pressure area or near an exhaust fan vented safely outside, and samples should be sent for acid-fast bacilli [AFB] smear and culture.)
- **Bronchoscopy with bronchoalveolar lavage (BAL):** Definitive diagnosis usually can be made through detection of organisms in BAL fluid obtained during bronchoscopy. Sensitivity is $>95\%$ at centers with an experienced staff. BAL fluid can be evaluated for bacteria, mycobacteria, and fungi, as well as for *P. jiroveci*. Polymerase chain reaction (PCR) testing increasingly is used; its specificity has not been well established.
- **Transbronchial biopsy:** May be performed if BAL is not diagnostic and if lung disease is progressive despite treatment, to look for diagnoses other than PCP. Open lung biopsy rarely is performed.

Treatment

Presumptive treatment often is initiated on the basis of clinical presentation, chest X-ray findings, and ABG results, while definitive diagnostic tests are pending. The standard and alternative treatment regimens are shown below. Duration of treatment is 21 days for all regimens.

Trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim, Septra, cotrimoxazole) is the drug of choice, administered IV or PO for 21 days (a typical PO dose is 2 double-strength tablets taken TID). Adverse effects of TMP-SMX (e.g., rash, fever, leukopenia, anemia, gastrointestinal intolerance, hepatotoxicity, hyperkalemia) are common, mostly mild, and usually “treated through” successfully. Patients who have had previous reactions to sulfa drugs also may be desensitized successfully (see chapter *Sulfa Desensitization*). TMP-SMX

requires dosage adjustment for patients with renal insufficiency.

Pentamidine has similar efficacy to TMP-SMX but greater toxicity (nephrotoxicity, pancreatitis, glucose dysregulation, cardiac arrhythmias). It usually is reserved for patients with severe disease who require IV therapy.

Adjunctive corticosteroids

Adjunctive corticosteroids should be given if the patient’s PO_2 is <70 mm Hg (breathing room air) or the A-a gradient is ≥ 35 mm Hg. Corticosteroids should be given as early as possible (preferably before or with the first dose of antibiotic therapy) and within 36-72 hours of the start of anti-PCP therapy:

- Prednisone 40 mg BID days 1-5; 40 mg QD on days 6-10; 20 mg QD on days 11-21. Alternatively, IV methylprednisolone can be given, at 75% of the prednisone dosage.

Moderate to Severe PCP
Preferred therapy • TMP-SMX (TMP 15-20 mg/kg/day + SMX 75- 100 mg/kg/day) IV in divided doses Q6H or Q8H (switch to PO after clinical improvement) Alternative therapy • Pentamidine 4 mg/kg IV QD (dosage reduction to 3 mg/kg QD may be needed if toxicities develop) • Clindamycin 600 mg IV or 900 mg IV Q8H (or 300 mg PO Q6H or 450 mg PO Q8H) + primaquine* base 30 mg PO QD
Mild to Moderate PCP
Preferred therapy • TMP-SMX (TMP 15-20 mg/kg/day + SMX 75- 100 mg/kg/day) PO, in divided doses TID • TMP-SMX double-strength (DS), 2 tablets TID Alternative therapy • Dapsone* 100 mg PO QD + TMP 15 mg/kg/day PO in 3 divided doses • Clindamycin (300 mg PO Q6H or 450 mg PO Q8H) + primaquine* base 30 mg PO QD • Atovaquone 750 mg PO BID with food

* Test for G6PD deficiency before use (most common among patients of African or Mediterranean descent); caution with use in patients with G6PD deficiency.

Other therapy notes

- Patients started on IV therapy can be switched to a PO treatment regimen to complete the 3-week course when they are afebrile, have improved oxygenation, and are able to take oral medications.
- For patients not already on ART, ART generally should be started within 2 weeks of initiating treatment for PCP.
- Paradoxical worsening of PCP resulting from presumed immune reconstitution inflammatory syndrome (see chapter *Immune Reconstitution Inflammatory Syndrome*) has been reported; monitor patients for worsening symptoms after ART initiation.
- Consultation with HIV experts is advisable when initiating of ART in the setting of PCP.

Treatment failures

The average time to clinical improvement for hospitalized patients is 4-8 days, so premature change in therapy should be avoided. For patients who fail to improve on appropriate therapy, it is important to exclude other diagnoses, rule out fluid overload, and consult an infectious disease specialist.

Secondary Prophylaxis

Anti-PCP prophylaxis (chronic maintenance therapy) should be given to all patients who have had an episode of PCP. Prophylaxis should be continued for life, unless immune reconstitution occurs as a result of ART and the CD4 count has been >200 cells/ μ L for more than 3 months.

In patients with stable CD4 count of >200 cells/ μ L on effective ART, it is recommended that PCP prophylaxis be discontinued because it offers little clinical benefit but may cause drug toxicity, drug interactions, and selection of drug-resistant pathogens, plus it

adds to the cost of care and to the patient's pill burden.

If PCP occurred at a CD4 count of >200 cells/ μ L, it is recommended to continue prophylaxis for life despite immune reconstitution; however, data to support this approach are limited.

Prophylactic therapy**Preferred:**

- TMP-SMX DS, 1 tablet PO QD, or 1 single-strength tablet PO QD

Alternative:

- TMP-SMX DS: 1 tablet PO TIW (e.g., Monday, Wednesday, Friday)
- Dapsone* 100 mg PO QD, or 50 mg PO BID
- Dapsone* 50 mg PO QD + pyrimethamine 50 mg PO once weekly + leucovorin 25 mg PO once weekly
- Dapsone* 200 mg PO + pyrimethamine 75 mg + leucovorin 25 mg, all once weekly
- Aerosolized pentamidine 300 mg once monthly, via Respigard II nebulizer (note: does not prevent toxoplasmosis) (Warning: May increase the risk of extrapulmonary pneumocystosis, pneumothorax, and bronchospasm.)
- Atovaquone 1,500 mg PO QD (with or without pyrimethamine 25 mg PO QD + leucovorin 10 mg PO QD)

* Use with caution in G6PD deficiency.

Primary Prophylaxis

- Primary prophylaxis against PCP should be given to all HIV-infected patients with a CD4 count of <200 cells/ μ L, CD4 percentage of $<14\%$, or a history of oral candidiasis; see chapter *Opportunistic Infection Prophylaxis*.

Patient Education

- Patients should be instructed to take all medications exactly as prescribed.
- Patients should call their health care provider if symptoms worsen.
- Patients being treated with TMP-SMX or dapsone who develop rash, fever, or other new symptoms should call their provider to be evaluated for a drug reaction.
- Patients should understand that taking anti-PCP prophylaxis is extremely important for preventing repeat episodes of illness. Patients should not stop taking these medicines without talking with their health care provider, and should not let their supply of medications run out.
- Patients should be counselled about the importance of ART in restoring immune system function to reduce the likelihood of illness and death from PCP and other OIs.

Progressive Multifocal Leukoencephalopathy

Background

Classic PML

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of the central nervous system (CNS) caused by reactivation of latent infection with JC virus, a polyomavirus that infects and lyses oligodendrocytes. Demyelination can occur along any part of the white matter, and often does so at multiple sites (hence the term multifocal). The severity of symptoms increases as demyelination progresses.

Among HIV-infected patients, PML occurs classically and most frequently in those with CD4 counts of <200 cells/ μL who are not receiving antiretroviral therapy (ART), but it can occur in patients with higher CD4 counts and in those on suppressive ART. Patients typically present with multiple focal deficits of the cerebrum and brainstem, such as cognitive decline, focal weakness, and cranial nerve palsies, with one focal deficit often predominating. Symptoms typically progress over the course of several weeks. Imaging studies show noninflammatory, nonenhancing white matter lesions, without mass effect, with an anatomical location that maps to deficits on the neurological examination. A presumptive diagnosis of PML often can be made on the basis of the patient's clinical presentation and results of neuroimaging studies. Cerebrospinal fluid (CSF) often tests positive for JC virus DNA by polymerase chain reaction (PCR), although brain biopsy is sometimes needed for definitive diagnosis.

Among untreated patients, the interval between the first manifestation of neurologic symptoms and death may be as short as 3-4 months. Although the prognosis for patients with PML has improved with the use of potent ART, there is no specific treatment for PML, and mortality rates remain high. Patients who survive PML are likely to have permanent neurologic deficits.

Inflammatory PML

Whereas PML in the absence of ART usually is not an inflammatory condition, initiation of ART may cause an immune reconstitution inflammatory syndrome, involving new or worsening neurologic deficits and inflammatory changes seen on brain imaging and biopsy specimens. (See chapter *Immune Reconstitution Inflammatory Syndrome*.) The initiation of ART in a patient with late-stage HIV-related disease may even reveal previously undetected PML. Although many patients with inflammatory PML improve or at least stabilize, some suffer exacerbation of symptoms, rapid progression of disease, cerebral edema, herniation, and death.

S: Subjective

The patient or a caregiver may note symptoms such as weakness, gait abnormalities, difficulties with speech, visual changes, altered mental status, personality changes, and seizures. Hemianopia, ataxia, dysmetria, and hemiparesis or hemisensory deficits often are seen. The onset is likely to be subacute, with progression over the course of weeks, though neurologic disturbances may become profound. PML is not associated with headache or fever (except in cases of immune reconstitution PML); this may help to distinguish it from other opportunistic illnesses of the CNS.

O: Objective

- Measure vital signs.
- Perform a full physical examination, including a thorough neurologic and mental status evaluation. Look for focal or nonfocal neurologic deficits, particularly cranial nerve abnormalities, visual field defects, weakness, gait abnormalities, and abnormalities in cognitive function, speech, or affect; deficits are likely to be multiple. The patient typically is alert.
- Review previous laboratory values, particularly CD4 count (usually <200 cells/ μ L in patients with PML).

A: Assessment

Rule out other causes of the patient's neurologic changes. A partial differential diagnosis includes the following:

- CNS lymphoma
- Toxoplasmosis
- HIV encephalopathy
- HIV dementia
- Other (non-HIV) forms of dementia
- Cerebrovascular disease
- Neurosyphilis
- CNS opportunistic infection (e.g., tuberculosis, cryptococcosis, and cytomegalovirus)
- Multiple sclerosis

P: Plan**Diagnostic Evaluation**

Presumptive diagnosis of PML often is made on the basis of clinical presentation, brain imaging, and laboratory tests.

Definitive diagnosis requires detection of JC virus DNA in CSF of patients with radiographic and clinical findings consistent with PML or a brain biopsy and identification of characteristic pathological changes. Definitive diagnosis should be attempted in all patients, if possible, and particularly in those patients for whom the diagnosis is unclear.

Radiographic Studies

CNS imaging may reveal changes typical of PML, but is nonspecific. Magnetic resonance imaging (MRI) is more sensitive than computed tomography (CT) for detecting PML. Classic PML presents as single or multiple hypodense lesions in the subcortical white matter, with no surrounding edema. On MRI, lesions show increased T2 signal and little or no enhancement with gadolinium. On CT, PML lesions typically are nonenhancing. In some patients, and particularly in

patients taking ART, PML lesions may show inflammatory changes, such as enhancement, and there may be cerebral edema.

CSF Evaluation

- CSF cell count, protein level, and glucose level generally are normal or show mild pleocytosis and slightly elevated protein.
- JC virus PCR assays are approximately 75–85% sensitive (lower in patients on ART); detection of JC virus in a patient whose clinical presentation and radiographic imaging results are consistent with PML is adequate to make a diagnosis. A negative result with JC virus PCR does not rule out PML.

Other Studies

- Other diagnostic tests should be performed as indicated to rule out other potential causes of the patient's symptoms.
- A brain biopsy should be considered if the diagnosis is unclear.

Treatment

- There is no specific treatment for JC virus. Potent ART with maximal virologic suppression and effective immune reconstitution is the only treatment that may be effective for patients with PML. Even with ART, however, mortality rates approach 40–50%, and neurologic deficits are unlikely to be reversed.
- Initiate ART for patients who are not already receiving treatment. It is not clear whether antiretroviral agents with good CNS penetration are more effective than those that are less likely to cross the blood-brain barrier.
- For patients who are on ART with incomplete virologic suppression, change the ART regimen appropriately to achieve virologic suppression, if possible. (See chapter *Antiretroviral Therapy*.)

- If symptoms are caused by immune reconstitution, consider adding corticosteroids (e.g., dexamethasone or methylprednisolone) to help decrease inflammation.
- The following agents have been proposed as specific therapy for PML, but have not been shown to be effective by prospective studies and are not recommended for treatment: cidofovir, cytarabine, and topotecan. Few data exist to assess the potential benefit of interferon-alfa and inhibitors of the serotonergic 5-HT_{2a} receptor.
- Depending on the patient's cognitive and physical status, he or she may need a care provider in the home to assure that medications are taken on schedule.
- The patient is likely to need supportive care for personal hygiene, nutrition, safety, and prevention of accidents or injury; refer as indicated.

Patient Education

- Most patients diagnosed with PML will need supportive treatment for an undetermined period of time, and hospice referral should be considered if the patient does not show clinical improvement in response to ART.
- If the patient is receiving ART, be sure that caregivers, family members, and friends are taught about the medications and are able to help the patient with adherence.
- When a diagnosis of PML has been established or suspected, initiate a discussion of plans for terminal care (including wills, advanced directives, and supportive care and services) with the patient and family members or caregivers.

Seborrheic Dermatitis

Background

Seborrheic dermatitis is one of the most common skin manifestations of HIV infection. It occurs in 3-5% of the general HIV-uninfected population but in up to 85-95% of patients with advanced HIV infection. Among HIV-infected individuals, seborrheic dermatitis often begins when their CD4 counts drop to the 450-550 cells/ μ L range. The disease is more likely to occur among young adults (because they have oilier skin) and males, and is more common in areas with cold, dry winter air. It is rarely found in African blacks, unless the person is immunocompromised. It is more common during times of mental stress and severe illness.

Seborrheic dermatitis is a scaling, inflammatory skin disease that may flare and subside over time. It is characterized by itchy reddish or pink patches of skin, accompanied by greasy flakes or scales. It most commonly occurs in the scalp and on the face, especially at the nasolabial folds, eyebrows, and forehead, but also may develop on the ears, chest, upper back, axillae, and groin. Dandruff is considered to be a mild form of seborrheic dermatitis. Occasionally, seborrheic dermatitis may be severe, may involve large areas of the body, and may be resistant to treatment. Severe manifestations are more likely with advanced HIV infection.

The etiology of seborrheic dermatitis is not entirely clear. *Malassezia* yeast (formerly called *Pityrosporum ovale*), a fungus that inhabits the oily skin areas of 92% of humans, is the most likely culprit. This same yeast also is thought to cause tinea versicolor and *Pityrosporum* folliculitis. Overgrowth of the *Malassezia* yeast in the oily skin environment, failure of the immune system to regulate the fungus, and the skin's inflammatory reaction to the yeast overgrowth appear to be the chief factors that cause the dermatitis.

S: Subjective

The patient complains of a new rash, sometimes itchy, or of "dry skin" that will not go away despite the application of topical moisturizers.

O: Objective

Perform a thorough evaluation of the skin with special attention to the scalp, medial eyebrows, eyelashes and eyelids, beard and other facial hair areas, nasolabial folds, postauricular areas, the concha of the auricle, glabella, umbilicus, central chest, back, axillae, and groin. Seborrheic dermatitis appears as white to yellow greasy or waxy flakes over red or pink patches of skin; however, discrete fine scales may indicate a mild form of the

disease. Around the eyes, seborrheic dermatitis can cause eyelid erythema and scaling. The distribution usually is symmetrical.

A: Assessment

The diagnosis of seborrheic dermatitis is based on the characteristic appearance. A partial differential diagnosis includes psoriasis, atopic dermatitis, contact dermatitis, erythrasma, tinea capitis (can be present on the scalp without hair loss), rosacea, and rarely, dermatomyositis.

P: Plan Treatment

- Initiate antiretroviral therapy (ART) for patients not on ART

- Specific treatments are divided into three types: antimycotic (first choice), antiinflammatory (second choice), and keratolytic. Shampoos may be used on the entire body, with avoidance of eyes and mucous membranes.
- Topical antifungal medications: The azoles and ciclopirox have been well studied and shown to have both antifungal and antiinflammatory activity. Various preparations are available; selection can be based on cost and availability. Antifungals may be used in combination with topical corticosteroid therapy (see below). Effective antifungals include but are not limited to the following:
 - Ketoconazole (Nizoral) 2% cream or shampoo; ketoconazole is one of the most widely studied of all topical treatments
 - Bifonazole ointment, miconazole cream (Monistat), terbinafine (Lamisil) 1% solution or cream, or clotrimazole (Lotrimin) 1% cream, lotion, or solution
 - Ciclopiroxolamine (Loprox) 1% shampoo, gel, or cream
 - Zinc pyrithione (keratolytic/antifungal) shampoo or cream
- Topical corticosteroids generally are effective and may be used in combination with topical antifungal therapy (see above). Low-potency agents (e.g., hydrocortisone 1%) rather than high-potency corticosteroids (e.g., betamethasone dipropionate, triamcinolone), are recommended, especially for the face, to reduce the risk of adverse effects associated with all corticosteroids (e.g., atrophy, telangiectasias, and perioral dermatitis). Corticosteroid shampoos also may be considered for scalp involvement.
- Selenium sulfide/sulfur preparations (the most common is selenium sulfide shampoo).
- Whole coal tar, crude coal tar extract: shampoos, creams, and gels.
- Lithium succinate or lithium gluconate ointment, available in some countries as a combination of lithium succinate 8% and zinc sulfate 0.05% (may have antifungal or antiinflammatory effects). Not for use on the scalp.
- Honey, 90% diluted with warm water, may be used to treat seborrheic dermatitis and dandruff.
- Azelaic acid, 15% gel or 20% cream, has sebosuppressive, antimicrobial, antifungal, and antiinflammatory activity (also used for acne and rosacea).
- Noncorticosteroid topical immunomodulators (calcineurin inhibitors):
 - Tacrolimus
 - Pimecrolimus
- Oral therapy may be used for patients who are refractory to topical treatment (may interact with protease inhibitors and nonnucleoside reverse transcriptase inhibitors; check for possible drug-drug interactions with antiretroviral and other medications before prescribing). There are limited data regarding the efficacy of systemic medication.
 - Fluconazole 300 mg once weekly for 2 weeks
 - Itraconazole 200 mg QD for 7 days
 - Ketoconazole 200 mg QD for no more than 4 weeks
 - Terbinafine 250 mg QD for 4 weeks

Potential adverse effects:

- With all topical products: skin burning, stinging, dryness; allergic or contact dermatitis. Tar shampoos may discolor light hair, leave an oily film on hair, and leave an odor. Coal tar may be carcinogenic; use shampoo no more than twice a week, leave on skin or hair for 5 minutes, and rinse well.
- Topical corticosteroids may cause skin atrophy, telangiectasias, folliculitis, striae, and excessive hair growth. Risk of adverse effects can be mediated by using product infrequently, diluting the product, or limiting the amount of time the product is on the skin.
- With oral therapy, monitor for hepato-toxicity.

Patient Education

- Although topical and oral medicines can relieve symptoms, recurrence is common. Effective antiretroviral therapy should be considered to control the effects of HIV on the immune system and thereby decrease exacerbations and the severity of seborrheic dermatitis associated with immunosuppression.

Sinusitis

Background

Sinusitis is defined as an inflammation involving the membrane lining of any sinus, and it occurs more frequently in people with HIV infection than in the general population. It commonly occurs as part of a viral upper respiratory infection (URI), and usually is self-limited. Bacterial sinusitis usually occurs as a secondary complication of a viral URI, which causes decreased patency of the nasal ostia, decreased nasal ciliary action, and increased mucus production. Acute sinusitis is defined as lasting up to 4 weeks, whereas chronic sinusitis persists for at least 12 weeks.

HIV-infected patients are susceptible to sinusitis for a number of reasons related to their immunosuppression. Pathophysiologic mechanisms for this susceptibility may include proliferation of lymphatic tissue contributing to nasal obstruction, defects in B-cell and T-cell immunity owing to HIV, and defects in production of immunoglobulins, specifically IgE, resulting in an exaggerated allergic response in the nasal mucosa. As in the general population, the most common pathogens causing acute bacterial sinusitis are *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*. However, HIV-infected patients have a greater incidence of sinusitis caused by *Staphylococcus aureus* and *Pseudomonas aeruginosa*. The bacterial causes of chronic sinusitis are not well defined, but may involve more polymicrobial and anaerobic infections. In patients with severe immunosuppression, particularly those with CD4 counts of ≤ 50 cells/ μ L, sinusitis may be caused by *Aspergillus* and other fungal pathogens.

S: Subjective

The patient may complain of facial pain, frontal or maxillary headache, postnasal drip, or fever.

Ask the patient about specific symptoms, the duration and progression of symptoms, and treatments attempted.

- Fever
- Facial pain or pressure, headache; positional pain (worse when patient bends forward)
- Purulent or bloody nasal discharge
- Postnasal drip
- Nasal congestion
- Recent URI
- Malaise
- Chronic cough

- Maxillary tooth pain
- Ear pressure
- History of chronic sinusitis, seasonal allergies, antibiotic allergies, atopy
- Tobacco use, inhaled recreational drugs

O: Objective

- Document vital signs.
- Perform a careful physical examination focusing on the head and face, neck, and lungs. Examine the nose, mouth, ears, and sinuses.
 - Look for nares inflammation and drainage from sinus ostia.
 - Examine the tympanic membranes and external auditory canals.

- Evaluate the oropharynx for mucus drainage, lesions, and exudates.
- Check the teeth and gums for tenderness and erythema.
- Palpate for tenderness over frontal and maxillary sinus cavities.
- Examine the face and orbits for swelling or erythema.
- Perform cranial nerve examination.
- Auscultate the chest for abnormal lung sounds.

A: Assessment

A partial differential diagnosis includes the following:

- Allergic rhinitis
- Sinus blockage by other lesions such as Kaposi sarcoma or lymphoma (particularly if the CD4 count is <200 cells/ μ L) or fungal infections (if the CD4 count is <50 cells/ μ L)
- Dental abscess, caries
- Meningitis
- Vasculitis
- Trauma

P: Plan

Diagnostic Evaluation

Uncomplicated acute sinusitis usually is a clinical diagnosis. There are no symptoms, physical findings, or tests that reliably distinguish bacterial from viral sinusitis. Patients generally can be assumed to have bacterial sinusitis if symptoms do not resolve, or if they worsen, over the course of 7-10 days. Any patient with high fever or severe or unusual symptoms should be evaluated urgently for other causes of illness.

Imaging studies usually are not indicated for uncomplicated acute sinusitis. In patients with a poor response to empiric antibiotic

therapy for acute bacterial sinusitis, worsening symptoms, and those with suspected chronic sinusitis, computed tomography (CT) scans of the paranasal sinuses are the best initial radiologic study. Standard X-rays (sinus series) can detect cloudiness or air-fluid levels and will show mucosal thickening (a nonspecific finding in HIV-infected individuals).

Cultures of nasal aspirates are not useful for diagnosis, because nasal fluids do not accurately represent pathogens in the paranasal sinuses. Sinus aspirate cultures will give definitive diagnosis of a specific organism in the majority of cases; this may be considered in complicated cases. Definitive diagnosis of invasive fungal sinusitis requires tissue for culture.

Treatment

Treatment is multimodal. For viral sinusitis, treatment is based on symptom suppression; for bacterial sinusitis, an antibiotic can be added to other therapies, e.g., if symptomatic treatment has not resulted in improvement after 10 days.

- Nasal irrigation with saline solution 1-2 times daily (solution should be prepared from sterile or bottled water)
- Nasal steroid (e.g., budesonide, fluticasone, mometasone, or triamcinolone) (see “Potential ARV Interactions,” below)
- Nonsteroidal antiinflammatory drugs (NSAIDs): ibuprofen or other
- Mucolytic agent: guaifenesin
- Cough suppressant as needed
- Antihistamine: chlorpheniramine or other
- Decongestant: e.g., ephedrine, pseudoephedrine

If acute bacterial sinusitis is suspected (e.g., symptoms have not improved within 10 days), treat as above and add an antibiotic for a 5-7 day course of therapy:

- Amoxicillin/clavulanate (Augmentin) 825/125 mg PO BID or 500/125 mg PO TID (more effective against resistant species of pneumococcus and *H. influenza* than amoxicillin)
- Doxycycline 100 mg PO BID
- Levofloxacin 500 mg QD or moxifloxacin 400 mg QD

For chronic sinusitis, administer multimodal treatments as listed above for 3-4 weeks.

The value of antibiotics in chronic sinusitis is unclear; consider especially if a trial of antibiotics has not been undertaken.

If symptoms persist or worsen, refer patients to an otolaryngologist for further evaluation and treatment.

Potential ARV Interactions

Protease inhibitors (PIs) (particularly ritonavir-boosted PIs) or cobicistat may increase serum glucocorticoid levels if used concurrently with nasal steroids. Fluticasone (e.g., Flonase) nasal spray or inhaler should not be used with ritonavir-boosted PIs or cobicistat, and should be avoided, if possible, in patients taking unboosted PIs. Budesonide (Rhinocort Aqua) nasal spray also should be avoided with ritonavir-boosted PIs or cobicistat. Interactions between PIs or cobicistat and other nasal steroids have not been well studied, though available data suggest that beclomethasone has no clinically significant interaction with protease inhibitors.

Patient Education

- Instruct patients in the correct use of medications used to treat sinusitis, including proper technique for nasal irrigation, as required.
- Advise patients that drinking eight glasses (8-12 oz each) of fluid daily helps to keep the mucus thin enough to drain from the sinus passages.
- Instruct patients to take antibiotics on schedule until the entire prescription is gone in order to prevent recurrence of the infection. Advise patients to call or return to clinic for swelling of the face or swelling around the eyes, increased facial tenderness, new or worsening fever, or other concerning symptoms.

Syphilis

Background

Syphilis is a sexually transmitted disease (STD) caused by the spirochete *Treponema pallidum*. It is a complex disease with protean variations that can mimic many common infections or illnesses. HIV infection may alter the natural history and management of syphilis, causing a more rapid course of illness, higher risk of neurologic complications, and potentially greater risk of treatment failure with standard regimens. Because many individuals with syphilis have no symptoms, or have symptoms that subside without treatment, sexually active individuals at risk of syphilis should receive regular screening for syphilis, as well as for other STDs.

There has been a resurgence of syphilis in the United States, particularly among men who have sex with men (MSM). This trend is concerning, because syphilis can have major health consequences if it is undetected and untreated, and because it increases the risk of HIV transmission. Risk assessment should be conducted at each patient visit for unprotected sex (including oral, anal, and vaginal sex), multiple sex partners, and use of recreational drugs (methamphetamine and cocaine, in particular, are associated with high-risk sexual practices among MSM). Sexually active persons with HIV who are at risk of acquiring syphilis should be screened at least annually, as discussed below. MSM with multiple partners should be tested every 3-6 months.

The natural history of untreated syphilis infection is divided into stages based on length of infection.

Primary Syphilis

Primary syphilis usually manifests after an incubation period of 1-3 weeks from exposure and is characterized by a painless self-limiting ulcer (chancre) at the site of inoculation, which usually occurs during sexual contact. The organism disseminates shortly after exposure via the lymphatics to the bloodstream and beyond. HIV-infected individuals often have multiple or atypical syphilitic lesions that could be misidentified. Some patients have no primary lesion, or have a primary lesion that is not visible. Associated regional lymphadenopathy can occur. Without treatment, the primary lesion generally lasts a few days to a few weeks. Individuals sometimes have a resolving chancre concurrently with a rash of secondary syphilis.

Secondary Syphilis

Secondary syphilis usually develops 2-8 weeks after initial infection and is caused by ongoing replication of the spirochete at disseminated sites of infection that may involve multiple organ systems but most commonly involves the skin and mucous membranes. Rash is the most common presenting symptom; skin lesions may be macular, maculopapular, papular, or pustular, or they may appear as condyloma lata (which may look like condyloma acuminata caused by human papillomavirus). The rash often appears on the trunk and extremities and may involve the palms and soles of feet. Constitutional symptoms, lymphadenopathy, arthralgias, and myalgias are common and neurologic or other symptoms may occur. In the absence of treatment, the manifestations of secondary syphilis last days to weeks, then usually resolve to the latent stages.

HRSA HAB Performance Measures

Percentage of adult patients with a diagnosis of HIV who had a **test for syphilis** performed within the measurement year

(Adult and Adolescent measure)

Latent Syphilis

Latent syphilis follows resolution of secondary syphilis. As in HIV-uninfected individuals, latent syphilis is asymptomatic and the diagnosis is determined by positive serologic tests. Latent syphilis is further classified as “early latent” if the infection is known to be <1 year in duration, “late latent” if the infection is known to be >1 year in duration, or “latent syphilis of unknown duration” if the duration of infection is not known.

Late or Tertiary Syphilis

Late or tertiary syphilis is caused by chronic infection with progressive disease in any system causing serious illness and death in untreated patients. The most common manifestations include cardiovascular syphilis, gummatous syphilis, and the late forms of neurosyphilis (tabes dorsalis and general paresis) (see the “Neurosyphilis” section, below).

Neurosyphilis

Neurosyphilis can occur at any time after initial infection, owing to early spread of the spirochete to the central nervous system (CNS) in approximately 30–40% of patients. The vast majority of these patients has no neurologic signs or symptoms and clears this site of infection. The early forms of neurosyphilis occur within weeks to a few years after infection, including during the secondary stage of syphilis. Early neurosyphilis can manifest as syphilitic meningitis (symptoms may include headache, confusion, nausea, vomiting, and a stiff neck); cranial nerve abnormalities (particularly extraocular or facial muscle palsies, causing visual changes, and facial weakness, tinnitus, and hearing loss) also may be present. The second manifestation of early neurosyphilis is meningovascular syphilis, which presents with stuttering stroke symptoms owing to increasing inflammation of the cerebral arteries causing intermittent occlusion. Ocular syphilis (uveitis, retinitis, retinal detachment, and other eye abnormalities) may occur early after infection with or without the early forms of neurosyphilis. Although these early forms of neurosyphilis, including ocular syphilis, occur in patients without HIV, they may be more common among HIV-infected individuals.

S: Subjective

Symptoms depend on the site of initial infection, the stage of disease, and whether neurosyphilis is present. Symptoms are not present in most patients.

If symptoms are present, the patient may experience the following:

- Painless sore(s), ulcer(s), or abnormal lesions in the genital area, vagina, anus, or oral cavity
- New rash, usually on the trunk, often on extremities, soles of the feet, or palms
- Wart-like growths, mucus patches, or patchy hair loss
- Fever, malaise, swollen glands, arthralgias, myalgias

- Neurosyphilis: vision changes, eye pain, tinnitus, hearing loss, headaches, dizziness, facial weakness, motor or sensory loss, altered mental status, changes in personality or affect, lightning-rod pains in the lower extremities

Conduct a targeted history of patients at risk of syphilis, those who are contacts to a case, or those with positive syphilis serologies, asking about symptoms listed above, including duration; inquire about other or associated symptoms. Ascertain the following:

- Previous diagnosis of syphilis, stage, treatment (including facility where diagnosed and treated), and last titer result
- New sex partners in past 90 days (for primary or secondary syphilis)
- Date of last negative syphilis test, and where obtained
- Pregnancy status

O: Objective

Check for fever, document other vital signs.

Perform a complete examination including the following:

- Skin and mucosal areas (including the palms and soles, genitals, perianal area): chancre/ulcers, abnormal lesions, rash, condyloma lata, patchy hair loss
- Oropharynx: chancres, mucus patches, condyloma lata
- Lymph nodes
- Ophthalmic examination (including slit-lamp examination for persons with ocular complaints; uveitis, retinitis, retinal detachment)
- Neurologic examination (mental status, cranial nerves [including visual acuity], sensory, motor, reflexes, coordination, gait): abnormal mental status, visual acuity changes, extraocular movement abnormalities, neurosensory hearing loss, facial palsy, paraesthesias, sensory or motor loss, hyperactive reflexes, ataxia

A: Assessment

Because syphilis has a wide range of manifestations, the differential diagnosis is broad. It is important to consider syphilis as a possible cause of many presenting illnesses. A partial differential diagnosis includes the following:

- Other causes of maculopapular rashes: pityriasis, tinea versicolor, drug eruption, folliculitis, scabies, psoriasis, acute HIV infection
- Other causes of genital ulcerative disease: herpes simplex virus (HSV), chancroid, trauma, other skin infections (e.g., those caused by *Staphylococcus* or *Candida*)
- Other causes of ocular disease; cytomegalovirus (CMV) retinitis, CMV immune reconstitution uveitis, HSV keratitis

- Other causes of neurologic disease: Bell palsy, CNS lymphoma, toxoplasmosis, other causes of meningitis, stroke
- Other causes of systemic symptoms (e.g., fever, malaise, adenopathy): acute HIV infection, acute hepatitis, other infections or malignancies

P: Plan

Diagnostic Evaluation

Darkfield examination and direct fluorescent antibody

Darkfield examination, direct fluorescent antibody (DFA), or polymerase chain reaction (PCR) testing of a sample from suspicious genital or anal chancres or moist dermatologic lesions (not oral lesions) are definitive tests for syphilis, although these are not available in most clinic settings.

Serologic tests

Nontreponemal tests (rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL]) traditionally have been used as initial serologic tests for syphilis. Because false-positive results may occur, particularly in the setting of HIV infection, positive nontreponemal test results must be confirmed with a treponemal test. Treponemal antibody tests (TP-PA [*T. pallidum* particle agglutination], EIA [enzyme immunoassay], or CIA [chemiluminescence immunoassay]) should be used to confirm a positive nontreponemal test. Many high-volume laboratories have begun to use a treponemal test as an initial screen for syphilis infection, followed by a quantitative nontreponemal test, to reduce the workload from the titration required for nontreponemal titers. The FTA-ABS (fluorescent treponemal antibody absorption) may lack specificity and is no longer recommended as the gold standard treponemal test.

Nontreponemal tests may be falsely negative in primary and secondary syphilis, before a sufficient antibody response has developed;

treponemal tests may be slightly more sensitive and should be ordered if the nontreponemal test result is negative in a patient with signs or symptoms suggestive of primary or secondary syphilis. Another possible cause of a false-negative nontreponemal result is the prozone phenomenon, seen when antibody concentrations are very high (usually in secondary syphilis) and the specimen is not diluted sufficiently. If serologic test results are negative and suspicion of syphilis is high, request that the laboratory perform additional dilutions on nontreponemal test specimens; if the diluted serum is nonreactive, perform other diagnostic tests (e.g., biopsy).

A nontreponemal test titer should be obtained on the day of treatment to use in determining response to treatment; a fourfold change in titer is considered a significant change. Although fluctuating titers after treatment in HIV-infected patients have been seen, a sustained (>2 weeks) fourfold increase in titer raises concerns about reinfection or treatment failure. Note that the same nontreponemal test should be used consistently for a single patient; RPR titers cannot be compared with VDRL titers.

Cerebrospinal fluid evaluation

HIV-infected patients with neurologic or ocular signs or symptoms of syphilis or tertiary syphilis should undergo lumbar puncture (LP) for cerebrospinal fluid (CSF) analysis. CSF evaluation also is indicated for patients in whom treatment for early syphilis fails (see below). Routine CSF evaluation is not indicated for HIV-infected patients who have syphilis without neurologic or ophthalmic signs or symptoms. CSF analysis should include the following:

- **CSF-VDRL:** This test is specific but not very sensitive; a positive result is diagnostic but a negative result does not rule out neurosyphilis.
- **Leukocytes:** Elevated white blood cell count (>10 cells/ μ L) is suggestive but not specific. Note that mononuclear pleocytosis (up to

5-20 cells/ μ L) is not uncommon in patients with HIV infection, particularly those with higher CD4 cell counts; a threshold of >20 cells/ μ L may improve the specificity of the neurosyphilis diagnosis.

- Some recommend checking CSF FTA-ABS. This is very sensitive but not very specific; a negative result indicates that neurosyphilis is highly unlikely.

Other testing

All patients who test positive for syphilis should be tested for gonorrhea and chlamydia, with sampling sites based on sexual practices and exposures (oropharyngeal, urethral, cervical or vaginal, or anorectal testing). Patients not known to be HIV infected also should be tested for HIV.

Treatment

Treatment of syphilis in HIV-infected individuals essentially is the same as in HIV-uninfected individuals, and depends on stage and the presence or absence of neurosyphilis. It is important to follow patients closely to assure the success of treatment. For further information, see the Centers for Disease Control and Prevention (CDC) STD treatment guidelines or the CDC/NIH/IDSA opportunistic infection (OI) guidelines (see “References,” below).

An RPR or VDRL test should be sent on the day of treatment; the titer will be the reference point for assessing treatment efficacy (see “Follow-Up,” below).

Early syphilis

(<1 year in duration [i.e., primary, secondary, and early latent]; no neurologic signs or symptoms)

- **Preferred therapy:** benzathine penicillin G, 2.4 million units IM (single dose)

- **Alternative therapy:** (for patients with penicillin allergy) note that penicillin is strongly preferred; consider allergy testing and desensitization to penicillin; alternative therapies are not as well proven in HIV-infected individuals; close monitoring for treatment response is recommended

- Doxycycline 100 mg PO BID for 14 days
- Tetracycline, 500 mg PO QID for 14 days*
- Ceftriaxone, 1 g IM or IV QD for 10-14 days

* Proposed in the STD guidelines; not mentioned in the OI guidelines

Treatment failures and resistance have been reported in patients treated with azithromycin (2 g, single dose); the STD and OI guidelines state that this regimen should not be used to treat MSM or pregnant women. For other patients, both guidelines state that azithromycin should be considered only when treatment with penicillin or doxycycline is not feasible, and with close follow-up.

Late latent syphilis

(>1 year in duration or of unknown duration; no neurologic signs or symptoms)

- **Preferred therapy:** Benzathine penicillin G, 2.4 million units IM weekly for 3 consecutive weeks (7.2 million units in total)
- **Alternative therapy:** For penicillin-allergic patients, refer for desensitization to penicillin. As an alternative, some specialists consider doxycycline 100 mg PO BID for 28 days, although efficacy in HIV-infected individuals is not proven. Referral to infectious disease specialist and close clinical monitoring are required.

Tertiary syphilis

Consult with specialists.

Neurosyphilis

(syphilis at any stage with neurologic or ocular symptoms, or CSF abnormalities consistent with neurosyphilis in patients who fail treatment)

Ideally, patients should be hospitalized and given 2 weeks of penicillin IV under close observation. Penicillin-allergic patients should be referred for desensitization, if possible.

- **Preferred therapy:** aqueous crystalline penicillin G, 18-24 million units IV per day (3-4 million units Q4H [or continuous infusion] for 10-14 days).
- **Alternative therapy (requires strict adherence with therapy):**
 - Procaine penicillin 2.4 million units IM per day, plus probenecid 500 mg PO QID, both for 10-14 days
 - Some experts consider use of ceftriaxone 2 g IM or IV QD for 10-14 days with close clinical monitoring
- Most experts recommend administration of benzathine penicillin, 2.4 million units IM weekly for 3 weeks, after completion of the standard 10- to 14-day course of therapy for neurosyphilis.
- Recheck CSF leukocyte count every 6 months until the cell count normalizes (if CSF pleocytosis was present at initial evaluation). If the leukocyte count is not lower at 6 months, consider retreatment (consult with a specialist). Normalization of serum RPR may predict normalization of CSF parameters.

Note: A **Jarisch-Herxheimer reaction** may occur after initial syphilis treatment, especially in primary, secondary, or even latent syphilis. This self-limited treatment effect should not be confused with an allergic reaction to penicillin. It usually begins 2-8 hours after the first dose of penicillin and consists of fever, chills, arthralgias, malaise, tender lymphadenopathy, and intensification of rash. It resolves within 24 hours and is best treated

with rest and acetaminophen. Patients should be warned about the possibility of a Jarisch-Herxheimer reaction.

Pregnancy

Pregnant women should be treated with penicillin, using a regimen appropriate for the stage of infection (see above). Additional treatment may be indicated in early syphilis; consult with a specialist. Penicillin-allergic pregnant women should be referred for desensitization to penicillin. Doxycycline and tetracycline may cause fetal toxicity and should not be used during pregnancy. Azithromycin and erythromycin do not have adequate efficacy in treating pregnant women or their fetuses and should not be used. The efficacy of ceftriaxone during pregnancy has not been studied adequately.

Women treated during the second half of pregnancy are at risk of contractions, early labor, and fetal distress if they develop a Jarisch-Herxheimer reaction; thus, they should be advised to seek obstetric attention if they develop fever or contractions, or note a decrease in fetal movement.

Sex partners

Syphilis is transmitted sexually only when mucocutaneous lesions of syphilis are present; this is uncommon after the first year of infection. Nevertheless, sex partners of a patient who has syphilis in any stage should be evaluated. For patients with primary syphilis, that means partners within the previous 3 months plus the duration of the lesion; for patients with secondary syphilis, partners within the previous 6 months plus the duration of signs; for patients with early latent syphilis, partners within the past 1 year.

- Persons exposed within 90 days preceding the diagnosis of primary, secondary, or early latent syphilis should be treated presumptively, as they may be infected with syphilis even if they are seronegative.
- Persons exposed more than 90 days before the diagnosis of primary, secondary, or early latent syphilis should be treated presumptively if serologic test results are not available immediately and their follow-up is in doubt. Otherwise, they should receive serologic testing and be treated appropriately if the test result is positive.

Follow-Up

All HIV-infected patients treated for early syphilis should be evaluated clinically and serologically at 3, 6, 9, 12, and 24 months (at 6, 12, 18, and 24 months for latent syphilis) to rule out treatment failure. Treatment success is determined by a fourfold decrease (equivalent to two dilutions) in RPR or VDRL titer by 6-12 months (for primary and secondary syphilis) or 12-24 months (for latent syphilis) of treatment. Patients whose titers do not decrease appropriately could have experienced treatment failure or may have been reinfected. Any patient with apparent treatment failure should undergo an LP for CSF analysis and be re-treated as appropriate.

For patients with neurosyphilis, current guidelines recommend that, if a CSF pleocytosis was present initially, the CSF cell count should be checked every 6 months until it decreases. If the CSF cell count is not normal after 2 years, retreatment for neurosyphilis should be considered.

After syphilis treatment that results in at least a fourfold decrease in RPR or VDRL titer, a sustained fourfold increase in titer most commonly reflects reinfection; the patient should be evaluated carefully for possible reexposure and treated for new infection if appropriate. If reinfection is unlikely, CSF testing should be done and appropriate treatment should be given. For patients with persistently high or fluctuating titers after CSF examination and appropriate re-treatment, consult with a specialist.

Some patients retain reactive (usually at low titer) nontreponemal test results after successful treatment for syphilis. In these “serofast” individuals, reinfection with syphilis is indicated by a rise in test titer of at least fourfold.

Risk-reduction counseling

All patients with syphilis should receive risk evaluation and risk-reduction counseling. Evaluate each patient’s sexual practices with

regard to risk of acquiring STDs and of transmitting HIV. Work with the patient to reduce sexual risks.

Patient Education

- Instruct patients to go to clinic for treatment at the intervals recommended. If patients are given oral antibiotics (penicillin-allergic individuals), instruct them to take their medications exactly as prescribed.
- Warn patients about the possibility of a Jarisch-Herxheimer reaction after an initial dose of penicillin and advise them about self-management of associated symptoms (e.g., acetaminophen or aspirin at usual doses, fluids, and rest).
- Instruct patients about the required follow-up laboratory and clinical evaluations necessary to document adequate treatment. Emphasize the need for regular evaluation of treatment efficacy.
- Sex partners from the previous 3-6 months (sometimes longer, depending on the stage of syphilis) need to be evaluated and treated as soon as possible, even if they have no symptoms. Advise patients to inform their partners that they need to be tested and treated. Ask patients whether they would like assistance with partner notification and refer to the local health department for partner services, if available.
- Syphilis is a reportable communicable disease in the United States. Inform patients that they may be contacted to verify adequate treatment and assist with partner notification and treatment.
- Provide education about sexual risk reduction. Review sexual practices and support patients in using condoms with every sexual contact to prevent becoming reinfected with syphilis or infected with other STDs, and to prevent passing HIV to sex partners.

Toxoplasmosis

Background

Toxoplasma gondii is a common intracellular protozoan that preferentially infects the central nervous system (CNS). In immunodeficient patients it may cause encephalitis; it also can cause local disease such as chorioretinitis and pneumonia. Clinical disease usually occurs through reactivation of latent infection in patients who have CD4 counts of <100 cells/ μ L. *Toxoplasma* seroprevalence varies widely, from 11% in the United States to 75% in some European countries, and even higher in certain resource-limited countries. In the absence of prophylaxis, toxoplasmic encephalitis occurs in more than 30% of patients with advanced HIV infection who are seropositive for *T. gondii*. There have been case reports of CNS toxoplasmosis in the setting of immune reconstitution on antiretroviral therapy (ART); see chapter *Immune Reconstitution Inflammatory Syndrome*.

Toxoplasma has an infectious reservoir in almost all animals; humans acquire infection either through ingestion of tissue cysts contained in undercooked meat (usually pork, lamb, or beef) or oocysts on contaminated vegetables or through exposure to cat feces containing oocysts. There is no transmission by person-to-person contact.

CNS toxoplasmosis is an AIDS-defining condition that can be progressive and fatal. However, antimicrobial therapy, especially if given in conjunction with ART that results in immune reconstitution, can be successful in treating toxoplasmosis. Specific prophylaxis and effective ART also may be used to prevent toxoplasmosis in patients with advanced AIDS who have latent *T. gondii* infection (as demonstrated by the presence of anti-*Toxoplasma* immunoglobulin G [IgG] antibodies; see chapter *Preventing Exposure to Opportunistic and Other Infections*).

S: Subjective

The patient may complain of subacute onset of dull, constant headache, fever, visual changes or other focal neurologic symptoms, confusion, or disorientation. Seizures may occur. Caregivers may report subtle alterations in mental status or mood.

Take a careful history from the patient and caregivers about the symptoms listed above and their duration, progression, and severity. Inquire about other related symptoms. Ask whether the patient is taking *Toxoplasma* prophylaxis or ART.

O: Objective

- Measure vital signs (temperature, heart rate, blood pressure, respiratory rate).

- Perform a full physical examination including a thorough neurologic examination, looking for focal or nonfocal neurologic deficits, particularly weakness, cranial nerve abnormalities, visual field defects, gait disturbances, and abnormalities in speech, cognitive, or affective functions.
- Review previous laboratory values, particularly the following:
 - CD4 count (usually <50 - 100 cells/ μ L in patients with toxoplasmosis)
 - *Toxoplasma* IgG ($>95\%$ of patients with toxoplasmosis have positive IgG)

A: Assessment

Rule out other infectious or neoplastic causes of headache, fever, and neurologic changes.

A partial differential diagnosis includes the following:

- CNS lymphoma
- Cryptococcal meningitis
- Progressive multifocal leukoencephalopathy (PML)
- Tuberculous meningitis
- Brain abscesses of bacterial, fungal, or mycobacterial etiologies
- Herpes simplex virus or cytomegalovirus (CMV) encephalitis
- Primary HIV encephalopathy
- AIDS dementia complex
- Cerebrovascular accident secondary to hemorrhage, hypoxia, or emboli from vegetative endocarditis
- Neurosyphilis
- Other causes of chorioretinitis such as CMV, HIV, and cryptosporidiosis

P: Plan

Diagnostic Evaluation

Definitive diagnosis requires identification of *T. gondii* in tissue biopsy or body fluid samples from a patient with a compatible clinical presentation. Brain biopsy usually is not performed if toxoplasmosis is strongly suspected; instead, presumptive diagnosis is made on the basis of clinical presentation, laboratory and imaging tests, and response to therapy. Brain biopsy should be considered for patients who do not respond to therapy and for those whose diagnosis is unclear.

- Serum *Toxoplasma* IgG antibody test results are positive in nearly all patients with toxoplasmic encephalitis. A negative IgG test result makes the diagnosis very unlikely but does not rule it out. (Antibody titer changes are uncommon in reactivation disease and are not useful in making a diagnosis.)

- CNS imaging with computed tomography (CT) typically shows multiple contrast-enhancing mass lesions, but may show a single lesion or no lesions. Magnetic resonance imaging (MRI) is more sensitive than CT for CNS toxoplasmosis. Other imaging studies, such as single photon emission CT (SPECT), may be useful in distinguishing toxoplasmic lesions from CNS lymphoma.
- If possible, cerebrospinal fluid should be checked for *T. gondii* by polymerase chain reaction (PCR).
- Other diagnostic tests should be performed as indicated to rule out other potential causes of the patient's symptoms.
- Patients with toxoplasmic encephalitis typically respond quickly to treatment. If clinical improvement is not seen after 10-14 days of appropriate treatment, or if clinical worsening is seen in the first week, consider brain biopsy for alternative diagnoses.

Treatment

Treatment consists of two phases: acute therapy and chronic maintenance therapy. If possible, consult with an expert on the management of toxoplasmosis.

Presumptive treatment often is begun on the basis of clinical presentation, positive *Toxoplasma* IgG, and results of brain imaging studies. If patients do not respond quickly to treatment, other diagnoses should be considered. The following recommendations are based on treatment guidelines published by the Centers for Disease Control and Prevention, National Institutes of Health, and HIV Medicine Association/Infectious Diseases Society of America (see "References," below).

Acute Therapy

Acute therapy should be given for at least 6 weeks, and until the patient has shown improvement by clinical and radiographic measures.

Preferred

- Pyrimethamine 200 mg PO as a single loading dose, then 50 mg (<60 kg body weight) or 75 mg (>60 kg body weight) QD + sulfadiazine 1,000 mg (<60 kg body weight) or 1,500 mg (>60 kg body weight) PO Q6H + folinic acid (leucovorin) 10-25 mg QD

Dosage adjustments to the lower end of therapeutic range of pyrimethamine and sulfadiazine may be considered for patients who have significant bone marrow suppression despite folinic acid supplementation. Monitor patients carefully for cytopenias, especially if they are taking other agents that cause bone marrow suppression, such as zidovudine, valganciclovir, and ganciclovir.

Note: Patients at risk of G6PD deficiency should be checked for G6PD deficiency before starting pyrimethamine.

Alternative

- Pyrimethamine + folinic acid (administered as described above) + clindamycin 600 mg PO or IV Q6H; recommended for patients with significant allergic reactions to sulfa medications
- Trimethoprim-sulfamethoxazole (TMP-SMX) 5 mg/kg TMP and 25 mg/kg SMX PO or IV BID. TMP-SMX can be considered when the availability of other regimens is limited or when patients need IV therapy
- Atovaquone 1,500 mg PO BID + pyrimethamine + folinic acid (pyrimethamine and folinic acid as described above)
- Atovaquone 1,500 mg PO BID + sulfadiazine 1,000-1,500 mg PO Q6H (sulfadiazine dosing as above)
- Atovaquone 1,500 mg PO BID
- Pyrimethamine + leucovorin (dosing as above) + azithromycin 900-1,200 mg PO QD

Note: The regimens that contain sulfadiazine, TMP-SMX, or atovaquone also are effective in

preventing *Pneumocystis jiroveci* pneumonia (PCP), so patients on these regimens do not need additional PCP prophylaxis.

Adjunctive corticosteroids (e.g., dexamethasone 4 mg PO or IV Q6H) may be indicated for patients with CNS mass effect or edema. Use is based on clinical judgment and should be discontinued as soon as it is feasible to do so.

Anticonvulsant therapy should be given to patients with a history of seizures (but not to those who have not had seizures).

Ventilatory support may be necessary if severe CNS symptomatology is present.

Chronic Maintenance Therapy

After at least 6 weeks of initial therapy and significant clinical and radiologic improvement, chronic maintenance therapy can be considered.

Preferred

- Pyrimethamine 25-50 mg PO QD + sulfadiazine 2,000-4,000 mg PO daily in 2-4 divided doses + folinic acid 10-25 mg PO QD (also effective as PCP prophylaxis)

Alternative

- Pyrimethamine 25-50 mg PO QD + clindamycin 600 mg PO Q8H + folinic acid 10-25 mg PO QD
- TMP-SMX double-strength 1 tablet PO BID
- Atovaquone 750-1,500 mg PO BID + pyrimethamine 25-50 mg PO QD (+ folinic acid 10-25 mg PO QD)
- Atovaquone 750-1,500 mg PO BID + sulfadiazine 2,000-4,000 mg PO daily in 2-4 divided doses (also effective as PCP prophylaxis)
- Atovaquone 750-1,500 mg PO BID

For patients who complete acute therapy successfully, have resolution of signs and symptoms of toxoplasmosis, and have immune

reconstitution (with CD4 counts >200 cells/ μ L) for more than 6 months on ART, it is reasonable to consider discontinuing maintenance therapy. Some specialists would require resolution of CNS lesions on radiologic studies before discontinuation of therapy. Patients must be observed for recurrence of symptoms, and treatment should be restarted if the CD4 count decreases to <200 cells/ μ L.

Considerations During Pregnancy

All pregnant women should be tested for *T. gondii*. If the result is positive, evaluate the pregnant woman for signs or symptoms of toxoplasmosis and the neonate for evidence of congenital infection. Perinatal transmission usually occurs only with acute maternal infection, but in advanced HIV, it may occur with reactivation of chronic infection. If *T. gondii* infection occurs during pregnancy, consult with maternal-fetal and infectious disease specialists. Treatment for pregnant women is the same as for nonpregnant adults (see above). Note that sulfadiazine taken at the time of delivery may increase the risk of neonatal hyperbilirubinemia and kernicterus.

Patient Education

- Advise patients that antimicrobial therapy alone will not eradicate toxoplasmosis, but should decrease symptoms and improve quality of life. If medications are discontinued, the disease is likely to recur, unless the CD4 count increases to >100-200 cells/ μ L in response to ART.
- Inform patients that suppressive therapy must be continued to prevent recurrence. The duration of this therapy may be lifelong.
- It is essential for patients to take all medicines exactly as prescribed. If doses are missed, or if the medications are stopped and restarted, *Toxoplasma* can develop resistance to the medications. If patients are having trouble taking the medication on schedule, they should contact their health care provider immediately.
- Educate patients about the benefits of ART in strengthening the immune system and preventing opportunistic infections such as toxoplasmosis.
- Advise patients to contact the clinic promptly if symptoms worsen or if new symptoms develop.
- Toxoplasmosis is a late-stage HIV opportunistic infection that indicates profound immune suppression. Some patients may not respond to treatment or to ART. As with any patient who is at risk of a life-threatening HIV-related disease, clinicians should discuss advance directives and durable power of attorney with patients. Referral to a social worker, mental health clinician, or chaplain experienced in such issues may facilitate this discussion.

Adverse Reactions to HIV Medications

Kirsten Balano, PharmD

Background

Clinicians and patients face many challenges associated with antiretroviral therapy (ART). These include making decisions about when to start therapy, what regimen to start, when to change medications, and how to switch if a regimen is failing. Although clinical research guides the selection of antiretroviral (ARV) regimens, it is important to remember that the best regimen for any patient is the regimen that individual is willing and able to take. No regimen, no matter how potent, will be effective if the patient does not take it properly. Adherence to ART is one of the most important predictors of treatment efficacy. Although many factors may interfere with proper adherence to ART, adverse reactions to the medications are among the most important. In one trial, patients experiencing adverse events were 13 times less likely than those not experiencing adverse events to have the highest levels (95-100%) of adherence. Monitoring and managing adverse reactions to ARVs are crucial to establishing a successful HIV regimen.

Although adverse reactions are common and often predictable, their management must be individualized. Several factors will affect the management of adverse reactions, including comorbid conditions, the patient's other current medications, the availability of alternative medications, and the patient's history of medication intolerance. In some cases, the patient's report of the severity of adverse effects can be inconsistent with the clinical interpretation (i.e., some patients may overemphasize symptoms, whereas others underemphasize them), and this must be considered when determining the management of adverse reactions.

Using a case-based approach, this chapter suggests strategies for the evaluation and management of adverse effects, and it reviews several of the most commonly noted adverse effects in patients starting an ARV regimen. It is not intended as a comprehensive guide to adverse effects. For detailed information regarding assessment of symptoms, see the complaint-specific chapters found in section *Common Complaints* of this manual. For information on common adverse reactions to ARV agents and to medications used to prevent and treat opportunistic infections, see chapter *Antiretroviral Therapy* and the Antiretroviral Reference Tables in this manual. In each case of suspected medication adverse effects, the patient should be evaluated for other possible causes of the symptoms. Consultation with an HIV expert can help in determining the best management strategy when symptoms may have multiple and overlapping causes.

S: Subjective

A pregnant woman presents 3 weeks after starting a new ARV regimen. She complains of fatigue, nausea, and rash. Her current ARV medications are nevirapine (NVP) plus a fixed-dose combination of zidovudine (ZDV) and lamivudine (3TC) (i.e., Combivir). This was selected on the basis of her pregnancy, her preferences, and her past treatment history. She also is taking trimethoprim-sulfamethoxazole

(TMP-SMX) as prophylaxis against PCP.

Although she reports that she had not missed any doses of her medications and she likes the low pill burden of this regimen, she does not want to continue because she has been feeling so sick that she cannot adequately care for her children. She is asking to stop her ARV therapy because of "too many side effects."

The patient should be evaluated in the clinic for her complaints about adverse effects.

O: Objective

The following are suggestions for this evaluation; they are not intended to be a complete review of the workup and management of each symptom or objective finding. For more-detailed information, refer to the complaint-specific chapters of this manual, as noted above.

Vital signs: Fever may indicate a hypersensitivity reaction (HSR) or acute hepatitis attributable to medications, or an immune reconstitution inflammatory syndrome in relation to an opportunistic infection in the setting of early ART therapy. See chapter *Fever* for a more complete discussion about fever workup and considerations. Tachycardia or hypotension may suggest anemia, HSR, dehydration, infection, or another illness.

Physical examination: Pay special attention to the skin (rash, pallor), mucous membranes, and liver (enlargement or tenderness). Positive physical examination findings should be evaluated for severity and extent of involvement.

Laboratory tests: Check the complete blood count when monitoring drugs that may cause bone marrow toxicity (e.g., anemia, neutropenia). Perform a complete metabolic panel including electrolytes and liver function tests (LFTs). If the history suggests pancreatitis, evaluate amylase and lipase.

Other studies: Perform as indicated by symptoms and examination (e.g., chest X-ray if respiratory symptoms are present).

A: Assessment

Step 1: Clarify the patient's reports of adverse reactions by requesting the following information for each symptom the patient describes:

- Characterize the symptoms by asking about severity, onset, timing, and frequency. It is

helpful to have the patient describe whether the symptoms have been improving or worsening over time.

- Ask whether the patient has tried any remedies to alleviate the symptoms and whether they were helpful.
- Explore how the patient is currently taking the regimen. Closed-end questions (e.g., "What are your current medications?" "How often do you take them?" "How many pills of each medicine do you take?" and "Do you take your medicines with or without food?") can be helpful in determining whether the patient has been taking medications correctly. Incorrect administration of medications (e.g., taking higher dosages than recommended) can lead to adverse effects and often is overlooked by providers.

Step 2: Assess the severity of the reaction against the need to continue the current regimen. For this assessment, it is important to have an understanding of the relative availability of alternative ARV regimens. Also try to determine the patient's risks of adverse reactions to specific medications. A review of the patient's clinical status, treatment history, resistance tests, and other testing is important.

- Most adverse effects are self-limited and mild-to-moderate in severity. With supportive care, patients often are able to continue their current medications. This is particularly true with regard to gastrointestinal symptoms (e.g., nausea, vomiting, bloating, diarrhea). Supportive care for gastrointestinal adverse effects includes reminding the patient to take medications with food (if appropriate), suggesting the use of symptomatic remedies (e.g., ginger-containing beverages or foods to relieve nausea [see "Nausea," below]), and prescribing medications such as antiemetics or antidiarrheals if needed. Other symptoms that can be monitored carefully with supportive care include fatigue, malaise, mild rashes, abdominal pain, and bloating.

- More severe reactions often require discontinuation of the offending medication. These include fever, liver function abnormalities, rash with mucous membrane involvement, or severe systemic symptoms.
- Determining which medication in a multidrug regimen is causing the reaction is often challenging because it is common for patients to concurrently take several medications with overlapping toxicities.
- Some patient factors affect the risk of particular adverse drug effects. For example, patients with higher CD4 cell counts at the time that nevirapine is initiated have a greater risk of hepatotoxicity (specifically, women with CD4 counts of >250 cells/μL or men with CD4 counts of >400 cells/μL), and patients with the HLA-B*5701 allele have higher rates of abacavir HSR. In patients with these risk factors, these drugs should be avoided.
- It is important to consider the possibility that non-ARV medications in the patient's regimen could be causing the adverse effects. This could include medications given as prophylaxis (or treatment) for opportunistic infections (e.g., TMP-SMX), or medications to treat other comorbidities. Even with patients who have been on other non-ARV medications for months or years, initiation of a new ARV regimen (e.g., one with potent hepatic CYP 450 inhibition or induction effects) may alter serum levels of these other medications (see chapter *Drug-Drug Interactions with HIV-Related Medications*). For example, an increase in anxiety symptoms after starting a new ARV regimen could be attributable to altered drug concentrations of a chronic antidepressant or antianxiety medicine caused by an ARV, not to the new ARV medications themselves.
- The threshold for stopping a medication depends in part on the availability of alternative agents for the individual patient. Some patients have limited alternatives

because their virus is resistant to other ARVs or because they have not tolerated certain ARVs in the past. For patients who develop significant adverse effects when starting their first ARV regimen, consider substituting alternative ARV medications (chosen with efficacy considerations in mind) that are better tolerated as early as possible to prevent nonadherence arising from a desire to avoid the adverse effects. For these situations, single-drug substitutions often improve tolerance and make it more likely that long-term viral suppression will be achieved.

- Some patients may refuse to attempt symptomatic treatment or to make substitutions in the ARV regimen. Although treatment interruptions generally should be avoided, in certain situations it may be best to discontinue all ARVs and return to an adherence-readiness assessment (see chapter *Adherence*) to determine when to restart ART and what medications to restart (see chapter *Antiretroviral Therapy*).

Gathering Additional Subjective and Objective Information

For the patient who reported nausea, fatigue, and rash 3 weeks after starting nevirapine and ZDV/3TC (Combivir) (see above), additional history, physical examination, and laboratory work yielded the following information:

- **Nausea:** This has been present since she started ART 3 weeks ago. She has had difficulty taking the ARVs with food, because of nausea. No actual vomiting or other abdominal pain has occurred. She has not tried any remedies. The nausea is not worsening and perhaps has improved slightly over the past few days.
- **Fatigue:** This has been present since she started ARVs 3 weeks ago. She is able to exercise and perform normal daily activities.
- **Vital signs:** Normal, with no fever or signs of hemodynamic changes.

- **Skin:** Skin and conjunctival pallor is noted, along with mild-to-moderate maculopapular rash on the trunk, back, and extremities. These are associated with slight itching, but no pain. No mucous membrane involvement is noted. The rash has been present for 6 days, with slight improvement over the past day.
- **Abdomen:** Nontender, with normal liver size.
- **Complete blood count:** Normal, except for a slight increase in mean corpuscular volume (MCV), probably from ZDV therapy and not indicating macrocytic anemia.
- **LFTs:** Normal.
- **Pretreatment laboratory results:** CD4 count of 190 cells/ μ L, HLA-B*5701 negative.

Assessing Availability of Alternative Regimens

A clarified ARV history yielded the following information. The patient took ZDV for 5 months during another pregnancy a few years ago, and she recalls similar feelings of nausea and fatigue that caused her distress at the time. She was able to continue ZDV through the end of her pregnancy. She has taken several ritonavir-boosted protease inhibitors briefly in the past; she did not tolerate these and subsequently has refused treatment with protease inhibitors. The resistance test done prior to initiation of ART shows no significant ARV resistance. She has no comorbidities. The patient has a number of treatment options, but these may be limited by tolerance issues (e.g., protease inhibitor intolerance).

Summary Assessment

The patient's symptoms are mild and are most likely related to starting ARV therapy, although pregnancy also can have associated nausea and fatigue. The laboratory evaluation does not reveal significant abnormalities (e.g., anemia, transaminitis). In particular, the symptoms, signs, and laboratory work

are not consistent with HSR, hepatotoxicity, or other serious adverse effects. Thus, no additional workup is needed at this time. Careful monitoring is important because, if symptoms do not improve over the next few days, the patient should have a more extensive workup for other possible causes of the symptoms. If other causes of her symptoms are ruled out and she is unable to tolerate supportive care, alternative ARV medications (e.g., tenofovir, abacavir, an integrase inhibitor, or perhaps an unboosted protease inhibitor) could be substituted for medications in her current regimen, keeping in mind the need to maintain efficacy of the overall regimen and the recommendations for ART in pregnancy (see chapter *Reducing Perinatal HIV Transmission*).

P: Plan

A suggested treatment plan for the mild adverse effects exhibited by the patient described above is as follows:

Fatigue

Fatigue is a common adverse effect among patients who are starting ART. It is usually self-limited, and, with reassurance that symptoms should improve over a few weeks, most patients are able to continue their regimens without any changes. If fatigue does not resolve within the first weeks of treatment, it is important to rule out other causes of fatigue, including depression. For ZDV-containing regimens, clinicians should rule out ZDV-induced anemia, especially when patients are taking other medications that can cause bone marrow toxicity (e.g., TMP-SMX). Some patients experience fatigue from ZDV even without anemia. If fatigue persists for several weeks or becomes debilitating, and other causes are ruled out, consider replacing ZDV in this regimen. Patients taking regimens containing efavirenz also may complain of fatigue. With efavirenz, the fatigue often is related to sleep disturbances and other

central nervous system (CNS) effects of this medication. Efavirenz-related CNS adverse effects, including fatigue, are likely to resolve over a period of days to weeks. Toxicities can be minimized by ensuring that patients take efavirenz on an empty stomach (1 hour before or 2 hours after eating). (See chapter *Fatigue*.)

Nausea

Nausea is another common adverse effect described by patients starting a new ARV regimen. As with fatigue, it usually is self-limited, and patients without other systemic symptoms, acute hepatitis, HSR, or pancreatitis usually can continue their regimens. Supportive care often helps patients to continue their regimens. For example, patients should take their medications with food, unless contraindicated for the ARV. Small, frequent snacks may be helpful for patients with significant nausea. Clinical trials have suggested that ginger extract may relieve nausea symptoms. Patients can take ginger (available in a variety of forms, including ginger ale, tea, cookies, and candies) or antiemetics.

Among the medications that the patient described above is taking, ZDV is the most likely culprit to cause persistent nausea. If nausea symptoms continue for several weeks despite taking the ARVs with food, using ginger, or taking other antiemetics, and if other underlying causes are ruled out, consider replacing ZDV in this regimen. (See chapter *Nausea and Vomiting*.)

Rash

Rash is a common adverse effect of certain ARVs and many other medications. It may present with a wide range of severity, as follows:

- Mild rash with no other related symptoms, resolving over the course of days or weeks
- Moderate rash, may be accompanied by

systemic symptoms (e.g., fever, liver function abnormalities, myalgias)

- Life-threatening rashes (e.g., Stevens-Johnson syndrome, toxic epidermal necrolysis) associated with pain, mucous membrane involvement, fever, liver function changes, and myalgias

If a patient is taking two or more medications that have rash as a possible adverse effect, it may be difficult to determine which medicine is the most likely cause of the rash. In the case of the patient described above, the rash most likely is related to one of two medications.

Her rash currently is mild, but drug rash can range from mild to severe and life-threatening (including Stevens-Johnson syndrome).

- Nevirapine
 - Mild nevirapine rash: usually a self-limited reaction that can be treated symptomatically
 - Moderate to severe nevirapine rash, with or without hepatitis: requires discontinuation of nevirapine
- TMP-SMX reaction: may be mild or severe, and onset may be delayed
- Other reactions: can be caused by other medications, by immune reconstitution inflammatory effects, contact dermatitis, folliculitis, and other causes

If the clinician discontinues all of the suspect medications and the rash resolves, the patient will be relieved, but the clinician will not be able to determine which medication caused the rash. In cases of mild rash, it is reasonable to try to identify the offending agent by discontinuing one medication at a time (a substitution should be made for a discontinued ARV, to maintain regimen potency). This situation would require careful clinical judgment or consultation with an expert regarding the advantages or disadvantages of discontinuing each of the suspect medications.

Other Adverse Reactions

Patients may describe any number of adverse effects after starting new medications.

Although some adverse effects are caused directly by the medications themselves, some symptoms may occur simply in the process of starting ART. The start of ART may precipitate a significant psychological shift in a patient's perception of self, in living with HIV infection, and in daily routine. In particular, patients who have kept their HIV infection distant from their "everyday" lives may notice significant psychological changes as they take medications every day, go to the pharmacy to pick up medications, and make frequent visits to the clinic for evaluation and laboratory work. Some patients become depressed upon realizing that the severity of their illness now requires them to be on treatment. These psychological adjustments can cause significant symptoms that should be assessed and managed in a manner similar to the way in which pharmacologic adverse reactions are managed.

These psychological effects can be considered "process" effects from starting ART rather than adverse effects of the ARV medications themselves. As with the self-limited adverse effects of early-stage ARV therapy, process effects should become more tolerable over time as the medication regimen becomes routine for the patient. One of the most common process effects is fatigue. Many patients hope that their ARV regimen will give them increased energy and health, and they become frustrated when they notice increasing fatigue after starting the regimen. These patients must

be evaluated to rule out common adverse effects that contribute to fatigue (e.g., anemia, hepatitis, lactic acidosis). Equally important, especially for patients beginning a new regimen, symptoms of fatigue could indicate depression or signal that the "process" of taking medications is emotionally difficult. Counseling, peer support, and antidepressant medications can be used to treat this type of fatigue. Often, once patients realize that some of the goals of treatment are being achieved (e.g., the CD4 cell count increases, the HIV viral load becomes undetectable, or symptoms of HIV infection resolve), they recognize the benefits of ARV medications, and their fatigue or other adverse symptoms associated with the process of starting the regimen may lessen.

This discussion has focused on the adverse reactions to ARV medications that patients are most likely to describe as they start a new regimen. Patients and providers also need to consider counseling about and management of long-term toxicities such as lipodystrophy, renal dysfunction, peripheral neuropathy, cardiac disease, diabetes, and dyslipidemia. As these long-term toxicities continue to challenge providers and patients alike, clinical trials and expert guidelines will provide support and information.

Clinicians are encouraged to report adverse reactions to medications to the U.S. Food and Drug Administration (FDA) MedWatch program by telephone at 800-FDA-1088, via fax at 800-FDA-0178, via the Internet at www.fda.gov/Safety/MedWatch/HowToReport/, or by mail at MedWatch HF-2, FDA, 5600 Fishers Lane, Rockville, MD 20857.

Patient Education

- All medications have potential to cause adverse reactions, which are defined as negative, unintended effects of medication use.
- Advise patients to report any adverse reaction to their medical care provider as soon as possible.
- Before starting a new medication, medical care providers or pharmacists should counsel patients about the most common adverse effects and about any remedies that are available to minimize the severity of those effects.
- Advise patients to talk to their provider or pharmacist before starting any new medications (including over-the-counter medications and herbs) because some drugs may interact with ARVs or other medications and can increase side effects or cause unwanted reactions.
- Nausea is one of the most common adverse effects. Counsel patients that nausea can be minimized by taking medications with food (if indicated, as some medications should be taken on an empty stomach) or by using ginger-based food or beverages (e.g., ginger ale, tea, cookies). If these measures do not work, patients should talk with their medical care provider; they may need medications to treat the symptoms.
- Counsel patients that they should not stop taking any medications unless instructed to do so by their medical care provider.

Drug-Drug Interactions with HIV-Related Medications

Kirsten Balano, PharmD

Background

Drug-drug interactions are common concerns of patients with HIV and their health care providers. The issues involved in evaluating drug interactions are complex. Although many questions can be articulated simply (e.g., “What antidepressant is least likely to have drug interactions with antiretroviral medications?”), the responses to these questions involve more complex concerns (e.g., “In choosing an antidepressant for my patient with HIV, I must consider efficacy, adverse effects, and tolerability as well as drug interactions.”).

This complexity is increased because antiretroviral (ARV) agents, particularly protease inhibitors (PIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), the pharmacokinetic booster cobicistat, and the CCR5 antagonist maraviroc, can cause or be affected by alterations in the activity of the cytochrome (CYP) P450 enzyme system in the liver, as well as by other mechanisms of drug metabolism. Interactions between an ARV and another drug (whether another ARV or a different type of medication) may result in an increase or a decrease in the serum levels of either the ARV or the interacting drug, potentially changing the effectiveness or the toxicity risk of substrate drugs. Understanding drug-drug interactions is challenging because of several factors, including the following:

- Different drugs affect different P450 enzymes.
- Some medications have dosage-related responses that influence their effects on P450 enzymes.
- Formal pharmacokinetic studies on drug combinations are limited.
- Even when pharmacokinetic data exist for specific drug combinations, the clinical significance of any changes in pharmacokinetic parameters may not be clear.
- Patients taking ARVs often have complex drug regimens. Patients typically are taking three or more medications that could influence interactions. Pharmacokinetic studies that evaluate the clinical significance of drug interactions involving more than two medications are less likely to be available.
- Other metabolic pathways of medications such as P-glycoprotein (P-gp) and UDP-glucuronosyltransferase (UGT)-1A1, can be altered by drug interactions. The integrase inhibitors dolutegravir and raltegravir, for example, are metabolized by UGT-1A1.
- Some drug interactions involve effects on absorption or drug availability rather than metabolism. For example, the PI atazanavir and the NNRTI rilpivirine require gastric acidity for absorption; integrase inhibitor activity is impaired by polyvalent cations (e.g., iron, aluminum, calcium, and magnesium, and antacids, laxatives, supplements, and other preparations that contain them).
- Other influences on medication activity include food-drug interactions, protein binding, and altered intercellular activation of medications.

Information on various drug-drug interactions is available in guidelines and via the Internet (see “Resources,” below). Such resources can provide data regarding two-drug combinations, but rarely consider all the complexities outlined above. What follows, therefore, is a suggested approach to considering drug-drug interactions in managing HIV-infected patients and making patient-specific decisions, illustrated by a case study.

S: Subjective

A new patient arrives for a clinic intake appointment. The patient receives medical care from a local infectious disease physician who treats only a handful of HIV-infected patients. The patient was recently released from hospital with a discharge diagnosis of pneumonia and *Mycobacterium avium* complex (MAC). The patient is not yet taking ARVs, but needs to start ART promptly, along with an adherence support program. The patient has other medical problems, including hyperlipidemia, erectile dysfunction, diabetes, depression, gastroesophageal reflux disease (GERD), and herpes. The clinician wants to review the patient’s medication list to check for any potential drug-drug interactions.

O: Objective

Review the patient’s pharmacy records for current medications, and ask about use of over-the-counter (OTC), herbal or natural products, and dietary supplements. As requested, the patient has brought in all medications from home for review. The current medication list includes the following:

- Clarithromycin 500 mg BID
- Ethambutol 1,000 mg QD
- Rifabutin 300 mg QD
- Trimethoprim-sulfamethoxazole (TMP-SMX) (Septra, Bactrim) double-strength, 1 tablet QD
- Lovastatin 20 mg QD

- Metformin 500 mg BID
- Bupropion 150 mg QD
- Acyclovir 400 mg BID
- Omeprazole 20 mg QD (patient buys OTC for heartburn)
- Milk thistle (silymarin) (patient takes as needed for energy and liver health)

A: Assessment

Step 1: Identify interactions and classify them as follows:

- Definite interactions
- Probable interactions
- Possible interactions

Definite Drug Interactions

A drug interaction is definite if a high level of evidence is available regarding the drug combination, the clinical significance of the interaction is well understood, and consensus exists regarding the management strategy (e.g., whether dosage adjustments are required, or concurrent use is contraindicated). Common definite interactions for HIV patients include the following:

- Certain combinations of HIV agents (e.g., certain PIs or integrase inhibitors with NNRTIs, maraviroc with PIs or NNRTIs, tenofovir with atazanavir)
- Rifamycins and PIs, NNRTIs, cobicistat, or maraviroc
- Statins with PIs or cobicistat
- Erectile dysfunction agents and PIs or cobicistat
- Methadone and certain PIs or NNRTIs
- Fluticasone and PIs or cobicistat

Probable Drug Interactions

A drug interaction is probable if the limited available evidence suggests that an interaction may occur, even if the clinical outcome or significance may not be clearly established. Effective management of a probable interaction

is based on assessment and clinical judgment about the risks and benefits of a particular combination for each patient. Examples of probable interactions with HIV-related medications include the following:

- Antidepressants and PIs or NNRTIs
- Oral contraceptives and PIs or cobicistat
- Warfarin and PIs, NNRTIs, or cobicistat
- Proton pump inhibitors (PPIs) or H-2 blockers and atazanavir or rilpivirine
- Polyvalent cations (e.g., calcium, iron, cation-containing antacids) and integrase inhibitors
- Certain antifungal agents and PIs, NNRTIs, or cobicistat (except in the case of voriconazole, for which definite information on interactions is available)
- Certain antiepileptic medications and PIs, NNRTIs, or cobicistat

Possible Drug Interactions

Possible drug interactions may be difficult to distinguish from probable drug interactions, but in these cases, only theoretical evidence is available. The proper management of such interactions requires weighing the risks and benefits of the combination and making sound clinical judgments. Examples of possible drug interactions with HIV medications include the following:

- Herbal products and PIs, NNRTIs, or cobicistat (except in the case of St. John's wort, for which definite information on interactions is available)
- Antidiabetic medications and PIs or NNRTIs
- Antipsychotic agents and PIs, NNRTIs, or cobicistat

Memorizing all the potential drug interactions is impossible. It is possible, however, to remember a few commonly encountered drug combinations that have the potential for clinically significant interactions. It is also

important to recognize that PIs (particularly ritonavir), NNRTIs, and cobicistat very commonly interact with other medications. The above examples of definite, probable, and possible interactions are reasonable “red flag” drug combinations that can be recalled easily. In addition, certain Internet resources allow providers to submit all of a patient's current medications and planned additions (e.g., atazanavir/ritonavir as part of a new ARV regimen) and receive information on potential interactions (see “Resources,” below). Finally, consultation with clinical pharmacists can aid in identifying and classifying potential interactions.

P: Plan

Step 2: The patient described above will start an ARV regimen of atazanavir/ritonavir + tenofovir + emtricitabine. The PI may cause problematic drug-drug interactions with some of the patient's preexisting medications, and tenofovir interacts with atazanavir. Develop a plan for management when these ARVs are added. For this patient, the following definite interactions should be of concern:

- Rifabutin and atazanavir/ritonavir
- Lovastatin and atazanavir/ritonavir
- Tenofovir and atazanavir
- Clarithromycin and atazanavir/ritonavir

Refer to available references for management suggestions. Such references include the following:

- U.S. Department of Health and Human Services. *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents* (aidsinfo.nih.gov/guidelines), relevant tables
- HIV InSite Database of Antiretroviral Drug Interactions (hivinsite.ucsf.edu/interactions)
- University of Liverpool HIV Drug Interaction Charts (www.hiv-druginteractions.org)

- Clinical Care Options (www.clinicaloptions.com/HIV.aspx)

Most of these resources include specific dosage adjustments or alternative agents to consider when managing these drug combinations. The suggestions for this patient are as follows:

- Rifabutin levels are increased by atazanavir/ritonavir. The rifabutin dosage should be decreased to 150 mg daily with standard atazanavir/ritonavir dosing. Alternatively, discuss with the patient's primary care provider whether rifabutin is important to the current MAC regimen or whether the patient could be treated adequately with just clarithromycin + ethambutol to avoid the above-cited interactions.
- Lovastatin levels are increased substantially by atazanavir/ritonavir; concurrent use with a PI can lead to potentially fatal rhabdomyolysis. Lovastatin should be discontinued when atazanavir/ritonavir is initiated. To manage hyperlipidemia, the patient should be switched to a statin whose metabolism is less affected by these PIs, such as pravastatin or low-dose atorvastatin (simvastatin, also is contraindicated for use by patients who take a PI).
- Tenofovir can decrease plasma concentrations of unboosted atazanavir, but can be administered safely with ritonavir-boosted atazanavir.
- Clarithromycin levels are increased by atazanavir/ritonavir; concurrent use can lead to QTc prolongation. If clarithromycin is co-administered with atazanavir/ritonavir, its dosage should be reduced by 50%.

Although this patient's current medication list does not contain an erectile dysfunction agent, the patient should be educated about the definite interactions and dosage adjustments recommended for patients using those agents with PIs. Some patients may obtain erectile dysfunction agents outside the care of their physician and, if unaware of the interactions

and suggested dosage adjustments, may be at risk of life-threatening consequences.

The following probable or possible interactions should be considered if PIs are begun, including:

- Omeprazole with atazanavir/ritonavir
- Bupropion with atazanavir/ritonavir
- Milk thistle with atazanavir/ritonavir

The web-based resources and other references listed above include some information about these potential interactions. The following are suggestions:

- **Omeprazole:** PPIs and H2-blockers decrease serum levels of atazanavir, even when boosted with ritonavir, but the clinical significance of this interaction has not been demonstrated. In general, it may be best to avoid concomitant use of these acid-blocking medications with atazanavir by either discontinuing the GERD medication or switching to another ARV. Unboosted atazanavir should not be used with PPIs. For patients without evidence of ARV resistance in whom coadministration of these medications is judged unavoidable, atazanavir/ritonavir may be used, but doses of omeprazole should not exceed 20 mg and must be taken at least 12 hours prior to taking atazanavir/ritonavir. Note that tenofovir also can lower atazanavir levels, so increasing atazanavir to 400 mg/day with ritonavir 100 mg/day could be considered.
- **Bupropion and milk thistle:** Specific management or dosage adjustments based on data are not available. This patient should be monitored for increased or decreased effects of bupropion and educated about potential interactions with milk thistle. Clinical judgment and decision making with the primary care provider and other specialists (e.g., psychiatrists) may be required.

Consultation with clinical pharmacy services may assist in evaluating the potential significance of drug interactions and developing management strategies.

Patient Education

- Instruct patients that HIV medications, in particular PIs, NNRTIs, cobicistat, and maraviroc, have a high potential for significant drug interactions.
- Tell patients to bring all their medicines, including any herbal, nutritional, and dietary supplements and OTC remedies, with them to all medical appointments. If they cannot bring the actual containers with them, they should bring a list of current prescribed medications, supplements, and OTC medications.
- Patients should have their primary care provider or pharmacist review any newly prescribed medications along with their current list of medicines. This is especially important if another physician prescribes a new medication.
- Patients should not “borrow” medications from friends or family. Assure patients that if they have a problem that needs medical treatment, their primary care provider will discuss it and choose the safest treatments for them.
- Tell patients that, if they are considering buying a new nutritional or herbal supplement or an OTC product, they should consult their pharmacist or primary care provider about interactions with drugs on their current medication list.
- Not all drug interactions are cause for alarm. Some drug combinations are safe for certain people, but less safe for others. Warn patients not to stop taking any medicines without the advice of their primary care provider.

Antiretroviral Medications and Hormonal Contraceptive Agents

Background

Few pharmacokinetic or clinical studies have examined interactions between antiretroviral (ARV) medications and hormonal contraceptives, but it is known that certain protease inhibitors (PIs) and nonnucleoside reverse transcriptase inhibitors (NNRTIs), as well as the boosted integrase inhibitor combination elvitegravir/cobicistat, do interact with hormonal contraceptives. These interactions may increase the risk of medication failure or medication adverse effects of either the ARV or the contraceptive. There are no known interactions between hormonal contraceptives and nucleoside analogues or the CCR5 antagonist.

Oral Contraceptives

All oral contraceptives currently marketed in the United States, with the exception of progestin-only pills (which contain norethindrone), contain both ethinyl estradiol and a progestin (desogestrel, drospirenone, ethynodiol diacetate, levonorgestrel, norethindrone, norethindrone acetate, norgestimate, or norgestrel). The oral contraceptives ethinyl estradiol and norethindrone may interact in complex ways with PIs and NNRTIs. The mechanism of these interactions may be multifactorial and includes the activity of these agents on cytochrome P450 enzymes. Pharmacokinetic studies have shown changes (either increases or decreases) in levels of ethinyl estradiol and norethindrone in women who are taking certain PIs, NNRTIs, or elvitegravir/cobicistat. Other studies have shown decreases in levels of amprenavir (the active agent of fosamprenavir) in women taking oral contraceptives.

The clinical significance of these drug interactions has not been evaluated thoroughly, but may cause oral contraceptive failure, ARV failure, or medication toxicity, depending on whether drug levels are lowered or raised by the interacting drug. The consequences of decreased hormone levels may include an increased risk of pregnancy, so an alternative or additional method of contraception is commonly recommended. The consequences of decreased ARV levels may include virologic failure and development of resistance mutations. The consequences of a higher level of hormones may include risk of thromboembolism, breast tenderness, headache, nausea, and acne.

The available pharmacokinetic data are summarized in Table 1. For further discussion of oral and non-oral contraceptives for HIV-infected women, see chapter *Health Care of HIV-Infected Women Through the Life Cycle*.

Table 1. Interactions Between Antiretroviral Agents and Oral Contraceptives**Key to symbols:**

- ☐ Use alternative/additional method or do not administer together
 ! Use with caution
 ✓ Safe to use in combination or no dosage adjustment necessary

Antiretroviral Agent	Pharmacokinetic Changes with Oral Contraceptives		Comments
Protease Inhibitors			
Atazanavir (ATV, Reyataz) (unboosted)	- EE AUC ↑ 48% - NE AUC ↑ 110%	!	OC should contain ≤30 mcg EE. Monitor for side effects, or use alternative method.
ATV/r	- EE AUC ↓ 19% 17-deacetyl norgestimate (active metabolite of NG) AUC ↑ 85%	!	- OC should contain ≥35 mcg EE. - OCs containing progestins other than norethindrone or norgestimate have not been studied.
Darunavir (DRV, Prezista) DRV/r	- EE AUC ↓ 44% - NE AUC ↓ 14%	⊗	Use alternative or additional method of contraception.
Fosamprenavir (FPV, Lexiva)	- EE C_{min} ↑ 32% - NE C_{min} ↑ 45%; AUC ↑ 18% - Amprenavir AUC ↓ 22% - Amprenavir C_{min} ↓ 20%	⊗	- Data are derived from studies with amprenavir (the active metabolite of FPV). - Risk of ARV failure and of EE or NE adverse effects: do not coadminister fosamprenavir with OCs. - Use alternative method of contraception.
FPV/r	- EE AUC ↓ 37% - NE AUC ↓ 34%	⊗	- Risk of contraceptive failure and of ritonavir adverse effects. - Use alternative method of contraception.
Indinavir (IDV, Crixivan)	- EE AUC ↑ 24% - NE AUC ↑ 26%	✓	- No dosage adjustment is recommended. - Monitor for EE or NE adverse effects.
IDV/r	No data	⊗	Risk of contraceptive failure; use alternative or additional method of contraception.
Lopinavir/r (LPV/r, Kaletra)	- EE AUC ↓ 42% - NE AUC ↓ 17%	⊗	Risk of contraceptive failure; use alternative or additional method of contraception.
Nelfinavir (NFV, Viracept)	- EE AUC ↓ 47% - NE AUC ↓ 18%	⊗	Risk of contraceptive failure; use alternative or additional method of contraception.
Ritonavir (RTV, Norvir)	EE AUC ↓ 40%	⊗	Risk of contraceptive failure; use alternative method of contraception.
Saquinavir (SQV, Invirase)/r	- No data; theoretic EE ↓ - SQV kinetics not affected by OC	⊗	Risk of contraceptive failure; use alternative or additional method of contraception.
Tipranavir (TPV, Aptivus)/r	- EE AUC ↓ 48% - NE no significant change	⊗	Risk of contraceptive failure; use alternative or additional method of contraception.

Antiretroviral Agent	Pharmacokinetic Changes with Oral Contraceptives		Comments
Nonnucleoside Reverse Transcriptase Inhibitors			
Efavirenz (EFV, Sustiva)	• EE AUC no significant change • 17-deacetyl norgestimate (active metabolite of NG) AUC ↓ 64% • LN AUC ↓ 58-83% • NE: AUC ↓ predicted	☒	• Decrease in progestin levels: risk of contraceptive failure (including failure of emergency contraception (Plan B)); use alternative or additional method of contraception.
Etravirine (ETR, Intelence)	• EE AUC ↑ 22% • NE AUC ↓ 5%	✓	• No dosage adjustment is necessary.
Nevirapine (NVP, Viramune)	• EE AUC ↓ 20% • NE AUC ↓ 19%	☒	• Risk of contraceptive failure; use alternative or additional method of contraception.
Rilpivirine (RPV, Edurant)	• EE AUC ↑ 14% • NE no significant change	✓	• No dosage adjustment is necessary.
CCR5 Antagonist			
Maraviroc (MVC, Selzentry)	• No significant effect on EE or LN	✓	• No dosage adjustment is necessary.
Integrase Inhibitor			
Dolutegravir (DTG, Tivicay)	• No significant change in EE AUC or NG AUC	✓	• No dosage adjustment is necessary
Elvitegravir (EVG, Stribild)	• NE AUC ↓ 25%, C_{min} ↓ 44% • NG AUC, C_{max}, C_{min} ↑ >2-fold	!	• Risk of NG adverse effects (not fully known; may include venous thrombosis); consider alternative method of contraception.
Raltegravir (RAL, Isentress)	• No significant change in EE AUC or NG AUC	✓	• No dosage adjustment is necessary.

Abbreviations: AUC = area under the time-concentration curve (drug exposure); C max = maximum concentration; C min = minimum concentration; EE = ethinyl estradiol; LN = levonorgestrel; NE = norethindrone; NG = norgestimate; OC = oral contraceptive; RTV = ritonavir; /r = low-dose ritonavir

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents. *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. Department of Health and Human Services. Available at aidsinfo.nih.gov/guidelines.

Non-Oral Hormonal Contraceptives

Hormonal contraceptives using delivery methods other than oral include the following:

- Products containing both progestin and estrogen components: transdermal patch, vaginal ring
- Products containing a progestin alone (medroxyprogesterone acetate, levonorgestrel, norelgestromin, or

etonogestrel): subcutaneous or IM injection, intrauterine system, implantable device

There has been little research on the interactions between ARVs and most of these agents. Theoretically, interactions with ARVs would be less likely with contraceptive methods that have primarily local action and minimal systemic absorption, and for injection or transdermal delivery systems, since first-pass metabolism is avoided. However, caution is still warranted, as this assumption has not been proven.

Because the transdermal patch and vaginal ring contain ethinyl estradiol, women who take ARVs that increase or decrease serum estradiol levels (see Table 1) are advised to use an alternative (or additional) contraceptive method. Small studies of depo-medroxyprogesterone acetate (DMPA, or Depo-Provera) have shown no significant interactions between DMPA and nelfinavir, efavirenz, or nevirapine. Interactions between DMPA and other ARVs have not been studied, but DMPA's interactions with PIs and NNRTIs would be expected to be similar to those of norethindrone (see Table 1). For other non-oral hormones, pending further study, an alternative (or additional) method of contraception should be considered.

Pain Syndrome and Peripheral Neuropathy

Background

The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.” Pain is subjective, it is whatever the patient says it is, and it exists whenever the patient says it does. Pain is a common symptom in people with HIV infection, especially those with advanced disease. It occurs in 30-60% of HIV/AIDS patients and can diminish their quality of life significantly. Like cancer patients, HIV patients experience an average of 2.5 to 3 types of pain at once. Pain in HIV-infected patients may have many causes (as discussed below).

Pain is significantly undertreated, especially among HIV-infected women, because of factors ranging from providers’ lack of knowledge about the diagnosis and treatment of pain to patients’ fear of addiction to analgesic medications. Pain, as the so-called fifth vital sign, should be assessed at every patient visit.

Peripheral Neuropathy

Pain from HIV-associated peripheral neuropathy is particularly common, and may be debilitating. Peripheral neuropathy is clinically present in approximately 30% of HIV-infected individuals and typically presents as distal sensory polyneuropathy (DSP). It may be related to HIV itself (especially at CD4 counts of <200 cells/ μ L), to medication toxicity (e.g., from certain nucleoside analogues such as stavudine or didanosine), or to the effects of chronic illnesses (e.g., diabetes mellitus). Patients with peripheral neuropathy may complain of numbness or burning, a pins-and-needles sensation, shooting or lancinating pain, and a sensation that their shoes are too tight or their feet are swollen. These symptoms typically begin in the feet and progress upward; the hands also may be affected. Patients may develop difficulty walking because of discomfort, or because they have difficulty feeling their feet on the ground. Factors associated with increased risk of peripheral neuropathy include the following:

- Previous peripheral neuropathy
- Low CD4 count (<200 cells/ μ L)
- Previous AIDS-defining opportunistic infection or neoplasm
- Vitamin B12 deficiency
- Exposure to stavudine or didanosine
- Use of other drugs associated with peripheral neuropathy (e.g., isoniazid, dapsone, metronidazole, hydroxyurea, thalidomide, linezolid, ribavirin, vincristine)
- Use of other neurotoxic agents (e.g., alcohol)
- Diabetes mellitus

Patients should be assessed carefully before the introduction of a potentially neurotoxic medication (including stavudine or didanosine), and the use of these medications for patients at high risk of developing peripheral neuropathy should be avoided.

S: Subjective

Self-report is the most reliable method to assess pain.

The patient complains of pain. The site and character of the pain will vary with the underlying cause. Ascertain the following from the patient:

- Duration, onset, progression
- Distribution, symmetry
- Character or quality (e.g., burning, sharp, dull)
- Intensity
- Severity (using the 0-10 scale; see Figure 1)
- Neurologic symptoms (e.g., weakness, cranial nerve abnormalities, bowel or bladder abnormalities)
- Exacerbating or relieving factors
- Response to current or past pain management strategies
- Past medical history (e.g., AIDS, diabetes mellitus)
- Psychosocial history
- Substance abuse and alcohol use history (amount, duration)
- Medications, current and recent (particularly zalcitabine, didanosine, stavudine, and isoniazid)
- Nutrition (vitamin deficiencies)
- Meaning of the pain to the patient

Measuring the severity of the pain: Have the patient rate the pain severity on a numeric scale of 0-10 (0 = no pain; 10 = worst imaginable pain), a verbal scale (none, small, mild, moderate, or severe), or a pediatric faces pain scale (when verbal or language abilities are absent). Note that pain ratings >3 usually indicate pain that interferes with daily activities. Use the same scale for evaluation of treatment response.

Figure 1. Faces Pain Rating Scale (0-10)

Quick screen for peripheral neuropathy: Ask about distal numbness and check Achilles tendon reflexes. Screening for numbness and delayed or absent ankle reflexes has the highest sensitivity and specificity among the clinical evaluation tools for primary care providers. For a validated screening tool, use the ACTG Brief Peripheral Neuropathy Scale (BPNS) to scale and track the degree of peripheral neuropathy (see www.hiv.va.gov/provider/manual-primary-care/peripheral-neuropathy.asp#S4.2X).

O: Objective

Measure vital signs (increases in blood pressure, respiratory rate, and heart rate can correlate with pain). Perform a symptom-directed physical examination, including a thorough neurologic and musculoskeletal examination. Look for masses, lesions, and localizing signs. Pay special attention to sensory deficits (check for focality, symmetry, and distribution [such as “stocking-glove”]), muscular weakness, reflexes, and gait. Patients with significant motor weakness or paralysis, especially if progressive over days to weeks, should be evaluated emergently.

To evaluate peripheral neuropathy: Check ankle Achilles tendon reflexes and look for delayed or absent reflexes as signs of peripheral neuropathy. Distal sensory loss often starts with loss of vibratory sensation, followed by loss of temperature sensation, followed by onset of pain. Findings are usually bilateral and symmetric.

A: Assessment

Pain assessment includes determining the type of pain, for example, nociceptive, neuropathic, or muscle spasm pain.

Nociceptive pain occurs as a result of tissue injury (somatic) or activation of nociceptors resulting from stretching, distention, or inflammation of the internal organs of the body. It usually is well localized; may be described as sharp, dull, aching, throbbing, or gnawing in nature; and typically involves bones, joints, and soft tissue.

Neuropathic pain occurs from injury to peripheral nerves or central nervous system structures. Neuropathic pain may be described as burning, shooting, tingling, stabbing, or like a vise or electric shock; it involves the brain, central nervous system, nerve plexuses, nerve roots, or peripheral nerves. It is associated with decreased sensation and hypersensitivity.

Muscle spasm pain can accompany spinal or joint injuries, surgeries, and bedbound patients. It is described as tight, cramping, pulling, and squeezing sensations.

Although pain in HIV-infected patients can result from opportunistic infections, neoplasms, or medication-related neuropathy, it is important to include non-HIV-related causes of pain in a differential diagnosis. Some of these other causes may be more frequent in HIV-infected individuals. A partial list for the differential diagnosis includes:

- Anorectal carcinoma
- Aphthous ulcers
- Appendicitis
- Arthritis, myalgias
- Candidiasis, oral or esophageal
- Cholecystitis
- Cryptococcal disease
- Cytomegalovirus colitis
- Dental abscesses
- Gastroesophageal reflux disease (GERD)
- Ectopic pregnancy
- Herpes simplex
- Herpes zoster
- Kaposi sarcoma
- Lymphoma
- Medication-induced pain syndromes (e.g., owing to growth hormone, granulocyte colony-stimulating factor)
- Medication-induced peripheral neuropathy (e.g., owing to didanosine, stavudine, isoniazid, vincristine)
- Other causes of peripheral neuropathy: diabetes, hypothyroidism, B12 deficiency, syphilis, cryoglobulinemia (especially in patients with hepatitis C coinfection)
- *Mycobacterium avium* complex
- Myopathy
- Pancreatitis
- Pelvic inflammatory disease
- Toxoplasmosis

P: Plan

Perform a diagnostic evaluation based on the suspected causes of pain.

Treatment

Treatment should be aimed at eliminating the source of pain, if possible. If symptomatic treatment of pain is needed, begin treatment based on the patient's pain rating scale, using the least invasive route. The goal is to achieve optimal patient comfort and functioning (not necessarily zero pain) with minimal medication adverse effects. Use the three-step pain analgesic ladder originally devised by the World Health Organization (WHO); see Figure 2.

Nonpharmacologic interventions

The following interventions can be used at any step in the treatment plan:

- A therapeutic provider-patient relationship
- Physical therapy
- Exercise
- Relaxation techniques
- Guided imagery
- Massage
- Biofeedback
- Reflexology
- Acupuncture
- Thermal modalities (hot and cold compresses or baths)
- Transcutaneous electrical nerve stimulation (TENS)
- Spiritual exploration
- Prayer
- Deep breathing
- Meditation
- Enhancement of coping skills
- Self-hypnosis
- Humor
- Distraction
- Hobbies

Pharmacologic interventions**Principles of pharmacologic pain treatment**

- The dosage of the analgesic is adjusted to give the patient adequate pain control.
- The interval between doses is adjusted so that the pain control is uninterrupted. It can take 4-5 half-lives before the maximum effect of an analgesic is realized.
- Chronic pain is more likely to be controlled when analgesics are dosed on a continuous schedule rather than “as needed.” Sustained-release formulations of opioids should be used whenever possible.
- For breakthrough pain, use “as needed” medications in addition to scheduled-dosage analgesics. When using opiates for both scheduled analgesia and breakthrough pain, a good rule of thumb is to use 10% of the total daily dosage of opiates as the “as needed” opiate dose for breakthrough pain.
- Oral administration has an onset of analgesia of about 20-60 minutes, tends to produce more stable blood levels, and is cheaper.
- Beware of the risk of prolonged analgesic half-lives in patients with renal or hepatic dysfunction.
- Caution when using combination analgesics that are coformulated with ingredients such as acetaminophen, aspirin, or ibuprofen. Determine the maximum daily dosage of all agents.

The following three steps are adapted from the WHO analgesic ladder. Agents on higher steps are progressively stronger pain relievers but tend to have more adverse effects.

Figure 2. Pharmacologic Approaches to Pain Management: WHO Three-Step Ladder

Adapted from World Health Organization. *Cancer Pain Relief and Palliative Care, Report of a WHO Expert Committee*. Geneva: World Health Organization; 1990.

Note: "Adjuvants" refers either to medications that are coadministered to manage an adverse effect of an opioid or to so-called adjuvant analgesics that are added to enhance analgesia.

Step 1: Nonopioids for mild pain (pain scale 1-3)

- The most common agents in this step include acetaminophen (650-1,000 mg PO Q6H as needed) and nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen 600-800 mg PO TID with food, and cyclooxygenase-2 (COX-2) inhibitors such as celecoxib and rofecoxib.
- A proton-pump inhibitor (such as omeprazole) can decrease the risk of gastrointestinal bleeding when using NSAIDs.

- Acetaminophen has no effect on platelets and no antiinflammatory properties; avoid use in patients with hepatic insufficiency, and in general limit to 4 g per day in acute use (or 2 g per day for patients with liver disease). Monitor liver function tests in chronic use.
- NSAIDs and acetaminophen can be used together for synergism.
- Note that COX-2 inhibitors have been associated with an increased risk of cardiovascular events and should be used with caution.

Step 2: Mild opiates with or without nonopiates for moderate pain (pain scale 4-6)

- Most agents used to treat moderate pain are combinations of opioids and Step 1 agents. The most common agents are acetaminophen combined with codeine, oxycodone, or hydrocodone. Codeine can be dosed as codeine sulfate, separately from acetaminophen. Beware of acetaminophen toxicity in these combination drugs.
- Other agents include buprenorphine (partial opiate agonist).
- Tramadol (Ultram) is a centrally acting nonopiate that can be combined with NSAIDs. As with opiates, it is prone to abuse. Tramadol lowers the seizure threshold; avoid use for patients with a seizure history. Avoid coadministration with selective serotonin reuptake inhibitors (SSRIs) and monoamine oxidase inhibitors (MAOIs) because of the risk of serotonin syndrome.

Step 3: Opioid agonist drugs for severe pain (pain scale 7-10)

- Morphine is the drug of choice in this step. Start with short-acting morphine and titrate the dosage to adequate pain control, then divide the 24-hour total in half to determine the dosing for the sustained-release morphine, given Q12H. When converting from IV to PO morphine, PO dosage is about two to three times the parenteral dosage.
- Other agents used are oxycodone, hydromorphone, fentanyl, levorphanol, methadone, codeine, hydrocodone, oxycodone, and buprenorphine.
- Avoid meperidine because of the increased risk of delirium and seizures.
- Around-the-clock, sustained-release PO dosing will achieve optimum pain relief.

- Patients unable to take PO therapy may use transdermal fentanyl patches or do rectal administration of sustained-release tablets such as long-acting morphine. Note that the onset of analgesia with fentanyl patches can take more than 12 hours, and the analgesic effect can last more than 18 hours after the patch is removed.
- Anticipate and treat complications and adverse effects of opioid therapy, such as nausea, vomiting, and constipation. Constipation often leads to nausea and can be prevented with prophylactic stool softeners (such as docusate) and stimulant laxatives (such as senna).

Adjunctive treatments

The addition of antidepressant medications can improve pain management, especially for chronic pain syndromes. These agents, and anticonvulsants, usually are used to treat neuropathic pain (discussed in more detail below), but should be considered for treatment of other chronic pain syndromes as well.

Treatment of neuropathic pain

Assess the underlying etiology, as discussed above, and treat the cause as appropriate. Review the patient's medication list for medications that can cause neuropathic pain. Discontinue the offending agents, if possible. For patients on stavudine or didanosine, in particular, switch to another nucleoside analogue if suitable alternatives exist, or at least consider dosage reduction of stavudine to 30 mg BID (consult with an HIV expert). For patients on isoniazid, ensure that they are taking vitamin B6 (pyridoxine) regularly to avoid isoniazid-related neuropathy.

Nonpharmacologic interventions for neuropathic pain

The nonpharmacologic interventions described above can be useful in treating neuropathic pain.

Pharmacologic interventions for neuropathic pain

Follow the WHO ladder of pain management described above. If Step 1 medications are ineffective, consider adding antidepressants, anticonvulsants, or both before moving on to opioid treatments.

Antidepressants

Antidepressant medications often exert analgesic effects at dosages that are lower than those required for antidepressant effects. As with antidepressant effects, optimum analgesic effects may not be achieved until several weeks after starting therapy.

- **Tricyclic antidepressants (TCAs):** Note that ritonavir and other protease inhibitors, and the pharmacokinetic booster cobicistat, may increase the level of TCAs, so start at the lowest dosage and titrate up slowly. Dosages may be titrated upward every 3-5 days, as tolerated. In general, TCAs are best avoided in elderly patients.
- **Nortriptyline (Pamelor):** Starting dosage is 10-25 mg QHS. Usual maintenance dosage is 20-150 mg QHS.
- **Desipramine (Norpramin):** Starting dosage is 25 mg QHS. Usual maintenance dosage is 25-250 mg QHS.
- **Imipramine:** Starting dosage is 25 mg QHS. Usual maintenance dosage is 25-300 mg QHS.
- **Amitriptyline (Elavil):** Starting dosage is 10-25 mg QHS. Usual maintenance dosage is 25-150 mg QHS. Amitriptyline has the highest rate of adverse effects among the TCAs, so other agents typically are preferred.

Adverse effects include sedation, anticholinergic effects (e.g., dry mouth, urinary retention), altered mental status, QT prolongation, arrhythmias, and orthostatic hypotension. Monitor TCA levels and EKG at higher dosage levels. There is a significant risk of overdose if taken in excess.

- **SSRIs:** See chapter *Major Depression and Other Depressive Disorders* for dosing, side effects, and drug interactions associated with this class of agents. SSRIs are less effective than TCAs in treating chronic pain.
- **Venlafaxine (Effexor):** Starting dosage is 37.5 mg daily. Usual maintenance dosage is 75-300 mg daily in divided doses or by extended-release formulation (Effexor XR). Note that there are limited data on using venlafaxine for patients with HIV infection.
- **Duloxetine (Cymbalta):** Starting dosage is 30-60 mg daily. Dosages of >60 mg per day are rarely more effective for either depression or pain treatment. Note that there are limited data on using duloxetine for patients with HIV infection.

Anticonvulsants

The following agents may be effective for neuropathic pain:

- **Gabapentin (Neurontin):** Considered first-line for HIV sensory neuropathy for its tolerability. Starting dosage is 100-300 mg QHS; may be increased every 3-5 days to BID or TID to achieve symptom relief. Monitor response and increase the dosage every 1-2 weeks by 300-600 mg/day. Usual maintenance dosage is 1,200-3,600 mg/day in divided doses. Adverse effects include somnolence, dizziness, fatigue, weight gain, and nausea. To discontinue, taper over the course of 7 or more days.
- **Pregabalin (Lyrica):** Starting dosage is 25-50 mg TID; may be increased by 25-50 mg per dose every 3-5 days as tolerated to achieve symptom relief. Maximum dosage is 200 mg TID. Adverse effects are similar to those of gabapentin. To discontinue, taper over the course of 7 or more days.
- **Lamotrigine (Lamictal):** Starting dosage is 25 mg QOD; titrate slowly to 200 mg BID over the course of 6-8 weeks to reduce the risk of rash (including Stevens-Johnson syndrome). Adverse effects include sedation,

dizziness, ataxia, confusion, nausea, blurred vision, and rash. Note that lopinavir/ritonavir (Kaletra) may decrease lamotrigine levels; higher dosages may be needed. To discontinue, taper over the course of 7 or more days.

- Although phenytoin and carbamazepine have some effectiveness in treating neuropathy, they have significant drug interactions with protease inhibitors and nonnucleoside reverse transcriptase inhibitors, and their use with HIV-infected patients is limited. Topiramate and valproic acid have been used for migraine prophylaxis and anecdotally may be useful for treating peripheral neuropathy, but have not been well-studied in HIV-related neuropathies.

Topical therapy

- **Capsaicin cream** (0.075%, 0.1%): Capsaicin inhibits the secretion of substance P and has been found to be effective for the management of pain associated with arthritis and neuropathy. It may be applied BID or TID. Patients must be instructed to wash their hands well after applying to avoid spreading the residual cream to sensitive areas such as the nose or eyes. It may cause burning.

Treatment of Muscle Spasm Pain

Stretching, heat, and massage may help the pain of muscle spasm. This pain also can respond to muscle relaxants such as baclofen, cyclobenzaprine, tizanidine, benzodiazepines, as well as intraspinal infusion of local anesthetics for spinal injuries.

Substance Abuse, HIV, and Pain

Some health care providers hesitate to treat pain in patients with current or past substance abuse because of concern about worsening these patients' dependence on opioids or suspicion that such patients are seeking pain medications for illicit purposes. However, the following points should be considered:

- Many patients with current or past substance abuse do experience pain, and this pain should be evaluated by care providers and treated appropriately.
- Failure to distinguish among addiction, tolerance, and dependence can lead to undertreatment of chronic pain by health care providers.
- Addiction (substance abuse) is a complex behavioral syndrome characterized by compulsive drug use for the secondary gain of euphoria.
- Pharmacologic tolerance refers to the reduction of effectiveness, over time, of a given dosage of medication.
- Physical dependence is the consequence of neurophysiologic changes that take place in the presence of exogenous opioids.
- Aberrant use of pain medications, if it develops, is best managed by an interdisciplinary team of providers from HIV clinical care, psychiatry, psychology, pharmacy, social services, and drug addiction management.
- Drug-drug interactions between certain antiretroviral medications and methadone can decrease methadone serum concentrations (see chapter *Drug-Drug Interactions with HIV-Related Medications*). If this occurs, methadone dosages may need to be increased to prevent opiate withdrawal.
- As part of chronic pain management in patients with substance abuse, consider establishing a written pain-management

contract to be signed by the clinician and the patient. The contract should:

- Clearly state limits and expectations for both the patient and provider.
- Identify a single clinician responsible for managing the pain regimen.
- Tell the patient what to do if the pain regimen is not working.
- Describe the procedure for providing prescriptions (e.g., one prescription given to the patient, in person, for a limited period of time, such as 1 month).
- List the rules for dealing with lost medications or prescriptions.

Patient Education

- Pain management is part of HIV treatment, and patients should give feedback to allow the best treatment decisions. If pain persists for more than 24 hours at a level that interferes with daily life, patients should inform their health care provider so that the plan can be changed and additional measures, if needed, can be tried.
- Patients should not expect full pain relief in most cases, but enough relief that they can perform their daily activities.
- “Mild” pain medications (e.g., NSAIDs, aspirin, acetaminophen) usually are continued even after “stronger” medications are started because their mechanism of action is different from that of opiates. This combination of pain medication has additive effects, so that pain may be controllable with a lower narcotic dosage.
- Patients taking “around-the-clock” medications should take them on schedule. Those taking “as needed” medications should take them between doses only if they have breakthrough pain.
- Patients who are prescribed opiates should be advised to take no more than the prescribed dosages. Misuse or inappropriate use can result in overdose.
- Opiates may cause severe constipation. Patients must remain hydrated and will likely need stool softeners, laxatives, or other measures. They should contact their health care provider promptly if constipation occurs.
- Patients taking opiates should avoid driving and operating machinery.

HIV-Associated Neurocognitive Disorders

Background

HIV is a neurotropic virus that directly invades the brain shortly after infection. HIV replicates in brain macrophages and microglia, causing inflammatory and neurotoxic host responses. HIV may cause cognitive, behavioral, and motor difficulties. These difficulties may range in severity from very mild to severe and disabling.

The American Academy of Neurology (AAN) recognizes three categories of HIV-associated neurocognitive disorder (HAND) (see Table 1, below).

- **Asymptomatic neurocognitive impairment (ANI)** is determined by neurocognitive testing and is not apparent clinically.
- **Mild neurocognitive disorder (MND)** is a diagnosis of exclusion; it may be made clinically if neurocognitive testing is not available, and it involves mild functional impairment.
- **HIV-associated dementia (HAD)** involves moderate to severe functional impairment.

[In the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) section on cognitive disorders, MND correlates with mild neurocognitive disorder, and HAD with major neurocognitive disorder.]

Both MND and HAD are AIDS-defining conditions (listed as “Encephalopathy, HIV Related” in the classification system used by the U.S. Centers for Disease Control and Prevention), and they are risk factors for death. Neurocognitive disorders associated with HIV are among the most common and clinically important complications of HIV infection. However, they are diagnoses of exclusion, and other medical causes must be ruled out.

Risk factors for developing an HIV-associated neurocognitive disorder include the following:

- Older age
- Female gender
- More advanced HIV disease (including CD4 count of <100 cells/μL, wasting)
- High plasma HIV RNA (viral load)
- Comorbid conditions (especially anemia and infection with cytomegalovirus, human herpesvirus 6, and JC virus)
- History of injection drug use (especially with cocaine)
- History of delirium

With the advent of ART, HAD prevalence has declined and MND prevalence has increased.

As people with HIV live longer and become older, the risk of developing cognitive impairment increases. The use of effective antiretroviral therapy (ART) that maintains the plasma HIV RNA at undetectable or low values is important for preventing and treating HIV-related neurocognitive disorders. In people with neurocognitive impairment, however, there may be some benefit in using antiretroviral (ARV) agents that penetrate the CNS. However, recent research suggests that neuroinflammation rather than the HIV viral load in the CNS is primarily responsible for cognitive impairment in HIV-infected individuals. In choosing an ART regimen, it is important to take into consideration resistance testing, CNS penetration, and adherence issues.

Minor Neurocognitive Disorder

MND is characterized by mild impairment in functioning and may escape diagnosis by the clinician. The onset and course of MND can vary dramatically. The more demanding the activities of a particular individual, the more likely that person would be to notice the difficulties in functioning.

HIV-Associated Dementia

HAD is characterized by symptoms of cognitive, motor, and behavioral disturbances. There is often a progressive slowing of cognitive functions, including concentration and attention, memory, new learning, sequencing and problem solving, and executive control. HAD also can present with behavioral changes, which mainly take the form of apathy, loss of motivation, poor energy, fatigue, and social withdrawal. Motor changes, including slowing, clumsiness, unsteadiness, increased tendon reflexes, and deterioration of handwriting may occur.

S: Subjective

If a neurocognitive disorder is suspected, obtain a history of the patient's symptoms (see below). Whenever possible, obtain a parallel history of the patient's past history and recent mental status changes from significant others or caretakers.

Patient self-reports of cognitive problems and bedside cognitive status tests may be insensitive, particularly to subtler forms of impairment. Often, other people may observe changes in the person's behavior or mood that indicate some change in cognitive functioning.

To help clarify factors that may be causing the changes in mental status, inquire about the following:

- Acuity of onset
- Recent changes or events
- Medications, particularly new medications
- Drug and alcohol use
- Symptoms of opportunistic illnesses, other infections
- HIV history, including duration, CD4 cell count, HIV viral load, history of ART
- History of other medical and psychiatric disorders

Table 1. AAN Criteria for HIV-Associated Neurocognitive Disorder

HIV-Associated Asymptomatic Neurocognitive Impairment (ANI)
• Acquired impairment in cognitive functioning, involving at least two ability domains, documented by performance of at least 1 SD below the mean for age-education-appropriate norms on standardized neuropsychological tests. The neuropsychological assessment must survey at least the following abilities: verbal/language; attention/working memory; abstraction/executive; memory (learning; recall); speed of information processing; sensory-perceptual, motor skills. • The cognitive impairment does not interfere with everyday functioning. • The cognitive impairment does not meet criteria for delirium or dementia. • There is no evidence of another preexisting cause for the ANI.
Mild Neurocognitive Disorder (MND)
• Acquired impairment in cognitive functioning, involving at least two ability domains, documented by performance of at least 1 SD below the mean for age/education-appropriate norms on standardized neuropsychological tests. The neuropsychological assessment must survey at least the following abilities: verbal/language, attention/working memory, abstraction/executive, memory (learning and recall), speed of information processing, sensory-perceptual and motor skills. • The cognitive impairment produces at least mild interference in daily functioning (at least one of the following): • Self-report of reduced mental acuity, inefficiency in work, homemaking or social functioning • Observation by knowledgeable others that the individual has undergone at least mild decline in mental acuity with resultant inefficiency in work, homemaking, or social functioning • The cognitive impairment does not meet criteria for delirium or dementia. • There is no evidence of another pre-existing cause for the mild neurocognitive disorder. If the individual with suspected mild neurocognitive disorder also satisfies criteria for a severe episode of major depression with significant functional limitations or psychotic features, or substance dependence, the diagnosis of mild neurocognitive disorder should be deferred to a subsequent examination conducted at a time when the major depression has remitted or at least 1 month after cessation of substance use.
HIV-Associated Dementia (HAD)
• Marked acquired impairment in cognitive functioning, involving at least two ability domains; typically the impairment is in multiple domains, especially in the learning of new information, slowed information processing and defective attention/concentration. The cognitive impairment must be ascertained by neuropsychological testing with at least two domains being 2 standard deviations or greater below that of demographically corrected means. • The cognitive impairment produces marked interference with day-to-day functioning (work, home life and social activities). • The pattern of cognitive impairment does not meet criteria for delirium. • There is no evidence of another, pre-existing cause for the dementia (e.g., other CNS infection, CNS neoplasm, cerebrovascular disease, pre-existing neurologic disease or severe substance abuse compatible with CNS disorder).

Adapted from Antinori A, Arendt G, Becker JT, et al. *Updated research nosology for HIV-associated neurocognitive disorders. Neurology.* 2007 Oct 30;69(18):1789-99.

Additionally, the AAN specifies that, for patients with severe depression or substance dependence who are suspected of having HAD, the neurocognitive assessment should be deferred until the depression or substance use is in remission.

Although the AAN criteria include assessment via neuropsychological testing, in the absence of such testing, it is acceptable to make a presumptive diagnosis of MND or HAD on the basis of clinical signs and symptoms once all other possible causes of changes in mental function have been ruled out.

O: Objective

- Check temperature and other vital signs (MND and HAD are not associated with fever).
- Perform a complete physical examination with special attention to signs of opportunistic illnesses.
- Perform a thorough neurological examination, including funduscopy. Rule out focal neurologic deficits.
- Perform Mini-Mental State Examination (note that this is not sensitive for HIV-associated neurocognitive disorders; negative results do not rule out these conditions).

Consider a neuropsychological screening test such as the Modified HIV Dementia Scale (see Figure 1), International HIV Dementia Scale, or the Montreal Cognitive Assessment. Others are noted in “Laboratory and Diagnostic Evaluation,” below.

A: Assessment

A differential diagnosis includes the following medical conditions, which may present with cognitive changes or delirium:

- Substance use: intoxication or withdrawal from alcohol, opioids, stimulants, etc.
- Psychiatric disorders, especially major depression
- Metabolic or systemic disorders, including hepatic encephalopathy, vitamin B12 or folate deficiency, uremia, endocrine disorders (e.g., hypogonadism)
- Central nervous system (CNS) opportunistic infections, such as cytomegalovirus encephalitis, cryptococcal meningitis, tuberculous meningitis, CNS toxoplasmosis, and progressive multifocal leukoencephalopathy (PML)
- Systemic infections
- Brain tumors, including CNS lymphoma and metastatic disease
- Other causes of cognitive impairment and dementia (e.g., neurosyphilis, substance-induced dementia, vascular dementia, brain injury, Alzheimer disease, and hydrocephalus)
- Medication adverse effects: ARV medications (especially efavirenz), psychotropic medications, interferon, anticholinergics, and others
- Poisoning with toxic substances

P: Plan**Laboratory and Diagnostic Evaluation**

A change in the mental status of an HIV-infected person should prompt a thorough search for underlying biological causes. As noted above, HIV-related neurocognitive disorders are diagnoses of exclusion, and other causes of the patient’s symptoms should be ruled out.

Perform the following tests:

- Laboratory tests: Complete blood count, electrolytes and creatinine, liver function, thyroid function, vitamin B12, rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL).
- Toxicology tests if substance use is suspected (e.g., opioids, ethanol, amphetamines).
- Brain imaging studies (computed tomography [CT] scan or magnetic resonance imaging [MRI]); rule out space-occupying masses and other lesions; cortical atrophy may be seen in advanced HAD; this finding is not specific.
- Cerebral spinal fluid (CSF) tests if CNS infection is suspected.
- Consider tests for neurocognitive impairment as noted in the table below; most of these can be found on the website of the New York State Department of Health AIDS Institute at www.hivguidelines.org/clinical-guidelines/hiv-and-mental-health.
- Refer to an HIV-experienced neuropsychologist, neurologist, or psychiatrist, if available.

Figure 1. Modified HIV Dementia Scale

Maximum Score	Score	Exercise
N/A	N/A	Memory/Registration: State four words for the patient to recall (dog, hat, green, peach), pausing 1 second between each. Then ask the patient to restate all four.
6	(__)	Psychomotor Speed: Ask the patient to write the alphabet in upper case letters horizontally across the page; record time: ____seconds. ≤ 21 sec = 6 21.1 - 24 sec = 5 24.1 - 27 sec = 4 27.1 - 30 sec = 3 30.1 - 33 sec = 2 33.1 - 36 sec = 1 > 36 sec = 0
4	(__)	Memory Recall: Ask the patient to restate the four words from Memory/Registration above. Give one point for each correct response. For words not recalled, prompt with a "semantic" clue, as follows: animal (dog); piece of clothing (hat), color (green), fruit (peach). Give 1/2 point for each correct after prompting.
2	(__)	Construction: Copy the cube below; record time: ____seconds. (< 25 sec = 2; 25 - 35 sec = 1; > 35 sec = 0) 

Maximum score: 12 points; a score of < 7.5 points suggests possible HAD (note, this test is not specific)

Adapted from McArthur JC. *Minor cognitive motor disorder: Does it really exist?* Hopkins HIV Rep. Nov 1996;8(4):8.

Table 2. Tests for Identifying and Staging HIV-Related Neurocognitive Impairment

HIV Dementia Scale	• Screens for the memory and attention deficits and psychomotor slowing that are typical of HAD • Requires training to administer and, therefore, may not be ideal for a clinic setting
Modified HIV Dementia Scale	• Designed specifically for use by non-neurologists and, therefore, may be more useful than the HIV Dementia Scale for a primary care setting • Requires approximately 5 minutes to administer • See Figure 1, above
Mental Alternation Test	• Useful for assessing patients with early dementia, who will show impairments in timed trials
Memorial Sloan-Kettering (MSK) Scale	• Can be used for assessing severity • Combines the functional impact of both cerebral dysfunction (dementia) and spinal cord dysfunction (myelopathy); the two entities can be separated and staged independently
Trail Making Test, Parts A and B (from the Halstead-Reitan Neuropsychological Battery)	• May be used as a screening tool, but results require interpretation by a neuropsychologist • May be used at the bedside to track a patient's response to ART over time
Grooved Pegboard (dominant and nondominant hand)	• May be used as a screening tool and does not require literacy

Treatment

There are no specific treatments for HIV-associated neurocognitive disorders, but ART may reverse the disease process, and a number of therapies may be helpful. The treatment of MND and HAD ideally utilizes a multidisciplinary approach that may involve HIV specialists, neurologists, psychiatrists, psychologists, nurse practitioners, social workers, substance-use counselors, case managers, and others.

Neurocognitive impairment in patients with HIV infection often is multifactorial. In addition to treating HIV-associated neurocognitive disorders themselves, it is important to correct, as much as possible, all medical conditions that may adversely affect the brain (e.g., psychiatric comorbidities, endocrinologic abnormalities, adverse medication effects). For patients using alcohol or illicit or nonprescribed drugs, implement strategies to reduce their use; these agents can further impair cognition.

Pharmacologic Management of HIV-Associated Neurocognitive Disorders

- **ART:** Maximal suppression of HIV replication via ART may partially or fully reverse HIV-associated neurocognitive disorders, and ART is the treatment of choice for both treatment and prevention of HIV-associated neurocognitive disorders, including dementia. In general, ART regimens that effectively suppress HIV RNA in the serum also suppress HIV in the CNS. However, ARV medications vary in their ability to penetrate the blood-brain barrier and, therefore, in their ability to act directly on the HIV in the CNS. Limited data suggest that using ARVs with good CNS penetration may be important in treating or preventing neurocognitive disorders, and some experts recommend the use of these ARVs, if otherwise appropriate, for patients with HIV dementia. ARVs with the best CNS penetration include the nucleoside reverse transcriptase inhibitors (NRTIs)

abacavir, emtricitabine, and zidovudine (AZT, ZDV); the nonnucleoside reverse transcriptase inhibitor (NNRTI) nevirapine; the protease inhibitors (PIs) indinavir/ritonavir and lopinavir/ritonavir; and the CCR5 antagonist maraviroc. The integrase inhibitor raltegravir has reasonably good CNS penetration. There currently is no role for testing levels of HIV RNA in the CSF outside research settings.

- **Stimulants:** Stimulant medications (e.g., methylphenidate, dextroamphetamine) have been used as palliative agents to help manage symptoms of fatigue, decreased concentration, and memory deficits among patients with MND and HAD. Starting dosages of both is 5 mg/day; maximum dosage is 60 mg/day. The response to stimulants is idiosyncratic and varies from patient to patient; begin with the lowest dose of 5 mg QAM and titrate upward as needed. If BID dosing is required as a result of afternoon fatigue, the afternoon dose should be taken before 2 p.m. to prevent interference with sleep. Consider referral to a psychiatrist or neurologist for evaluation and initiation of treatment; after a stable dosage is achieved, treatment may be continued. These medications should be used with caution for patients who have a history of stimulant abuse.
- For comorbid depression, consider prescribing antidepressant medications as for other medically ill HIV-infected patients (see chapter *Major Depression and Other Depressive Disorders*).
- Antipsychotic medications may be useful in treating agitation and hallucinations but should be used for patients with dementia only when nonpharmacologic measures are insufficient for patient management; consult with a psychiatrist. All antipsychotic medications increase the risk of death in elderly patients with dementia. Start antipsychotic medications at the lowest possible dosage and increase slowly as needed.

- Many agents are being studied for either their neuroprotective effects or their therapeutic effects on HIV-associated neurocognitive disorders. The data are not sufficient at present to make specific recommendations. Patients with dementia often are sensitive to medication side effects; follow closely.
- Benzodiazepines have been shown to increase confusion and decrease concentration, and generally should be avoided.

Nonpharmacologic Management of MND and Mild HAD

- Encourage patients to remain appropriately active
- Explain the benefits of structured routines
- Encourage good nutrition
- Use strategies to minimize use of alcohol and illicit drugs
- Use memory aids such as lists
- Simplify complex tasks, especially drug regimens
- When giving instructions, do the following:
 - Repeat information
 - Write instructions to provide structure for patients and caregivers
 - Ask patients to express the information and instructions in their own words
- Adherence to medical regimens, including ART, often is particularly difficult for patients with neurocognitive disorders. Encourage use of medication adherence tools such as pill boxes, alarms, and, if available, packaged medications (e.g., blister packs) or prefilled medi-sets. Encourage patients to enlist adherence support from family members and friends.
- Cognitive skills building can be helpful (e.g., reading, solving puzzles, intellectual conversation).

Nonpharmacologic Management of Moderate to Severe HAD

The strategies noted above should be utilized, but additional measures are needed.

Management of patients with severe or late-stage HAD requires an evaluation of their safety and a determination of the environment and level of supervision that are needed. The clinician should attend to the following:

- Help determine whether patients can be left alone at home or whether doing so would present the risk of them wandering away or sustaining an injury in the home (e.g., from the use of an appliance such as the oven).
- For patients who cannot be left alone at home, assess options for support (e.g., help from family members or paid home attendants).
- Utilize fall prevention strategies.
- For patients who smoke, decide whether smoking can be done safely; if smoking is deemed unsafe, consider smoking cessation programs or supervision.
- If lesser measures fail, explore options for placement in a skilled nursing facility.

Additional helpful strategies for managing patients who are confused, agitated, or challenged by their experience include the following:

- Keep their environments familiar to the extent possible (e.g., in terms of objects, people, locations).
- Redirect or distract patients from inappropriate behavior.
- Remain calm when patients become confused or agitated; refrain from confronting an agitated patient; reorient confused or agitated patients.
- Provide a clock and calendar in the room to help keep patients oriented to time and to day of the week.

- Provide lighting that corresponds with day and night.
- Emphasize routines.
- Ensure that patients who require eyeglasses or hearing aids wear them to help lessen confusion and disorientation.
- Prepare patients for any planned changes.
- Ensure that patients are receiving their prescribed medications.
- Protect wandering patients.
- Supervise any cigarette smoking.
- Offer activities that keep patients' minds alert.
- Educate family members about the nature of dementia and methods for helping patients maintain activities of daily living.
- Suggest that patients or their family members make arrangements for financial, health, and other matters in the event they become unable to make decisions about their affairs (e.g., advance health care directives, durable powers of attorney, wills).

Patient Education

- Advise patients that ART can be effective in preventing and treating HIV-related neurocognitive impairment.
- Inform patients and family members of the many other strategies that may aid in managing neurocognitive impairment. Such strategies may help patients maintain the highest possible level of skills and independence.
- Family members and significant others can be important sources of support (e.g., by providing assistance with medication adherence).
- Advise patients with advanced HAD that placement in a residential facility may be the best option for ensuring their safety.

Major Depression and Other Depressive Disorders

Background

Major depression is the most prevalent psychiatric comorbidity among people with HIV infection and commonly has a significant impact on health. The etiology may be multifactorial, as with depression in HIV-uninfected persons, but HIV infection may bring additional complexity. A diagnosis of HIV may cause a psychological crisis, but also may complicate underlying psychological or psychiatric problems (e.g., preexisting depression, anxiety, or substance abuse). Direct viral infection of the central nervous system (CNS) can cause several neuropsychiatric syndromes. In addition, both HIV-related medical conditions and HIV medications can cause or contribute to depression.

Patients with untreated depression experience substantial morbidity and may become self-destructive or suicidal. They are at continuing risk of engaging in unsafe behaviors that may lead to HIV transmission and poor adherence to care and treatment.

Major depression in persons with comorbid medical illness, including HIV infection, has been associated with the following:

- Decreased survival
- Impaired quality of life
- Decreased adherence to antiretroviral therapy (ART)
- Increased risk behaviors
- Suicide
- Longer hospital stays and more frequent medical visits (e.g., emergency room, medical clinics)
- Higher treatment costs

Stress and depressive symptoms, especially when they occur jointly, are associated with diminished immune defenses in HIV-infected individuals, and severe depression is associated with higher mortality rates. Anxiety symptoms are common among people with major depression (see chapter *Anxiety Disorders*). Psychotic symptoms may occur as a component of major depression and are associated with an increased risk of suicide. Even one or two symptoms of depression

HRSA HAB Performance Measures

Percentage of patients aged 12 years and older **screened for clinical depression** on the date of the encounter using an age-appropriate standardized depression screening tool AND, if positive, a follow-up plan is documented on the date of the positive screen

(Adult and Adolescent measure)

increase the risk of an episode of major depression.

All clinicians should do the following:

- Maintain a high index of suspicion for depression and screen frequently for mood disorders.
- Elicit any history of psychiatric diagnoses or treatment.

Rule out medical conditions that may cause mood or functional alterations.

Refer for psychiatric evaluation and psychosocial support, including, as appropriate, to substance abuse counselors and domestic violence service providers.

A screening test for depression such as the Patient Health Questionnaire-2 (PHQ-2) should be administered yearly or whenever a patient's complaints or symptoms suggest depressive disorders.

Patient Health Questionnaire-2 (PHQ-2)

Over the past 2 weeks, how often have you been having little interest or pleasure in doing things?

0 = Not at all

1 = Several days

2 = More than half the days

3 = Nearly every day

Over the past 2 weeks, how often have you been feeling down, depressed, or hopeless?

0 = Not at all

1 = Several days

2 = More than half the days

3 = Nearly every day

Calculate the total point score: ____

Score interpretation: Patient Health Questionnaire-2 (PHQ-2)

Score	Probability of major depressive disorder (%)	Probability of any depressive disorder (%)
1	15.4	36.9
2	21.1	48.3
3	38.4	75.0
4	45.5	81.2
5	56.4	84.6
6	78.6	92.9

Depression is diagnosed, as in HIV-uninfected individuals, according to the criteria of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-5.

Major Depression

The patient may complain of either or both of two cardinal symptoms:

- Diminished interest or pleasure in activities
- Depressed mood, sadness

If either or both of these are present, other complaints may be used to diagnose major depression, including the following:

- Decreased ability to concentrate
- Appetite changes with weight changes (increase or decrease)
- Fatigue or loss of energy
- Feelings of worthlessness or guilt
- Insomnia or hypersomnia
- Psychomotor agitation or retardation
- Recurrent thoughts of death or suicide

The diagnosis of major depression is made if five of the above symptoms occur on most days for at least 2 weeks. Depressed mood or diminished interest or pleasure must be one of the five symptoms present.

Other subjective symptoms of depression may include the following:

- Hopelessness
- Helplessness
- Irritability or anger
- Somatic complaints in addition to those noted above

Other Depressive Disorders

- **Persistent depressive disorder:** A new DSM category that subsumes dysthymia and chronic major depressive disorder. This is another very common depressive disorder found among HIV-infected patients. Treatments for major depression and persistent depressive disorder are similar.

Dysthymia has been characterized by more chronic but less severe symptoms than those

found in major depression. The diagnosis is made when a person has had a depressed mood for most of the day, for more days than not, for at least 2 years. While depressed, the patient exhibits two or more of the following symptoms:

- Poor appetite or overeating
- Insomnia or hypersomnia
- Low energy or fatigue
- Low self-esteem
- Poor concentration or difficulty making decisions
- Feelings of hopelessness

In addition, the symptoms must cause clinically significant distress or impairment in functioning, and there can have been no major depressive episode during the first two years of the disturbance.

- **Bipolar disorder:** Major depression may be a manifestation of bipolar disorder. Bipolar disorder should be ruled out before giving an antidepressant to a patient with major depression, as bipolar disorder usually requires the use of mood stabilizers before, or instead of, beginning antidepressant medications (antidepressant therapy may precipitate a manic episode). Bipolar disorder should be suspected if a patient has a history of episodes of high energy and activity with little need for sleep, has engaged in risky activities such as buying sprees and increased levels of risky sexual behavior, or has a history of taking mood stabilizers (lithium and others) in the past. If bipolar disorder is suspected, refer the patient to a psychiatrist for further evaluation and treatment.
- **Other forms of depression** include adjustment disorder with depressed mood (acute reaction to a life crisis, such as the loss of a job), premenstrual dysphoric disorder, disruptive mood dysregulation disorder, and depressive disorder not otherwise specified.

S: Subjective

- Inquire about the symptoms listed above, and about associated symptoms.
- Take a careful history of the timing and duration of symptoms, their relationship to life events (e.g., HIV testing, loss of a friend, onset of physical symptoms), and any other physical changes noted along with the mood changes.
- Elicit personal and family histories of depression, bipolar disorder, or suicidal behavior.
- Probe for suicidal thoughts, plans, and materials to execute the plans (see chapter *Suicide Risk*).
- Inquire about hallucinations, paranoia, and other symptoms.
- Ask about current and past medication use and substance abuse.

O: Objective

Perform mental status examination, including evaluation of affect, mood, orientation, appearance, agitation, or psychomotor slowing; perform thyroid examination, inspection for signs of self-injury, and neurologic examination if appropriate.

A: Assessment

Partial Differential Diagnosis

Rule out nonpsychiatric causes of symptoms, which may include the following:

- Hypothyroidism or hyperthyroidism
- Hypotestosteronism (hypogonadism) – very common with HIV disease in both men and women
- Other endocrine disorders such as Addison disease
- Substance-induced mood disorder (intoxication or withdrawal)
- Medication adverse effects (e.g., from steroids, efavirenz, isoniazid, or interferon-alfa)

- HIV dementia or minor cognitive motor disorder
- HIV encephalopathy
- Neurosyphilis
- Opportunistic illnesses affecting the CNS (e.g., toxoplasmosis, cryptococcal disease, CNS cytomegalovirus, progressive multifocal leukoencephalopathy)
- Vitamin B12, folate (B6), zinc, vitamin A, or vitamin D deficiency

P: Plan

Evaluation

The diagnosis is based on clinical criteria as indicated above. Rule out medical and other causes. An initial screening includes the following:

- Complete blood count, electrolytes, creatinine, blood urea nitrogen (BUN), glucose
- Thyroid function tests (thyroid stimulating hormone [TSH], T4)
- Vitamin B12, vitamin D, and folate levels
- Testosterone (both in men and women)
- Other tests as suggested by history and physical examination

Treatment

Refer immediately for psychiatric evaluation or treatment if the patient is:

- Hopeless
- Suicidal (see chapter *Suicide Risk*)
- Displaying psychotic symptoms
- Debilitated or functionally impaired by severe symptoms
- Not responding to treatment

The combination of psychotherapy and antidepressant medication is more effective than either treatment modality alone. Social

support interventions (e.g., community-based HIV support groups) also can help; refer to available resources. Patients should be encouraged to discontinue alcohol or substance use, and should be referred for treatment as indicated.

Psychotherapy

Individual psychotherapy with a skilled, HIV-experienced mental health professional can be very effective in treating depression. Several specific types of individual and group psychotherapies for depression (e.g., interpersonal therapy, cognitive-behavioral therapy, behavioral activation, supportive psychotherapy, coping effectiveness) have been shown to be effective for HIV-infected individuals.

Pharmacotherapy

For most patients, a selective serotonin reuptake inhibitor (SSRI) or a serotonin-norepinephrine reuptake inhibitor (SNRI) is the most appropriate initial treatment for depression. For patients who experience treatment failure with these agents (or have an incomplete response) at a customary therapeutic dosage, consultation with a psychiatrist is recommended.

When selecting antidepressant medications, consider their side effect profiles as a means to manage other symptoms the patient may be experiencing. For example, activating antidepressants (taken in the morning) may help patients who complain of low energy; antidepressants that increase appetite may be useful for patients with wasting syndrome; sedating antidepressants (taken at bedtime) may help patients with insomnia. Medications that may be lethal if overdosed (e.g., tricyclic antidepressants) should not be prescribed to patients for whom suicidality may be a concern.

The information below describes specific antidepressant medications, with information on dosage and possible adverse effects.

Most antidepressants should be started at low dosages and gradually titrated upward to avoid unpleasant side effects that might lead to nonadherence. Antidepressant effect usually is not noticed until 2-4 weeks after starting a medication. If there is no improvement in symptoms in 2-4 weeks, and there are no significant adverse effects, the dosage may be increased.

A therapeutic trial consists of treatment for 4-6 weeks at a therapeutic dosage. If the patient's symptoms have not improved, an increase in dosage or a switch to another medication should be considered. Patients who remain depressed should be referred to a psychiatrist.

Monitor all patients closely after starting them on antidepressant medications. Depressive symptoms may continue to worsen while on medication; improved energy is the initial effect of antidepressants, whereas hopelessness and sadness improve later. In addition, some young persons are at risk of worsening depression caused by antidepressants. Black-box warnings advise that antidepressants may cause increased risk of suicidality in children, adolescents, and young adults (<24 years of age) with major depressive or other psychiatric disorders, especially during the first month of treatment.

Medications should be continued for 6-9 months beyond the resolution of symptoms, to reduce the risk of recurrence. After this time, treatment may be tapered down gradually if the patient wishes, with careful monitoring for depressive symptoms. The risk of recurrence is higher if the first depressive episode is inadequately treated or if the patient has had multiple depressive episodes. For patients with recurrent depression, consider long-term maintenance antidepressant treatment. See "Discontinuing antidepressant medication," below.

Potential ARV Interactions

Interactions may occur between certain ARVs and agents used to treat depression. Some combinations may be contraindicated and others may require dosage adjustment. Refer to medication interaction resources or consult with an HIV expert, psychiatrist, or clinical pharmacist before prescribing.

Some ARV medications (particularly protease inhibitors [PIs]) and the pharmacokinetic booster cobicistat may affect the metabolism of some antidepressants via cytochrome P450 interactions. For example, ritonavir can significantly increase serum levels of tricyclic antidepressants, increasing the risk of tricyclic toxicity. In the case of most other antidepressants, interactions with ARVs generally are not clinically significant, but most antidepressants used concomitantly with PIs or cobicistat should be started at low dosages and titrated cautiously to prevent antidepressant adverse effects and toxicity. On the other hand, some PIs may decrease levels of paroxetine, sertraline, and bupropion, and efavirenz also lowers sertraline and bupropion levels; these antidepressants may require upward titration if used concurrently with interacting ARVs. Further information is presented under individual agents and classes, below.

For patients who are starting ARV medications (particularly PIs) or cobicistat and are on a stable antidepressant regimen, monitor carefully for adverse effects and for efficacy of the antidepressant; dosage adjustments may be required.

The available antidepressant medications (SSRIs and SNRIs), including therapeutic dosages and possible positive and negative effects, are listed in Table 1.

Table 1. SSRI and SNRI Antidepressant Medications and Possible Positive and Negative Effects

Medication/Usual Dosage	Possible Positive Effects	Possible Negative Effects
SSRIs	No anticholinergic or cardiovascular effects, nonfatal in overdose; may help treat anxiety	- Sexual dysfunction (men and women) - Serotonin withdrawal syndrome if discontinued abruptly
Citalopram (Celexa): 10-60 mg QD	May have lower risk of significant drug-drug interactions than other SSRIs	Mild nausea, possible sedation
Escitalopram (Lexapro): 10-20 mg QD	May have lower risk of significant drug-drug interactions than other SSRIs	Mild nausea, possible sedation
Fluoxetine (Prozac): 10-40 mg QD	Rarely sedating, often energizing, lower risk of SSRI withdrawal syndrome if discontinued abruptly	Insomnia, agitation, nausea, headache, sexual dysfunction in men and women, long half-life
Paroxetine (Paxil): 10-40 mg QD	May be sedating (for patients experiencing sedation with paroxetine, dose at bedtime; can be useful with depression-associated insomnia)	Insomnia, agitation (for patients experiencing these effects, administer dose in mornings), nausea, headache, higher risk of SSRI withdrawal syndrome, weight gain
Sertraline (Zoloft): 50-200 mg QD	May have lower incidence of significant drug-drug interactions compared with fluoxetine and paroxetine	Insomnia, agitation, nausea, headache
SNRIs		- Nausea, headache, nervousness, sexual dysfunction (men and women) - Serotonin withdrawal syndrome if discontinued abruptly
Duloxetine (Cymbalta): 30-60 mg QD	May be used also for pain management and neuropathy; may have lower risk of significant drug-drug interactions compared with SSRIs	Nausea, somnolence
Venlafaxine (Effexor): 37.5-75 mg BID or TID OR Venlafaxine XR (Effexor XR): 75-375 mg QD	May have lower risk of significant drug-drug interactions compared with SSRIs	Hypertension (monitor blood pressure at higher dosages) Higher risk of SSRI/SNRI withdrawal syndrome
Desvenlafaxine (Pristiq): 50 mg QD	May have lower risk of significant drug-drug interactions compared with SSRIs	Higher risk of SSRI/SNRI withdrawal syndrome

Other agents

- **Bupropion (Wellbutrin and others):** Bupropion is available in immediate-release form (requires TID dosing), sustained-release (SR) (requires BID dosing), or extended-release (XL) (QD dosing) formulations. At higher bupropion dosages, there is an increased risk of seizures, and this drug is contraindicated in patients who have risk factors for seizures. For patients taking PIs, caution should be used as the dosage approaches 300-400 mg per day because of possible increases in levels of bupropion (however, tipranavir and efavirenz may decrease bupropion levels). Bupropion may have an activating effect, which some patients may experience as agitation, insomnia, or both, and also may have an appetite suppressant effect. It usually does not cause sexual dysfunction, and therefore may be helpful for individuals with depression who experience adverse sexual effects with other antidepressants.
- **Mirtazapine (Remeron):** (15-45 mg QPM) May have lower risk of significant drug-drug interactions compared with SSRIs; can be useful when weight gain and sleep induction are needed. Potential adverse effects include sedation, increased appetite, weight gain, constipation, and dry mouth. Note that the higher dosages may result in increased activation owing to increased norepinephrine (NE) receptor antagonism.
- **Tricyclics:** Tricyclic antidepressants may be effective, but generally are not recommended for treatment of depression because they have a higher risk of adverse effects than do SSRIs and SNRIs. They also are more dangerous (potentially fatal) in overdose. Adverse effects include anticholinergic effects, sedation, and cardiac conduction abnormalities. Levels of tricyclics are increased by ritonavir, so lower dosages may be needed for patients taking ritonavir or ritonavir-boosted PIs.

Routine monitoring of blood levels of tricyclics should be performed on patients receiving higher doses (e.g., 100 mg per day; 50 mg for nortriptyline), those on concurrently on ritonavir, and those with risk factors for cardiac conduction abnormalities. A routine electrocardiogram should be performed before prescribing tricyclics, and this class of drugs should not be prescribed to patients with cardiac conduction problems.

The adverse effects of tricyclics can be used to treat insomnia or diarrhea, for example, and tricyclics can be effective for neuropathic pain.

- **Imipramine (Tofranil):** FDA indications for depression and chronic pain. The full recommended dosage for either problem is 150-300 mg QHS. Starting dosage: 25-75 mg PO QHS.
- **Doxepin (Sinequan):** FDA indications for depression and anxiety at adult dosages of 150-300 mg QHS. Starting dosage: 25-75 mg PO QHS.
- Three other available tricyclics have an FDA indication for depression only: **nortriptyline (Pamelor)** at dosages of 50-150 mg QHS; **desipramine (Norpramin)** at dosages of 50-200 mg a day; and **protriptyline (Vivactil)** at dosages of 5-10 mg, either TID or QID.
- **Tricyclics need to be started at low dosages and titrated gradually.** Lower dosages (or alternative agents) often are more appropriate for patients who are elderly, medically ill, or taking ritonavir or a ritonavir-boosted PI.

- **Trazodone:** a highly sedating antidepressant that is rarely used at an antidepressant dosage. Rather, it is often given at lower dosage for insomnia associated with depression, at a dosage of 25-50 mg 1-2 hours before bedtime. Ritonavir and other PIs can increase trazodone levels significantly; start at low dosage and use the lowest effective dosage; monitor for adverse effects.
- **Nefazodone (Serzone):** an antidepressant that usually should be avoided in people with HIV infection. Little information on interactions with ARVs is available, but it appears that nefazodone may increase levels of maraviroc and saquinavir, and that ritonavir may increase nefazodone levels. It has a black-box warning for severe liver toxicity. If the patient has ever had liver toxicity from the drug, restarting it is contraindicated.
- **St. John's wort:** an herbal antidepressant that can significantly decrease serum concentrations of PIs, NNRTIs, and maraviroc; it is contraindicated for use by patients taking those ARVs.

Treatment may involve antidepressant combinations, including psychostimulants; consult with a psychiatrist.

Discontinuing antidepressant medication

Antidepressant medication generally should be continued for at least 6 months following resolution of a first episode of major depression. Longer term, and even indefinite, maintenance treatment may be necessary for people with recurrent major depression. When discontinuing antidepressants, it is important to taper them gradually to avoid withdrawal symptoms or rebound depression. Abrupt discontinuation of SSRI and SNRI antidepressants often precipitates unpleasant withdrawal symptoms such as confusion, agitation, irritability, sensory disturbances, and insomnia. This is particularly true for paroxetine and venlafaxine. Fluoxetine, because of its long half-life, is uncommonly associated with withdrawal symptoms.

Brain stimulation treatments

There are a variety of brain stimulation treatments that usually are reserved for patients who have inadequate responses to medication. Electroconvulsive therapy (ECT) is the best known of these treatments and, despite the stigma associated with it, is more effective than antidepressant medication. Newer brain stimulation treatments also are available. These treatments require referral to the specialty care locations that offer them. Antidepressant medication often is used for maintenance after stabilization with ECT, but for some people, maintenance ECT is needed to prevent the relapse of depression.

Patient Education

- Providers should explain to patients that illness (physical or emotional) is not a character flaw or a moral or spiritual weakness. It is a common aspect of HIV infection. Sadness is a normal part of life, but major depression always is abnormal and often can be alleviated with medication, psychotherapy, or both.
- Providers should help patients identify the symptoms of depression and the factors that led them to seek treatment. Patients will need to monitor themselves for recurrences or exacerbations and get help if the symptoms recur. Patients should be told to contact providers if they notice changes in their sleep, appetite, mood, activity level, or concentration, or if they notice fatigue, isolation, sadness, or feelings of helplessness.
- When starting an antidepressant medication, patients should expect that it will take 2-4 weeks for them to notice any improvement. Their symptoms should continue to decrease over the following weeks. If they do not have much improvement in symptoms, providers may choose to adjust the dosage of the medication or to change medications. Patients must continue taking their medications so that the symptoms of depression do not return.
- Providers should let patients know that St. John's wort can lower levels of ARVs and cannot be taken if they are on ART.
- Antidepressants typically are given for a long time, usually for a year or longer, to help patients with the chemical imbalances associated with major depression. Patients should be told that they should not suddenly stop antidepressants they have been taking for a long time, and that these medications need to be discontinued gradually.
- Some patients develop problems with sexual function while they are taking antidepressants. They should report any problems to their prescribers. (Note: Providers should let patients know that sexual well-being is fundamental to quality of life and can be talked about and addressed in the clinical setting.)

Suicide Risk

Background

Transient suicidal thoughts are common for some people throughout the course of HIV disease and often do not indicate significant risk of suicide. However, persistent suicidal thoughts with associated feelings of hopelessness and intent to die are very serious and must be assessed promptly and carefully. Compared with people at high risk of suicide who are not HIV infected, people living with HIV have significantly increased frequency and severity of both suicidal ideation and thoughts of death. The risk of suicide is especially high for patients who are depressed and for those at pivotal points in the course of HIV infection. Stigma, quality of life concerns, and issues regarding disclosure may be contributing factors.

Suicidality may be the direct physiological result of HIV (e.g., owing to the impact of HIV in the brain), a reaction to chronic pain, or an emotional reaction to having a chronic and life-threatening illness (e.g., major depression as a result of physical illness or psychiatric side effects caused by medications used to treat HIV infection and associated comorbidities). Many events may trigger suicidal thoughts among people with HIV. Such events include learning of their positive HIV status, disclosing to family and friends, starting antiretroviral therapy (ART), noticing the first symptoms of infection, having a decrease in CD4 cell count, undergoing a major illness or hospitalization, receiving an AIDS diagnosis, losing a job, experiencing major changes in lifestyle, requiring evaluation for dementia, and losing a significant relationship.

Evaluation of suicide risk must be included as part of a comprehensive mental health evaluation for HIV-infected patients. Note that asking patients about suicidal thoughts does not increase their risk of suicide.

HRSA HAB Performance Measures

Percentage of patients aged 12 years and older **screened for clinical depression** on the date of the encounter using an age-appropriate standardized depression screening tool AND, if positive, a follow-up plan is documented on the date of the positive screen

(Adult and Adolescent measure)

Risk factors for suicide attempts include the following:

- Previous suicide attempts
- Abandonment by or isolation from, family, friends, or significant others
- Age >45 for men, >55 for women; or teen years
- Male gender
- Gay sexual orientation
- Transgender
- Any acute change in health status; worsening of HIV-related illness or other physical illnesses
- Family history of completed suicide
- Alcohol and other substance misuse, abuse, or dependence
- Relapse into drug use after significant recovery
- Severe anxiety, depression, psychotic disorder, or other mental health disorder
- Domestic violence
- Social isolation (e.g., being single, divorced, or alone, or experiencing the death of a spouse)
- Multiple losses or recent stressors
- Financial difficulty, unemployment

- Hopelessness and lack of pleasure
- Impulsivity
- Pain
- Perception of poor prognosis
- Perception of poor social support
- Planning for death
- Stigmatization associated with illness, sexual orientation, substance use history, or other factors
- Fear of HIV-associated dementia

Protective factors include the following:

- Strong psychosocial support
- Evidence of good coping mechanisms
- Cultural and religious beliefs against suicide
- Reasons for living
- No specific plan for suicide

S: Subjective

The patient expresses or exhibits, or a personal care giver discloses, the following:

- Active suicidal ideation with intent and plan, such as giving away significant personal belongings, saying goodbye, acquiring the means (e.g., gun, pills), writing a suicide note
- Depressed mood, hopelessness, agitation, intoxication with alcohol or other drugs
- Passive withdrawal from therapy or medical care or decreased adherence (e.g., stopping medications, missing appointments)
- A desire for HIV disease to progress more rapidly

Inquire about the following during the history (*again, note that asking patients about suicidal thoughts does not increase their risk of suicide*):

- Previous suicide attempt(s) – one of the best predictors of eventual death by suicide
- Friend or family member who has committed suicide
- Personal or family history of depression
- Previous episode of psychosis
- Presence of risk factors described above

Probe for other depressive symptoms and the immediacy of potential suicidal intent. Sample questions may include the following:

- “It sounds as if you’re in great pain. Have you ever thought that life is not worth living?”
- “Do you often think of death?”
- “Do you think about hurting yourself?”
- “How might you do that?”
- “Do you have a plan?” Ask whether the patient has access to the components of the plan (e.g., gun, pills)
- “Is this something you feel you might do?”
- “What would prevent you from doing this?”
- “Have you ever attempted suicide? What did you do?”

O: Objective

- Perform a mental status examination and suicide assessment.
- Look for signs of self-inflicted injuries such as wrist lacerations or neck burns.
- Look for signs of depression, agitation, or intoxication.

A: Assessment

See chapter *Major Depression and Other Depressive Disorders* for differential diagnosis of possible causes of depression and suicidality.

P: Plan**Evaluation**

Evaluate the patient for depression, risk factors for suicide, and contributing psychiatric illnesses or situational stressors. Determine the immediacy of potential suicidal intent. If a mental health professional is available on site or can be summoned, an urgent consultation often is helpful in making these determinations.

Treatment

- If the patient exhibits active suicidal ideation with a plan, hospitalize the patient immediately, preferably in a psychiatric facility.
- If suicidal thoughts are passive, refer for evaluation for specific psychiatric disorders and refer for psychotherapy with an HIV-experienced mental health provider.
- Encourage the patient to contact you or another specified clinician for help, or to go to a hospital if suicidal ideation worsens or patient worries about acting upon suicidal thoughts.
- Note that making a contract with a patient against suicide is not recommended; research shows it is not effective, and it can provide a false sense of security.

- Inform patients about local suicide prevention resources, including suicide hotlines, emergency response (e.g., 911), and local emergency departments.
- Contact the patient between appointments. Enlist the help of significant others (if the patient agrees); invite them to accompany the patient on the next visit and see all of them together. Consider a support group or peer referral, if available.
- Consider dispensing medications on a weekly basis for the following purposes:
 - Monitoring emotional status and treatment adherence
 - Preventing the availability of lethal doses of medications
- Perform appropriate follow-up. In consultation with a skilled mental health provider, be sure that the patient is receiving appropriate ongoing treatment for underlying or persisting psychiatric illness. Assess at each visit for adherence to mental health care and for recurrence of symptoms.

Patient Education

- Suicidal ideation and severe depression are not normal aspects of HIV infection, and usually can be treated effectively.
- Patients should report suicidal thoughts to their health care provider.
- Inform patients about local suicide prevention resources, including suicide hotlines, emergency response (e.g., 911), and local emergency departments.

Anxiety Disorders

Background

Anxiety symptoms are common and can develop or recur for many reasons, including a patient's worries about HIV infection and treatment, or issues unrelated to HIV. Symptoms can range from mild distress to full-blown anxiety disorders. Symptoms of anxiety can mimic symptoms of physical illness, and an appropriate workup should be performed to rule out other illnesses. Use of illicit drugs (e.g., amphetamines, cocaine) or alcohol can cause or substantially worsen anxiety symptoms; all patients should be screened for substance use.

Anxiety disorders include generalized anxiety disorder, specific phobia, and social phobia; related disorders include posttraumatic stress disorder (PTSD) and panic disorder. This chapter focuses primarily on anxiety symptoms and generalized anxiety disorder. See chapters *Panic Disorder* and *Posttraumatic Stress Disorder* for further information about these conditions.

HRSA HAB Performance Measures

Percentage of patients aged 12 years and older **screened for clinical depression** on the date of the encounter using an age-appropriate standardized depression screening tool AND, if positive, a follow-up plan is documented on the date of the positive screen

(Adult and Adolescent measure)

S: Subjective

The criteria for a diagnosis of generalized anxiety disorder include unrealistic or excessive worry about two or more life circumstances for ≥ 6 months, and at least three of the following subjective complaints:

- Restlessness or feeling keyed-up or on edge
- Difficulty concentrating or mind going blank
- Irritability
- Muscle tension
- Being easily fatigued
- Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep)

Other subjective complaints may include the following:

- Shortness of breath or smothering sensations
- Palpitations or accelerated heart rate
- Dizziness or lightheadedness
- Exaggerated startle response

- Trembling, twitching, or feeling shaky
- Dry mouth
- Flushes or chills
- Frequent urination
- Muscle aches or soreness
- Nausea, diarrhea, or other abdominal distress
- Skin rashes
- Sweating or cold, clammy hands
- Trouble swallowing or "lump in the throat"

Ask about the symptoms indicated above, and about the following:

- Anxiety patterns (e.g., constant or intermittent; timing, duration, precipitants)
- Onset: sudden or gradual
- Caffeine intake
- Recreational drug or alcohol use (current or recent)
- Concomitant illnesses (e.g., cardiac, pulmonary, endocrine)

- Family history of similar problems
- Medications, supplements, and herbal preparations
- History of previous episodes
- Recent stressors
- Sleep disturbances
- Other physical symptoms

O: Objective

Measure vital signs, with particular attention to heart rate (tachycardia) and respiratory rate (shortness of breath, hyperventilation).

Perform a physical examination, including mental status and neurologic, cardiopulmonary, and thyroid examinations.

A: Assessment

A differential diagnosis may include the following medical conditions:

- Substance use (e.g., amphetamines, cocaine)
- Substance or medication withdrawal (e.g., alcohol, benzodiazepines)
- Excessive caffeine intake
- Electrolyte imbalances
- Heart disease, arrhythmias
- Hyperthyroidism
- Hypoglycemia
- Immune disorders
- Respiratory disease, hypoxia
- Medication adverse effects (e.g., with efavirenz, isoniazid, corticosteroids, theophylline, or stimulants)
- Sleep disturbances or sleep deprivation
- Allergic reactions
- Anemia
- Central nervous system (CNS) or opportunistic infections or malignancies

- Systemic or other infections
- Vitamin B12 deficiency

P: Plan

Diagnostic Evaluation

Perform the following tests:

- Blood glucose, electrolytes
- Thyroid function tests (TSH, T4)
- Electrocardiogram (EKG) if patient has shortness of breath or palpitations
- Arterial blood gases (if difficulty breathing is not self-limited)
- Other tests as indicated by symptoms and physical examination

Treatment

Once medical disorders have been ruled out, and the diagnosis of an anxiety disorder is established, several options are available:

Psychotherapy

Options include cognitive-behavioral therapy, interpersonal therapy, exposure therapy, a stress-management group, relaxation therapy, visualization, guided imagery, supportive psychotherapy, and psychodynamic psychotherapy. Long-term psychotherapy may be indicated if experienced professionals are available and the patient is capable of forming an ongoing relationship. If possible, refer to an HIV-experienced therapist. The type of psychotherapy available to the patient often depends on the skills and training of the practitioners in a given health care system or region. In addition, the patient may be referred to available community-based support.

Pharmacotherapy

Medications, with or without psychotherapy, may alleviate symptoms of anxiety. Patients with advanced HIV disease, like geriatric patients, may be more vulnerable to the CNS effects of certain medications. Medications that affect the CNS should be started at low

dosage and titrated slowly. Similar precautions should apply to patients with liver dysfunction.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) are effective in treating patients with anxiety. They are favored for long-term use when a specific anxiety disorder is present and persistent. These medications do not cause tolerance or pose a risk of addiction. Below is a list of antidepressants approved by the U.S. Food and Drug Administration (FDA) for specific anxiety disorders, and their usual recommended dosages. FDA recommendations are based on availability of specific study data, but all SSRIs (regardless of whether they have an FDA indication for anxiety) may be helpful for a broad range of anxiety disorders.

Common adverse effects of SSRIs and SNRIs include sexual dysfunction, sleep disturbance, and nausea. For patients who are medically ill, these medications should be started at low dosage and titrated up slowly; a low dosage may be effective. These medications also should be down-tapered slowly; SSRI/SNRI discontinuation syndrome may occur if they are discontinued abruptly.

See chapter *Major Depression and Other Depressive Disorders* for further information about antidepressant medications, including adverse effects.

SSRI antidepressants:

- Fluoxetine (Prozac): FDA indication for panic disorder with a recommended dosage of 20 mg QD. Also recommended for obsessive-compulsive disorder, but higher dosages are needed, sometimes up to 80 mg daily.
- Escitalopram (Lexapro): FDA indication for generalized anxiety disorder at a dosage of 10 mg QD.
- Citalopram (Celexa): Does not have specific FDA indications for anxiety

disorders. Suggested dosage: start at 10 mg QD and titrate as needed; maximum dosage: 60 mg daily.

- Paroxetine (Paxil): FDA indications for obsessive-compulsive disorder and panic disorder both at a recommended dosage of 40 mg QD. Also indicated for social anxiety disorder at a dosage of 20-40 mg daily. Usual starting dosage: 10 mg daily.
- Sertraline (Zoloft): FDA indications for panic disorder and PTSD at dosages of 50-200 mg QD. Usual starting dosage: 25 mg daily.

SNRI antidepressants:

- Venlafaxine timed-release formulation (Effexor XR): FDA indication for generalized anxiety disorder, at recommended dosages of 75-225 mg per day. Note: There is a risk of hypertension at the higher dosages of venlafaxine; monitor blood pressure.
- Duloxetine (Cymbalta): FDA indication for generalized anxiety disorder at a recommended dosage of 60 mg QD.

Other antidepressants:

- Some sedating antidepressants are effective, nonaddictive agents that are helpful when taken at bedtime for both insomnia and anxiety symptoms. These include trazodone 25-100 mg QHS or imipramine (Tofranil) 25 mg QHS. Note that imipramine and other tricyclics must be used with caution but are not contraindicated for use by patients taking ritonavir (including ritonavir-boosted protease inhibitors [PIs]).
- Gabapentin (Neurontin), which sometimes is used as a mood stabilizer, may be given at dosages of 200-400 mg BID to QID and may help to diminish anxiety.

Anxiolytics

Short-term use of benzodiazepines sometimes is appropriate for mild and brief situational anxiety symptoms, even without the presence of a specific anxiety disorder. For longer-term use, non-benzodiazepines (e.g., buspirone [see below], SSRIs, or SNRIs) are preferred.

- Buspirone (BuSpar) is a nonaddictive anxiolytic. Start at 5 mg PO TID. If symptoms persist, the dosage can be increased by 5 mg per dose each week to a maximum of 10-15 mg TID (for a total daily dosage of 30-45 mg). It will take several weeks for patients to notice a decrease in anxiety; low-dose benzodiazepines may be used during this interval. The major potential adverse effects of buspirone are dizziness and lightheadedness.
- Consider intermediate half-life benzodiazepines such as lorazepam (Ativan) 0.5 mg PO Q8H or oxazepam (Serax) 10 mg PO Q6H if buspirone is not tolerated or to alleviate anxiety symptoms until buspirone takes effect. Longer-acting benzodiazepines such as clonazepam (Klonopin) also may be useful at dosages of 0.25-0.5 mg PO BID.
- Benzodiazepines generally should be used only for acute, short-term management because of the risk of tolerance and physiologic dependence. These risks are even more problematic for patients with a history of addiction.

Potential ARV Interactions

Interactions may occur between certain ARVs and agents used to treat anxiety. Some combinations may be contraindicated and others may require dosage adjustment. Refer to medication interaction resources or consult with an HIV clinical pharmacist, HIV specialist, or psychiatrist before prescribing.

Antidepressants

- Some ARV medications (particularly PIs) and the pharmacokinetic booster cobicistat may affect the metabolism of some antidepressants via cytochrome P450 interactions. For most SSRIs and SNRIs, interactions with ARVs generally are not clinically significant; in the case of tricyclics, their levels may be significantly increased by ritonavir. On the other hand, some PIs may decrease levels of paroxetine and sertraline, and efavirenz also lowers sertraline levels. See chapter *Major Depression and Other Depressive Disorders* for further information.

Anxiolytics

- PIs, nonnucleoside reverse transcriptase inhibitors (NNRTIs), and cobicistat may raise blood concentrations of many benzodiazepines. Consider using a benzodiazepine metabolized by glucuronidation (e.g., lorazepam, oxazepam), particularly in patients with liver disease. For benzodiazepines metabolized by the CYP system (e.g., clonazepam), start at low dosages and titrate slowly. Given the very long half-life of both the parent drug and its metabolites, diazepam is best avoided in patients receiving ART. Other CNS depressants and alcohol should be avoided in patients taking these benzodiazepines.
 - Midazolam (Versed) and triazolam (Halcion) are contraindicated for use with all PIs and with cobicistat, delavirdine, and efavirenz.
- Buspirone levels may be increased by ritonavir-boosted PIs and cobicistat, and may be decreased by CYP inducers. Monitor patients for adverse effects and for efficacy.

Patient Education

- Behavioral interventions can help to reduce anxiety, but may take practice. Patients should seek help from a therapist or another experienced source.
- Advise patients that misuse of alcohol or illicit drugs can cause or substantially worsen anxiety symptoms; advise patients to decrease or eliminate use. Refer for substance abuse treatment if indicated.
- Inform patients that they may develop problems with sexual function because of antianxiety medications. Patients should report any problems to their prescribers. (Note: Providers should let patients know that sexual well-being is fundamental to quality of life and can be talked about and addressed in the clinical setting.)

Panic Disorder

Background

Panic disorder is an anxiety disorder whose essential feature is the presence of recurrent, unexpected panic attacks. Panic attacks are discrete, sudden-onset episodes of intense fear or apprehension accompanied by specific somatic or psychiatric symptoms (e.g., palpitations, shortness of breath, fear of losing control). A patient is diagnosed as having panic disorder when he or she has experienced such attacks, and at least one of the attacks has been followed by ≥ 1 month of persistent concern about additional attacks, worry about the implications or consequences of the attack, or a significant change in behavior related to the attack.

The symptoms of panic disorder usually begin in late adolescence to the mid-30s and may coincide with the presentation of major depressive disorder, social phobia, or generalized anxiety disorder. Panic disorder can interfere with the ability to conduct activities of daily living. Patients with panic disorder have an increased incidence of suicide.

Symptoms may mimic those of various physical illnesses or be caused by other medical conditions (e.g., hyperthyroidism, brain tumors, adrenal tumors, heart arrhythmias, hypoglycemia, anemia). Substance or alcohol intoxication or withdrawal also may cause panic symptoms. Patients with panic symptoms should be evaluated for other causative conditions.

Major depressive disorder occurs in 50-65% of people with panic disorder. Major depression may precede or follow the onset of panic disorder. Patients with panic disorder therefore should be screened for depression initially and periodically thereafter (see chapter *Major Depression and Other Depressive Disorders*). Anxiety also commonly is experienced by persons with panic disorder; see chapter *Anxiety Disorders* for further information about this condition.

S: Subjective

The patient complains of discrete periods of intense fear or discomfort in which four or more of the following symptoms developed abruptly and reached a peak within 10 minutes:

- Shortness of breath or smothering sensation
- Sweating
- Trembling or shaking
- Dizziness, lightheadedness, faintness, or feeling of unsteadiness
- Numbness or tingling sensations
- Chest pain or discomfort
- Palpitations or accelerated heart rate
- Hot flashes or chills
- Sensation of choking

- Depersonalization or derealization
- Fear of dying
- Fear of going crazy or losing control
- Nausea or abdominal distress

Other subjective complaints may include the following:

- Apprehension about the outcome of routine activities and experiences
- Anticipation of a catastrophic outcome from a mild physical symptom or from medication side effects
- Discouragement and demoralization

Panic attacks are, by definition, self-limited and they peak quickly. Symptoms that persist continuously for longer periods suggest other causes.

Ask about the symptoms indicated above and about the following:

- Frequency, duration, and onset of panic episodes
- Possible precipitants, (e.g., settings in which attacks occur), situations (e.g., being alone outdoors), relationship to food or hunger
- Current medications, herbal products, and supplements; recent medication changes
- Multiple visits to health care providers with complaints suggesting panic attacks
- Family history of mood and psychiatric illnesses, particularly anxiety and panic
- Use of recreational drugs (especially stimulants such as cocaine or amphetamines), alcohol (current and recent), and caffeine
- Sleep disturbances
- Concomitant illnesses (e.g., endocrine, cardiac, pulmonary)
- Any associated or concurrent symptoms that could suggest a medical etiology
- Screen for depression (see chapter *Major Depression and Other Depressive Disorders*)

O: Objective

Measure vital signs, with particular attention to heart rate (tachycardia) and respiratory rate (shortness of breath, hyperventilation). Perform a complete physical examination, including thyroid, cardiac, pulmonary, and neurologic evaluation.

During actual panic attacks, patients may have increases in heart rate, respiratory rate, or systolic blood pressure.

A: Assessment

A differential diagnosis may include the following conditions:

- Congestive heart failure, myocardial ischemia, arrhythmias
- Hyperthyroidism
- Intoxication with or withdrawal from psychoactive substances (e.g., amphetamines, cocaine, hallucinogens, caffeine, medications)
- Hypoglycemia
- Hypoxia
- Hyperparathyroidism
- Medication side effects
- Pheochromocytoma
- Adrenal disorders, Cushing syndrome, electrolyte abnormalities
- Respiratory infection
- Seizure disorder
- Vestibular dysfunction
- Allergic reactions
- Posttraumatic stress disorder
- Social phobia or specific phobia (specific phobia is a response to a specific stimulus, whereas a patient with panic attacks is unsure when they will recur and what will trigger them)
- Agoraphobia
- Obsessive-compulsive disorder
- Separation anxiety disorder

P: Plan

Diagnostic Evaluation

Perform the following tests:

- Electrolytes, blood glucose
- Thyroid function tests (thyroid stimulating hormone [TSH], T4)
- Arterial blood gases if the patient has persistent shortness of breath
- Electrocardiogram if chest pain or other cardiac symptoms are present
- Other tests as indicated by symptoms and physical examination

Treatment

Once other diagnoses have been ruled out, consider the following treatments:

Psychotherapy

Options include cognitive-behavioral therapy, interpersonal therapy, exposure therapy, a stress-management group, relaxation therapy, visualization, guided imagery, supportive psychotherapy, and psychodynamic psychotherapy. Long-term psychotherapy may be indicated if experienced professionals are available and the patient is capable of forming an ongoing relationship. If possible, refer to an HIV-experienced therapist. The type of psychotherapy selected often will depend on the skills and training of the practitioners available in a given health care system or region. In addition, refer the patient to available community-based support. Emergency referrals may be needed for the most anxious patients and those with comorbid depression.

Pharmacotherapy

Patients with advanced HIV disease and geriatric patients may be more vulnerable to the central nervous system (CNS) effects of certain medications. Medications that affect the CNS should be started at low dosage and titrated slowly. Similar precautions should apply to patients with liver dysfunction.

Options

A number of medications have an approved indication by the U.S. Food and Drug Administration (FDA) for panic disorder. These include the serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine extended-release, and benzodiazepines listed below. For most patients, SSRIs are preferable to benzodiazepines for the treatment of panic disorder because they do not have the potential for addiction and they do not pose the same level of risk if drug interactions cause an elevation of their levels. Other medications used to treat anxiety disorders, such as SNRIs may be considered, and some of them are less likely to interact with ARV medications. See chapter *Anxiety Disorders* for descriptions of these medications.

SSRI antidepressants approved for panic disorder include the following:

- Fluoxetine (Prozac), recommended dosage 20 mg PO QD (usual starting dosage 10 mg daily)
- Paroxetine (Paxil), recommended dosage 40 mg PO QD (usual starting dosage 10 mg daily)
- Sertraline (Zoloft), recommended dosage 50-200 mg PO QD (usual starting dosage 25 mg daily)

SNRI antidepressant approved for panic disorder:

- Venlafaxine (Effexor XR), recommended dosage 75-225 mg PO QD (usual starting dosage 37.5 mg daily)

Benzodiazepines approved for panic disorder include the following:

- Clonazepam (Klonopin), recommended dosage 0.5-2 mg PO BID
- Alprazolam (Xanax), recommended dosage 0.5-3 mg PO TID or Xanax XR at a recommended dosage of 3-6 mg PO QD; start at low dosage, may increase every 3-4 days in increments of ≤ 1 mg/day if tolerated

Potential ARV Interactions

Interactions may occur between certain ARVs and agents used to treat panic. Some combinations may be contraindicated and others may require dosage adjustment. Refer to medication interaction resources or consult with an HIV expert or clinical pharmacist before prescribing.

Some ARV medications (particularly protease inhibitors [PIs]) and the pharmacokinetic booster cobicistat may affect the metabolism of some SSRIs via cytochrome P450 interactions. These generally are not clinically significant, but SSRIs used concomitantly with PIs or cobicistat should be started at low dosages and titrated cautiously to prevent antidepressant adverse effects and toxicity. On the other hand, some PIs may decrease levels of paroxetine and sertraline, and efavirenz also lowers sertraline levels; these antidepressants may require upward titration if used concurrently with interacting ARVs.

PIs and cobicistat can significantly elevate the levels of clonazepam and alprazolam, resulting in the potential for severe sedation or respiratory depression. For patients receiving clonazepam or alprazolam, it is recommended that these medications be used at the lowest dosages for the shortest duration possible.

Patient Education

- Inform patients that behavioral interventions can help to reduce the frequency and severity of panic attacks.
- Some antidepressants and anti-anxiety medications can prevent or reduce the severity of panic attacks.
- Advise patients that they may develop problems with sexual function because of the medications. Patients should report any problems to their prescribers. (Note: Providers should let the patient know that sexual well-being is fundamental to quality of life and can be talked about and addressed in the clinical setting.)

Posttraumatic Stress Disorder

Francine Cournois, MD; and Milton Wainberg, MD

Background

Symptoms of posttraumatic stress disorder (PTSD) can develop after exposure to a traumatic event. A traumatic event may be a single instance, such as a car accident or experience of a natural disaster, or an ongoing pattern of events, such as continuous neglect, physical or sexual abuse, or chronic exposure to war or violent conflict. PTSD causes intrusive memories, hyperarousal, and psychological numbing or avoidance, among other symptoms. It may impair an individual's psychological and physical functioning, decreasing immune system function and increasing susceptibility to illness. Untreated PTSD can increase the risk of HIV transmission or acquisition and worsen the course of HIV treatment.

Individuals with PTSD may experience depression, anxiety, social isolation, impairments in trust and attachments, and feelings of anger, and PTSD often coexists with depression, anxiety, or other psychiatric illnesses. PTSD may be associated with increased risk-taking behavior (e.g., substance abuse, unsafe sex).

The rate of PTSD among individuals with HIV infection (in whom the lifetime prevalence is possibly as high as 42%) is higher than that of the general population (1.3%-7.8%). Women experience PTSD at a higher rate than men. The likelihood of developing PTSD increases in relation to the severity of or proximity to the traumatic event. A history of traumatic experiences may increase an individual's risk of developing PTSD after a new trauma. Although a diagnosis of HIV may trigger PTSD symptoms, a history of trauma or abuse often is present as well. A personal or family psychiatric history may increase the likelihood of developing PTSD.

PTSD is diagnosed, as in HIV-uninfected individuals, according to the criteria of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-5 (see "References," below). It is treatable through diverse therapies and psychopharmacology.

S: Subjective

The following reflect DSM-5 diagnostic criteria; include them in the history.

- The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death, serious injury, or sexual violence, or a threat to the physical integrity of self or others.
- The person's response involved intense fear, helplessness, or horror.
- The person complains of persistently reexperiencing the event in one or more of the following ways:
 - Recurrent and intrusive distressing recollections of the event, including

images, thoughts or perceptions

- Recurring distressing dreams of the event
- Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations and dissociative flashback episodes, including those that occur when awakening or intoxicated)
- Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
- Physiological reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event

592 | Guide for HIV/AIDS Clinical Care

- The person makes efforts to avoid thoughts or reminders of the trauma.
- The person has disturbances in mood or cognition that began or worsened after the traumatic event.

Other complaints may include the following:

- Overwhelming emotions caused by memories of the event
- Emotional numbness
- Disruptions in consciousness, memory, or identity
- Depersonalization (i.e., a feeling of watching oneself act, while having no control over a situation)
- Derealization (i.e., alteration in the perception or experience of the external world so that it seems strange or unreal)
- Feelings of estrangement from others
- Episodes of lost time

The patient may experience the following:

- Recurrent distressing recollections of the event
- Recurrent distressing dreams of the event
- Illusions/hallucinations of the event actually occurring
- Psychological distress triggered by cues reminiscent of the event
- Avoidance of thoughts, feelings, or conversation associated with the event
- Avoidance of activities, places, or people associated with the event
- Inability to recall important aspects of the event
- Diminished interest in significant activities
- Detachment
- Restricted range of affect
- Difficulty falling or staying asleep
- Irritability or outbursts of anger

- Difficulty concentrating
- Hypervigilance

Ask about the duration of symptoms (PTSD is characterized by symptoms that last for more than 1 month).

Also screen for the following:

- Clinical depression
- Anxiety disorders
- Alcohol or other substance-use disorders

O: Objective

- Check vital signs, with particular attention to heart rate (tachycardia) and respiratory rate (shortness of breath, hyperventilation).
- Perform a physical examination, including mental status and neurologic examination (tremor, hyperreflexia, focal abnormalities).
- Look for signs of physical trauma or sexual assault.

A: Assessment

A differential diagnosis may include the following:

- Substance use (e.g., amphetamines, cocaine)
- Substance withdrawal (e.g., alcohol, benzodiazepines)
- Electrolyte imbalances
- Excessive caffeine intake
- Hyperthyroidism
- Medications effects (e.g., efavirenz, isoniazid, steroids, theophylline)
- Allergic reactions
- Head trauma
- Hypoglycemia
- Sleep disturbances or sleep deprivation
- Central nervous system (CNS) or opportunistic infections or malignancies

- Systemic or other infections
- Respiratory disease
- Heart disease, arrhythmias
- Anemia
- Vitamin B12 deficiency

P: Plan

Evaluation

Perform the following tests:

- Complete blood count, electrolytes, creatinine, blood urea nitrogen, glucose
- Thyroid function tests (thyroid stimulating hormone [TSH], T4)
- Vitamin B12 levels
- Other tests as suggested by history and physical examination

Treatment

Once other diagnoses have been ruled out and the diagnosis of PTSD is established, several treatment options are available.

Psychotherapy

Options include individual cognitive-behavioral therapy, cognitive processing therapy, exposure therapy, eye movement desensitization and reprocessing, interpersonal therapy, a stress-management group, relaxation therapy, visualization, guided imagery, supportive psychotherapy, and other forms of therapy. Long-term psychotherapy may be indicated if experienced professionals are available and the patient is capable of forming an ongoing relationship. If possible, refer to an HIV-experienced therapist. The specific psychotherapy often depends on the skills and training of the practitioners available in a given health care system or region. In addition, refer the patient to available community-based support.

Pharmacotherapy

Antidepressants

Most antidepressants should be started at low dosages and gradually titrated upward to avoid unpleasant side effects. Therapeutic effects may not be noticed until 2-4 weeks after starting a medication. If there is no improvement in symptoms in 2-4 weeks, and there are no significant adverse effects, the dosage may be increased. Before prescribing a medication, always remember to check for drug-drug interactions, particularly with concurrent antiretrovirals (ARVs). See “Potential ARV Interactions,” below, and chapter *Major Depression and Other Depressive Disorders* for further information about antidepressants, including possible adverse effects and interactions with ARVs.

- **Selective serotonin reuptake inhibitors** (SSRIs) have the strongest evidence for efficacy and tolerability for PTSD and are first-line medication treatment. Two SSRI antidepressants have a specific indication for PTSD approved by the U.S. Food and Drug Administration (FDA): sertraline (Zoloft) at recommended dosages of 50-200 mg QD (usual starting dosage: 25 mg daily) and paroxetine (Paxil) at recommended dosages of 20-50 mg QD (usual starting dosage: 25 mg daily). Other SSRIs include fluoxetine (Prozac), citalopram (Celexa), and escitalopram (Lexapro).
- The **serotonin norepinephrine reuptake inhibitor** (SNRI) antidepressants such as venlafaxine (Effexor), desvenlafaxine (Pristiq), and duloxetine (Cymbalta), as well as the antidepressant mirtazapine (Remeron), are second-line treatments if SSRIs prove ineffective or are not well tolerated.
- **Tricyclic antidepressants** (TCAs) may be employed if the individual has had a good response to them in the past and they do not cause severe side effects, or if the individual

has failed to respond to or cannot tolerate SSRIs or SNRIs. TCAs in low dosages also may be used for sleep; see chapter *Insomnia*.

Anxiolytics

Antianxiety medications have not been shown to be effective treatments for PTSD when used alone but may be effective, as adjunctive therapy, in reducing anxiety symptoms. Benzodiazepines can reduce anxiety rapidly, often within hours, but may have counterbalancing side effects early in the course of their use that include sedation and incoordination. In addition, physical dependency may develop in patients who use them for more than a few weeks. Benzodiazepines are not recommended for people who have a history of alcohol abuse or dependence. Benzodiazepines ideally would be used only briefly and intermittently to quell acute and severe anxiety symptoms. Levels of many benzodiazepines may be increased by certain protease inhibitors and nonnucleoside reverse transcriptase inhibitors; see “Potential ARV Interactions,” below.

Buspirone (BuSpar) is a nonaddictive anxiolytic. It usually must be taken for at least 1-2 weeks before anxiety symptoms begin to lessen. Starting dosage is 5 mg PO TID. If symptoms persist, the dosage can be increased by 5 mg per dose each week to a maximum of 10-15 mg PO TID (for a total daily dosage of 30-45 mg). Low-dose benzodiazepines may be used during the initial weeks of buspirone therapy, until the effects of buspirone are felt. The major potential adverse effects of buspirone are dizziness and lightheadedness.

Anticonvulsants

Mood stabilizers such as valproate (Depakote), carbamazepine (Tegretol), lamotrigine (Lamictal), and topiramate (Topamax) may be added for patients with a partial response to an antidepressant. They may be helpful for those who have considerable irritability, anger, or hostility, as well as those with reexperiencing symptoms (e.g., flashbacks, intrusive memories). Gabapentin (Neurontin) 200-400 mg BID or QID sometimes helps to diminish anxiety. Treatment with these agents usually should be done by or in consultation with a psychiatrist.

Antipsychotics

Older and newer antipsychotics (aripiprazole, olanzapine, paliperidone, quetiapine, risperidone, and ziprasidone) may be suitable for individuals with psychotic features of PTSD or those who have a comorbid psychotic illness. These medications also may be helpful for some individuals who have not benefited from medications indicated for PTSD. Adverse effects may include dyslipidemia, hyperglycemia, weight gain, and sudden cardiac death. Consultation with a psychiatrist is recommended.

Other medications

A variety of other medications have been used as adjunctive treatment when insomnia and nightmares persist despite adequate use of psychotropic medications. Research is still quite limited, but suggests that the antihypertensive drugs clonidine (Catapres) and prazosin (Minipress) may help with the insomnia and nightmares of PTSD.

Patients with advanced HIV disease and geriatric patients may be particularly vulnerable to the CNS effects of certain medications. Medications that affect the CNS should be started at low dosage and titrated slowly. Similar precautions should apply to patients with liver dysfunction.

Potential ARV Interactions

Interactions may occur between certain antiretrovirals and agents used to treat PTSD. Some combinations may be contraindicated and others may require dosage adjustment. Refer to medication interaction resources or consult with an HIV expert or pharmacist before prescribing.

Antidepressants

- Levels of many SSRIs and SNRIs may be increased or decreased by certain protease inhibitors (PIs) or NNRTIs and by the pharmacokinetic booster cobicistat. These interactions generally are not clinically significant, but most agents should be started at low dosages and titrated cautiously while monitoring efficacy and adverse effects. See chapter *Major Depression and Other Depressive Disorders*.
- Tricyclic levels can be increased substantially by ritonavir and cobicistat. If they are used for patients taking ritonavir, ritonavir-boosted PIs or cobicistat, they should be started at low dosage, patients should be followed closely, and tricyclic levels should be monitored.

Anxiolytics

- PIs, cobicistat, and nonnucleoside reverse transcriptase inhibitors may raise blood concentrations of many benzodiazepines. If benzodiazepines are used, they should be started at low dosage, and other CNS depressants should be avoided. Consult with a clinical pharmacist before prescribing. See chapters *Anxiety Disorders* and *Insomnia* for additional information.
 - Midazolam (Versed) and triazolam (Halcion) are contraindicated for use with all PIs or cobicistat and with delavirdine and efavirenz.
- Buspirone levels may be increased by ritonavir-boosted PIs or cobicistat and may be decreased by CYP inducers. Monitor patients for adverse effects and for efficacy.

Anticonvulsants

- Most anticonvulsants may have significant interactions with certain ARVs and other medications; check for drug-drug interactions before prescribing.

Antipsychotics

- Potential interactions vary according to the specific medications used; consult with a pharmacist or psychiatrist.

Patient Education

- Explain to patients that illness (physical or emotional) is not a character flaw or a moral or spiritual weakness.
- Inform patients that both behavioral interventions and medication can be very helpful in treating PTSD. If one strategy is not successful, many others are available.
- Advise patients that psychiatric medications are often given for a long time, usually for a year or longer.
- Advise patients that, when they start taking an antidepressant medication for PTSD, they should expect that it will take 2-4 weeks for them to notice any improvement. Their symptoms should continue to decrease over the following weeks. If they do not have much improvement in symptoms, providers may choose to adjust the dosage of the medication or to change medications. Patients must continue taking their medications so that symptoms do not return.
- Advise patients that they may develop problems with sexual function because of psychiatric medications. They should report any problems to their prescribers.

Insomnia

Background

Insomnia is a common accompaniment to HIV infection, especially as the disease progresses and complications worsen. Once present, insomnia tends to be chronic, unlike the transient disturbances of sleep that are a normal part of life. Most insomnia related to HIV can be characterized by the amount, quality, or timing of sleep. Insomnia may cause progressive fatigue and diminished functioning.

S: Subjective

The patient may complain of the following:

- Difficulty initiating sleep
- Early-morning awakening
- Mind-racing thoughts (e.g., “I can’t turn off my thoughts.”)
- Difficulty maintaining sleep
- Nonrestorative sleep (i.e., although the amount of sleep is adequate, the patient does not feel rested upon awakening)
- Nighttime restlessness

Ask about the symptoms above, and about the following:

- Determine the patient’s bedtime sleep habits; request additional history from a sleep partner, if possible
- Try to quantify how long the patient actually sleeps each night

Ask about the following:

- Alcohol and recreational drug use
- Caffeine intake (quantity, times of day)
- Nightmares, life stressors
- Concurrent medications that may cause insomnia as an adverse effect (e.g., efavirenz, corticosteroids, pseudoephedrine, and decongestants)
- Medications (prescription or over-the-counter) or supplements used to promote sleep

- Shift work, exercise, nighttime reflux or heartburn, snoring, and periods of apnea (not breathing)
- Collar size (size >16 more often associated with sleep apnea)

Screen for depression and anxiety.

O: Objective

Perform a general symptom-directed physical examination, including evaluation of body habitus, neurologic status, and mental status.

A: Assessment

A partial differential diagnosis includes the following:

- Alcohol intake (interferes with sleep 2-4 hours after ingestion, may cause nocturnal awakening)
- Caffeine intake
- Recreational drug use
- Anxiety disorder
- Major depression (insomnia is a primary symptom)
- Transient insomnia related to acute stress
- Cognitive impairment
- Disturbance of the sleep/wake cycle because of excessive time in bed or inadequate sleep hygiene (e.g., noise in the bedroom)
- Medication adverse effects (e.g., from steroids, efavirenz)

- Other identifiable sleep disorders (e.g., obstructive sleep apnea, periodic leg movements)
- Pain
- Underlying systemic medical conditions that can interfere with sleep, such as delirium, lung disease, congestive heart failure, renal failure, diarrhea, and incontinence

P: Plan

Evaluation

The diagnosis usually is based on history. A sleep evaluation (including polysomnography) may be indicated when a physiologic cause (e.g., obstructive sleep apnea) is suspected or insomnia is severe.

Treatment

Treat underlying illnesses that may be causing or contributing to insomnia.

- Manage correctible medical conditions that may interfere with sleep.
- Treat depression and anxiety disorders. These are very common contributors to insomnia among people with HIV infection. See chapters *Major Depression and Other Depressive Disorders*, *Anxiety Disorders*, and *Panic Disorder*.
- If the patient is suspected of having sleep apnea, periodic limb movements in sleep, or restless limb syndrome, refer to a specialist in sleep medicine for evaluation.

The following options are available for treatment:

Behavioral strategies

- To correct deleterious sleep habits, patients should do the following:
 - Establish a bedtime routine.
 - Avoid stimuli before bedtime.
 - Avoid vigorous exercise within 3-4 hours of bedtime.
 - Reduce or eliminate daytime napping.
 - Avoid eating, reading, watching TV, or working in bed.
 - Wake up at the same time each day regardless of total hours of sleep.
 - Have a dark, cool, quiet, comfortable environment conducive to sleep.
 - Place the bedroom clock out of sight.
- If unable to fall sleep after 15-20 minutes, the patient should get up, go into another room for nonstimulating activity in dim light (such as reading), and not go back to bed until sleepy.
- The patient should discontinue use of caffeine, central nervous system stimulants, alcohol, and tobacco, with tapering if necessary, to avoid withdrawal symptoms.
- Teach or refer the patient for relaxation techniques.

Pharmacotherapy

Choosing a pharmacologic agent for insomnia

A number of medications may be effective in treating insomnia. In selecting a medication for an individual patient, consider the following about a specific medication:

- Is it likely to improve symptoms that may be contributing to the patient's insomnia (e.g., depression, anxiety, psychosis, neuropathic pain)?
- Does it pose risks to the patient based on comorbid medical conditions (e.g., benzodiazepines should not be given to patients with sleep apnea, tricyclic antidepressants should not be given to patients with cardiac conduction problems)?
- Does it have adverse interactions with other medications (e.g., zolpidem [Ambien], zaleplon [Sonata], and eszopiclone [Lunesta] should be used with caution in patients taking protease inhibitors [PIs])?
- Is it the optimal agent for a patient with a current or past history of alcohol or sedative abuse/dependence?
- Is it affordable (e.g., formulary or co-pay issues)?

Treatment considerations

There are limited data to guide the frequency (nightly, intermittently, as needed) and duration (brief, intermediate, long-term) of hypnotic medications. Hypnotics should be prescribed at the lowest effective dosage for the shortest possible period. The greater the degree of physical illness, the more likely the patient will need a low dosage of a hypnotic agent. When long-term treatment is necessary, benzodiazepines pose the greatest risk of tolerance, abuse, and dependence.

Possible adverse effects of all hypnotics include excess sedation, daytime grogginess, impaired judgment, behavior changes, and disruption of the sleep architecture. In addition, persons taking hypnotics may engage in overnight activities or behaviors without being fully awake, and may not remember these activities afterwards (e.g., walking, driving, eating); they also may have impairment in cognition and motor skills the next morning.

Interactions may occur between certain antiretrovirals (ARVs) and agents used to treat insomnia. Some combinations may be contraindicated and others may require dosage adjustment. Refer to medication interaction resources or consult with an HIV expert, psychiatrist, or pharmacist before prescribing.

Agents with FDA-Approved Indications for Insomnia

Antihistamines

- The antihistamines diphenhydramine, doxylamine, and hydroxyzine, given at doses of 25-50 mg QHS, can be used for sleep. Adverse anticholinergic effects often interfere with long-term use.

Antidepressants

- Trazodone, 25-50 mg; maximum dose: 200 mg QHS.
 - Trazodone, a triazolopyridine derivative antidepressant and sedative, is the only antidepressant with a U.S. Food and Drug Administration (FDA) indication for insomnia, and it is widely used for this purpose. However, levels may be increased by ritonavir-boosted PIs and by the pharmacokinetic booster cobicistat. Do not use with saquinavir/ritonavir; use lower dosages for patients receiving other PIs or cobicistat. Trazodone may (rarely) cause priapism. Trazodone can be used for an indefinite period of time as it is not associated with tolerance or addiction.

Non-benzodiazepine hypnotics (agonists of the benzodiazepine receptor)

- Zolpidem (Ambien) 5 mg for women, 5-10 mg for men, 5 mg for geriatric patients; zolpidem-CR (Ambien-CR) 6.25 mg for women, 6.25-12.5 mg for men; zaleplon (Sonata) 5-10 mg; and eszopiclone (Lunesta) 2-3 mg QHS.
 - These newer hypnotic agents are benzodiazepine receptor agonists with shorter half-lives than benzodiazepines and may be less likely to result in day-after drowsiness. They may have decreased addiction potential compared with benzodiazepine hypnotics. Higher doses and extended-release formulations appear to increase the risk of next-morning impairment. Patients should be advised to use these hypnotics on an as-needed basis rather than nightly; it is easier for patients to discontinue a drug that they are not taking every day. The inhibition of CYP 3A4 enzyme activity by PIs or cobicistat may increase levels of these benzodiazepine receptor agonists, particularly eszopiclone; this may cause excessive sedation or respiratory depression.

Melatonin agonists

- Ramelteon (Rozerem), 8 mg QHS.
 - The first of a new class of melatonin agonists to receive FDA approval, ramelteon may have some advantages over sedative/hypnotic agents, such as reduced dependence and overuse. However, it may have severe adverse reactions, including hypersensitivity reactions such as anaphylaxis and angioedema. Long-term interactions with ARV agents are unknown.

Benzodiazepine hypnotics

- A number of benzodiazepines have FDA-approved indications for the short-term treatment of insomnia. They carry a risk of addiction and residual drowsiness the following day.
- Metabolized by glucuronidation; predicted to have few drug interactions with ARVs:
 - Temazepam (Restoril) 7.5-30 mg; intermediate half-life
 - Lorazepam (Ativan), 1-2 mg; intermediate half-life.
- Metabolized by CYP 3A4; PIs and cobicistat may prolong their duration, resulting in excessive daytime somnolence. These may be most beneficial for use with patients whose insomnia is associated with anxiety:
 - Flurazepam (Dalmane) 15-30 mg
 - Quazepam (Doral) 7.5-15 mg
 - Estazolam (ProSom) 1-2 mg
- Clonazepam (Klonopin) at a dose of 0.5-2 mg has been approved for treatment of periodic leg movements. PIs and cobicistat may prolong its duration and increase risk of adverse effects; start at low dosage and titrate slowly.
- Triazolam (Halcion), another approved agent for insomnia, is contraindicated for use with all PIs, some nonnucleoside reverse transcriptase inhibitors (NNRTIs) (delavirdine, efavirenz), and cobicistat because of potentially life-threatening reactions (e.g., respiratory depression)

Agents Used for Sedating Side Effects (no FDA indication for insomnia)

Antidepressants

- Tricyclic antidepressants at doses of 10-50 mg can be beneficial for sleep, but they have longer half-lives than short-acting hypnotic agents, and potential adverse effects include cardiac dysrhythmias and pulmonary complications. Tricyclics generally should be avoided for geriatric patients. Levels of tricyclics are elevated by ritonavir and by cobicistat, and lower dosages may be needed for patients taking ritonavir or ritonavir-boosted PIs or cobicistat. Routine testing of tricyclic blood levels should be performed on patients receiving higher doses (e.g., 100 mg per day; 50 mg for nortriptyline), those concurrently on ritonavir, and those with risk factors for cardiac conduction abnormalities. A routine electrocardiogram should be performed before prescribing tricyclics, and this class of drugs should not be prescribed to patients with cardiac conduction problems. However, tricyclic antidepressants also have characteristics that may benefit some patients, including treatment of chronic pain, promotion of weight gain, and reduction of diarrhea. Amitriptyline (Elavil) and doxepin (Sinequan) are the most sedating of the tricyclic antidepressants and therefore are the drugs in this class most often used for sleep.
- The tetracyclic antidepressant mirtazapine (Remeron) is sedating and has been effective in treating insomnia at low dosages (7.5-15 mg). Higher dosages may result in increased activation owing to increased norepinephrine (NE) receptor antagonism.
- The selective serotonin reuptake inhibitor (SSRI) antidepressants are not sufficiently sedating to be used as sleeping agents, but when insomnia is caused by depression, sleep will improve as the depression lifts.

Anticonvulsants

- Gabapentin (Neurontin) can be useful for patients with insomnia and has been demonstrated to be particularly beneficial for patients with alcohol and other substance-use disorders; it is widely prescribed for neuropathic pain.

Patient Education

- Instruct patients in behavioral interventions that can help to reduce insomnia.
- Additional interventions are available when behavioral interventions are not sufficient.
- Patients should be warned strongly about risks associated with medications used to treat insomnia, including the risk of sleepwalking and other overnight activities and next-morning impairment in cognition and coordination.
- Patients should report new or worsening symptoms to their health care provider. These may be not only signs of worsening insomnia, but also of symptoms of anxiety, depression, medications, or changes in medical conditions

Oral Health

Background

Examination of the oral cavity should be included in both the initial and interim physical examination of all HIV-infected patients. Patients with lesions suspected to be oral manifestations of HIV disease should be referred to an oral health expert with experience in treating oral lesions associated with HIV/AIDS. Other oral lesions may be a sign of a systemic disease, a side effect of medications, or a result of poor oral hygiene.

The following is an overview of conditions commonly seen in patients with HIV infection. See chapters *Oral Hairy Leukoplakia*, *Oral Warts*, *Oral Ulceration*, and *Necrotizing Ulcerative Periodontitis and Gingivitis* for more information about those conditions.

HRSA HAB Performance Measures

Percentage of HIV-infected oral health patients who had a **dental and medical health history** (initial or updated) at least once in the measurement year

Percentage of HIV-infected oral health patients who had a **dental treatment plan** developed and/or updated at least once in the measurement year

Percentage of HIV-infected oral health patients who received **oral health education** at least once in the measurement year

Percentage of HIV-infected oral health patients who had a **periodontal screen or examination** at least once in the measurement year

Percentage of HIV-infected oral health patients with a **Phase 1 treatment plan** that is completed within 12 months

Xerostomia (Dry Mouth)

S: Subjective

The chief complaint may be a dry, “sticky,” or possibly a burning sensation in the mouth, or an inability to “taste” food. The patient may present with difficulty swallowing.

O: Objective

The oral mucosal tissues appear dry and sometimes “shiny” in appearance. The lips may be dry and cracked, and the tongue is dry. Dental decay may be present on the cervical portion of the teeth (near the gingival margin or “gumline”). Oral candidiasis (thrush) may or may not be present.

A: Assessment

The differential diagnosis for the cause of xerostomia includes but is not limited to medication side effects (e.g., from anticholinergics), systemic diseases (e.g., Sjögren syndrome), adverse effects of radiation therapy, and salivary gland diseases.

P: Plan

Identify the cause of xerostomia and modify, if possible. Treat with artificial saliva products or oral lubricant products (e.g., Salivart, Biotene Oral Balance Dry Mouth Relief Moisturizing Gel, TheraSpray). Discourage sucking on hard candies with sugar that can promote caries (dental decay). Encourage patients to use sugar-free gums and candies to help promote salivary function. Promote good oral hygiene with flossing and brushing with a fluoride

toothpaste, and encourage regular (every 3-4 months) dental recall visits. Severe cases of xerostomia may be treated by prescribing cholinergic stimulants such as pilocarpine (Salagen).

Burning Mouth Syndrome; Atrophic Glossitis

S: Subjective

The patient may complain of a constant burning sensation in the mouth or a numbness or tingling feeling of the tongue. Eating certain foods or spices may trigger the burning sensation. The patient also may complain of dry mouth or a metallic taste in the mouth.

O: Objective

The tongue and oral mucosal tissues may be normal in appearance or there may be a slight redness on the tip and lateral margins of the tongue. In other cases, the tongue may appear “bald,” owing to the loss of papillae on the dorsal surface, and it may be “beef red” in color.

A: Assessment

Possible systemic etiologies include nutritional and vitamin deficiencies (atrophic glossitis), chronic alcoholism, medication adverse effects, diabetes mellitus, and gastric reflux. Local etiologies include denture irritation, oral habits such as tongue or cheek biting, and excessive use of certain toothpastes or mouthwashes. Psychological factors and nerve damage also may cause burning mouth. Erythematous candidiasis also can present as a burning sensation.

P: Plan

Identify the cause of the burning sensation, if possible, by review of the medical history and by performing diagnostic tests as indicated (e.g., complete blood count, biopsy, or oral cytological smears). Once the underlying cause is identified, treatment may be as simple as changing a dentifrice or eliminating the identified irritant, or the condition may require systemic treatment.

Recurrent Aphthous Ulceration (RAU)

S: Subjective

The patient complains of a painful ulcer or ulcers in the mouth that recur.

O: Objective

The typical appearance of an aphthous ulcer is a “red raised border with a depressed, necrotic (white-to-yellow pseudomembrane) center.” Aphthous ulcers tend to present on nonkeratinized or nonfixed tissues such as the buccal mucosa or posterior oropharynx and may be small or large, solitary or in clusters, and can resemble intraoral herpetic lesions (although herpetic lesions tend to present on keratinized tissues such as the roof of the mouth and gingival tissues).

A: Assessment

The differential diagnosis includes traumatic ulcers and herpes simplex virus ulcers.

P: Plan

The diagnosis usually is based on appearance. For further information, see chapter *Oral Ulceration*.

Recurrent Herpes Simplex

S: Subjective

The patient complains of a locally painful ulcer or ulcers on the lips or intraoral areas.

O: Objective

Herpes lesions are located on the lips, gingival tissues, or the hard palate. They may appear as small vesicular lesions that rupture, forming small ulcers. They may rupture and coalesce into larger lesions.

A: Assessment

The differential diagnosis includes aphthous ulcer and traumatic ulcer.

P: Plan

The diagnosis usually is based on appearance. For further information, see chapters *Oral Ulceration* and *Herpes Simplex, Mucocutaneous*.

Periodontal Disease

The medical evaluation of patients with HIV infection should include assessment of periodontal health. Whereas the same type of plaque-induced periodontal diseases can be seen in both immunocompetent and immunosuppressed individuals, periodontal disease in HIV-infected patients can be a marker of HIV disease progression. In the HIV-infected patient with periodontal disease, it is important to distinguish whether the periodontitis represents an acute/aggressive or chronic presentation unique to those with HIV disease. In addition, it is important to determine whether the patient has an inflammatory oral disease process that may further compromise his or her health.

Various illnesses and systemic factors (e.g., diabetes mellitus, hormonal abnormalities, medications, and malnutrition) can complicate the clinical presentation of periodontal disease. If significant periodontal disease is suspected, refer to an experienced dentist for diagnosis and treatment. Gingivitis (gum disease), a milder form of periodontal disease, usually is reversible with proper professional and home oral health care. For further information on necrotizing ulcerative periodontitis or necrotizing ulcerative gingivitis, see chapter *Necrotizing Ulcerative Periodontitis and Gingivitis*.

S: Subjective

The patient may complain of red, swollen, or painful gums, which may bleed spontaneously or with brushing; chronic bad breath or bad taste in the mouth; loose teeth or teeth that are separating; or a “bite” that feels abnormal.

O: Objective

Examine the gingival tissues. Periodontitis appears as localized or generalized gingival inflammation. The gingivae appear bright red or reddish-purple, ulcerated, or necrotic. Spontaneous gingival hemorrhage and purulent discharge may be evident around the teeth, especially if pressure is applied to the gingivae. Gingiva may be pulling away from the teeth. Fetor oris may be present.

A: Assessment

The differential diagnosis includes gingivitis, periodontitis, trench mouth, and oral abscesses. Diagnosis usually is based on appearance. Patients with severe or recalcitrant disease should be referred to an oral health care provider for definitive diagnosis and treatment.

P: Plan

Treatment may include:

- Warm saline rinses
- Daily brushing and flossing
- Antimicrobial mouth rinse (e.g., Listerine, chlorhexidine)
- Antibiotic therapy

For further information, see chapter *Necrotizing Ulcerative Periodontitis and Gingivitis*.

Dental Caries Caused by Methamphetamine and Cocaine Use

Dental decay seen in individuals who smoke methamphetamine or crack cocaine, or use cocaine orally, often is referred to as “meth mouth.”

S: Subjective

The chief complaint may be pain in one or more teeth. However, if the condition is chronic, the patient may not complain of pain.

O: Objective

In meth mouth, the enamel on all teeth or multiple teeth is grayish-brown to black in color (owing to decay), and appears “soft” (this has been described as a “texture less like that of hard enamel and more like that of a piece of ripened fruit”). Oral mucosal tissues appear dry as a result of decreased salivary flow. The gingiva appears red or inflamed, and there may be spontaneous bleeding of the gingiva around the teeth.

Another pattern of dental decay can be seen in cocaine users who rub the drug along the gingiva in order to test its strength or purity. This can lead to localized dryness of the gingival tissues. Consequently, plaque sticks to the cervical portion of the teeth in the area where the cocaine is rubbed, resulting in dental caries along the cervical portion of the teeth.

A: Assessment

The differential diagnosis includes other causes of caries.

P: Plan

Refer to a dentist for appropriate care, which may involve restorative, endodontic therapy, periodontal care, and oral surgery. In severe cases, extraction of the involved teeth and replacement with a partial or complete denture may be necessary. Encourage proper oral hygiene; evaluate sucrose intake.

Oral Cancer

S: Subjective

Oral malignancies may be symptomatic or asymptomatic. Data suggest two distinct pathways for the development of oropharyngeal cancer: one driven predominantly by the carcinogenic effects of tobacco or alcohol (or both), the other by genomic instability induced by human papillomavirus.

The patient may complain of a mouth sore that fails to heal or that bleeds easily, or a persistent white or red (or mixed) patch. The patient may note a lump, thickening, or soreness in the mouth, throat, or tongue; difficulty chewing or swallowing food; difficulty moving the jaw or tongue; chronic hoarseness; numbness of the tongue or other areas of the mouth; or a swelling of the jaw, causing dentures to fit poorly or become uncomfortable.

O: Objective

Perform a thorough evaluation of the oropharynx, as well as lymph nodes in the head and neck. Suspicious lesions may occur on the lips, tongue, floor of the mouth, palate, gingiva, or oral mucosa, and may appear as an ulcer or a soft-tissue mass or masses that can be pink, reddish, purple, white, or mixed red and white. The lesion typically is indurated and may be painful. It may enlarge rapidly between examinations.

A: Assessment

The differential diagnosis includes oral squamous cell carcinoma, lymphoma, Kaposi sarcoma, traumatic ulcer, hyperplasia, and hyperkeratosis.

P: Plan

An ulcerated lesion or symptom described above that is present for 2 weeks or longer should be evaluated promptly by a dentist or physician. If cancer is suspected, a biopsy should be obtained to make a definitive diagnosis. Treatment will be based on the specific diagnosis.

Bruxism**S: Subjective**

The patient may complain of chronic facial or jaw pain, sensitive teeth, earache, or waking up with a headache or facial pain. Often, the patient is not aware that he or she is clenching or grinding the teeth. Bruxism very often is a result of increased stress or anxiety, causing the patient consciously or unconsciously to clench or grind the teeth. However, some people may be “nighttime bruxers” and grind their teeth while sleeping, often loudly enough to wake others sleeping in the same room.

O: Objective

Perform a focused evaluation of the oropharynx, jaw, and facial muscles. The teeth may appear shortened, flattened, or worn down as a result of chronic grinding or clenching of the teeth. There may be hyperkeratotic lesions on the inside of cheeks as a result of chronic grinding or biting. There may be tenderness with palpation of facial muscles.

A: Assessment

The differential diagnosis includes other causes of facial or jaw pain, such as caries, dental abscesses, and trauma.

P: Plan

Refer the patient to a dentist for treatment. Treatment may include wearing a bite guard or psychological or behavioral management therapy.

Oral Piercing**S/O/A: Subjective/Objective/
Assessment**

Jewelry worn in piercings in the tongue, lips, or cheeks can chip or fracture the teeth. Chronic rubbing of jewelry against the gingiva can cause the gingiva to recede, leading to periodontal problems. (These complications occur apart from procedure- or technique-associated complications associated with body piercing, such as inflammation and infection, bleeding, and transmission of bloodborne pathogens.)

P: Plan

Refer the patient to a dentist for treatment. Recommend plastic tongue jewelry as opposed to metal to prevent fracture of teeth. Removal of the jewelry may be warranted.

Maxillary Tori; Mandibular Tori

S: Subjective

The patient may complain of a “lump” in the roof or floor of the mouth, or behind the lower front teeth.

O: Objective

Exostosis of normal bone (covered by oral mucosal tissue) can appear as a nodular or lobulated protuberance centrally located on the hard palate (maxillary tori) or unilaterally or bilaterally located behind the mandibular incisors (mandibular tori). This develops slowly and the patient may become aware of exophytic growth only if the area is inadvertently traumatized.

A: Assessment

Differential diagnosis includes other benign or malignant lesions, including oral cancer.

P: Plan

No treatment is indicated unless the exostosis interferes with speech or swallowing, or removal is needed for fabrication of dentures or a partial denture. Tori are a variation of normal anatomy.

Oral Ulceration

Background

Oral ulcerations appear as necrotic or eroded areas on the oral mucosa, including the tongue. Most such lesions are idiopathic (aphthous) or of viral etiology (e.g., herpes simplex virus [HSV]; rarely herpes zoster [VZV]). Oral ulcerations may be caused by fungal, parasitic, or bacteriologic pathogens; malignancy; or other systemic processes. This chapter will focus on herpetic and aphthous ulcers.

Herpetic ulcerations tend to appear on keratinized tissues such as the hard palate or gingiva. Recurrent aphthous ulcers tend to manifest on nonkeratinized tissues such as buccal mucosa, soft palate, and lingual (bottom) surface of the tongue, and, by definition, recur.

S: Subjective

The patient complains of painful ulcerated areas in mouth. He or she may have difficulty eating, drinking, swallowing, or opening the mouth, and may complain of sore throat.

Inquire about previous occurrences of oral ulcerative disease as well as ulcerative gastrointestinal diseases, including HSV, cytomegalovirus (CMV), or histoplasmosis. Ask about recent sexual exposures. Inquire about recent trauma or burns. Note current medications and any recent changes in medications; obtain history of tobacco (smoked and chewed) and alcohol use.

O: Objective

Look for red or white-bordered erosions or ulcerations varying in size from 1 mm to 2 cm on the buccal mucosa, oropharynx, tongue, lips, gingiva, and hard or soft palate. Lesions caused by HSV tend to be shallow and occur on keratinized tissues. HSV lesions may appear as clusters of vesicles that may coalesce into ulcerations with scalloped borders. Aphthous ulcers present with a white or gray pseudomembrane surrounded by a halo of inflammation.

A: Assessment

Rule out syphilis and other suspected pathogens as well as trauma, seizure, and other physical injury.

P: Plan

Diagnostic Evaluation

The diagnosis of HSV and aphthous ulcers usually is made on the basis of characteristic lesions. Location, duration, and recurrence are key elements in determining the nature of the oral ulcer. As mentioned previously, HSV-related ulcers most often present on keratinized fixed tissues; aphthous ulcers appear on nonfixed tissues such as buccal mucosa, and have a tendency to recur. Check the absolute neutrophil count (ANC), as a low count (<500 cells/ μ L) may be associated with nonresponsive ulcerative disease. If diagnosis is uncertain, it is possible to perform HSV culture or polymerase chain reaction (PCR) testing on oral ulcerations that appear on keratinized tissues or the dorsal and lateral surfaces of the tongue, scraping near the margin of the lesion or unroofing a fresh vesicle, if available, and scraping the base. The sensitivity of HSV testing decreases when collections are taken from older, resolving herpetic areas; herpetic lesions >72 hours old usually will not yield a positive culture.

If other diagnoses are suspected, perform culture or biopsy as indicated. Also perform biopsy for ulcers that do not respond to therapy (in nonneutropenic patients).

Note that syphilis is very common among some HIV-infected populations. For patients in whom primary syphilis (manifested by an oral chancre) is suspected, perform (or refer for) darkfield examination; check Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) results (note that VDRL or RPR results may be negative in primary syphilis); see chapter *Syphilis* for further information. It is worth noting that, whereas chancres are described as painless, open sores in the mouth usually are associated with some degree of pain.

Treatment

If HSV culture is positive, or if HSV is strongly suspected owing to the appearance of the lesions or the patient's history, treat with HSV antiviral medication (e.g., valacyclovir, famciclovir, or acyclovir) while waiting for results of culture. Do not use topical steroids without a concomitant oral HSV antiviral if the lesion is of possible herpetic etiology. Refer to chapter *Herpes Simplex, Mucocutaneous* for more information regarding management and treatment of HSV lesions.

Recalcitrant minor aphthous ulcerations should be treated with topical corticosteroids (e.g., fluocinonide 0.05% or clobetasol 0.05% ointments mixed 1:1 with Orabase). For multiple small lesions or lesions in areas where topical ointments are difficult to apply, consider dexamethasone elixir (0.5 mg/5 mL); the patient is to rinse TID with 5 mL for 1 minute, then expectorate. As with all oral topical steroids, patients should not drink or eat for 30 minutes after rinsing. Continue treatment for 1 week or until lesions resolve.

In some cases, recurrent aphthous ulcers may respond to one of the various “magic mouthwashes” that contain combinations of antibiotic, antifungal, corticosteroid, antihistamine, and anesthetic medication. The inclusion of an antihistamine (e.g., diphenhydramine) or an anesthetic (e.g., lidocaine) may be helpful in treating pain associated with these ulcers.

For large or extensive aphthous ulcers, systemic corticosteroids may be needed: prednisone 40–60 mg PO daily for 1 week followed by a taper should prove beneficial. If this is ineffective, refer for biopsy to rule out CMV, other infection, or neoplastic disease.

For patients with major oral aphthous ulcers that are recalcitrant to other therapies, thalidomide 200 mg daily for 2 weeks may be considered. Thalidomide is teratogenic and should not be used for women of childbearing potential without thorough patient education and two concomitant methods of birth control. Consult with an expert.

Pain control may be needed in order for the patient to maintain food intake and prevent weight loss. Most of the topical treatments noted above will ease pain as well as treat the ulcer. Additional considerations for pain control include the following:

- **Oral anesthetics:** Various products are available, including gels (e.g., Gelclair, an adherent oral rinse that acts as an oral bandage), viscous liquids, and sprays (e.g., benzocaine, lidocaine). These may be applied topically or swished and expectorated. They will provide temporary relief, but may lead to a temporary loss of taste sensation.
- **Systemic:** If topical treatments are inadequate, consider systemic analgesics (e.g., nonsteroidal antiinflammatory drugs or opiates). Refer to chapter *Pain Syndrome and Peripheral Neuropathy*.

Assess nutritional status and consider adding liquid food supplements, if indicated. Suggest soft, nonspicy, or salty foods if the ulcer is interfering with food intake. Refer to a registered dietitian if client is experiencing pain, problems eating, or weight loss.

Refer to an oral health specialist or an HIV-experienced dentist as needed.

Patient Education

- Advise patients to report any oral pain or difficulty swallowing to their health care provider.
- Instruct patients in the application of topical ointments, and indicate that they may require assistance if the lesion is difficult for them to see on their own.
- It is important for patients to maintain good nutrition and food intake while their oral ulcers heal. Advise them to eat soft, bland foods, and refer to a nutritionist if they have difficulty.
- Antiretroviral therapy should be initiated or optimized to improve immune function in patients with recurrent aphthous ulcers.

Oral Warts

Background

Oral warts are caused by human papillomavirus (HPV) and may appear anywhere within the oral cavity or on the lips. They occur more frequently and more extensively in people with HIV infection than in those with normal immune function, especially in patients with advancing immune suppression (CD4 counts of <200 - 300 cells/ μ L). Oral warts may be refractory to therapy. The frequency of oral warts may increase, at least temporarily, in patients treated with antiretroviral therapy.

It should be noted that HPV infection is strongly associated with oropharyngeal cancer among subjects with or without the established risk factors of tobacco and alcohol use, although oral warts normally are not caused by the HPV types that are associated with oncogenic changes. One analysis of stored samples suggests that the percentage of all oropharyngeal cancers that are HPV-positive has increased from about 20% to 60% since about 1980. Researchers also have reported that HPV-related oral cancers were among the most responsive to chemotherapy and radiation.

S: Subjective

The patient notices raised lesions in the mouth or on the lips. Warts are not painful unless they have been traumatized.

O: Objective

Examine the oral cavity carefully for abnormalities. Wart lesions may vary in appearance from smooth, small, and slightly raised lesions to cauliflower-like or spiked masses with prominent folds or projections. They may be single or multiple.

Review recent CD4 counts. In patients with oral warts, the CD4 count usually is <300 cells/ μ L.

A: Assessment

A partial differential diagnosis includes: squamous cell carcinoma, lichen planus, and traumatic hyperkeratinized areas resulting from cheek biting or tongue thrusting.

P: Plan

Diagnostic Evaluation

- The diagnosis of oral warts usually is based on the appearance of the lesions. If lesions are unusual in appearance, are ulcerated, or have grown rapidly, perform biopsy to rule out cancer. If there is suspicion of other causes, perform other diagnostic evaluations as indicated.
- HPV may be demonstrated with electron microscopy or in situ hybridization; this testing is not routinely required.
- Observation of these lesions is important because of the potential, however minimal, for development of squamous cell carcinoma.

Treatment

- Treatment is difficult, as these lesions tend to recur. Treatment options include cryosurgery and surgical or laser excision. Care must be taken when using laser excision, as HPV can survive in an aerosol. Extraoral lesions (lip or corner of mouth) may be treated with topical agents such as podofilox topical solution (Condylox) or fluorouracil 5% topical (Efudex). Imiquimod 5% cream (Aldara) may help to prevent recurrence once the lesions have resolved.
- Refer to an oral health specialist or dentist for treatment.

Patient Education

- Instruct patients to comply with regular dental and medical care regimens.
- Instruct patients to use medications exactly as prescribed.

Oral Hairy Leukoplakia

Background

Oral hairy leukoplakia (OHL) is an oral infection caused by Epstein-Barr virus (EBV). It appears as white corrugated lesions (sometimes “hairy” in appearance) primarily on the lateral aspects of the tongue. The infection may spread across the entire dorsal surface onto the ventral surface of the tongue, and occasionally may be found on buccal mucosa. It is common in people with HIV infection, particularly in those with advanced immunosuppression (CD4 count <200 cells/ μ L), and may serve as a marker of HIV.

S: Subjective

The patient notices new, white lesions on the tongue that cannot be wiped off or removed by scraping or brushing. The OHL lesions usually are asymptomatic, but occasionally may cause alteration in taste, discomfort, or other symptoms.

O: Objective

Perform a focused examination of the oropharynx. OHL appears as unilateral or bilateral white plaques or papillary lesions on the lateral, dorsal, or ventral surfaces of the tongue or on buccal mucosa. The lesions may vary in appearance from smooth, flat, small lesions to irregular, “hairy” or “verrucous” lesions with prominent vertical folds or projections.

A: Assessment

A partial differential diagnosis for OHL includes:

- Oral candidiasis
- Squamous cell carcinoma
- Geographic tongue
- Lichen planus
- Smoker’s leukoplakia
- Epithelial dysplasia
- White sponge nevus
- Irritation leukoplakia

P: Plan

Diagnostic Evaluation

A presumptive diagnosis of OHL usually is made on the basis of the clinical appearance of the lesions. OHL often is confused with candidiasis; the diagnosis of OHL should be considered for lesions that do not wipe away, as would be the case for pseudomembranous candidiasis. Definitive diagnosis of OHL requires biopsy and demonstration of EBV.

- Perform biopsy of lesions only if they are ulcerated or unusual in appearance, to distinguish OHL from cancer or other causes.

Treatment

- Because OHL usually is asymptomatic, specific treatment generally is not necessary.
- Immune system reconstitution through antiretroviral therapy will resolve OHL; encourage initiation of HIV treatment if the patient is not yet on antiretroviral therapy.
- If specific treatment is required, the following options may be considered. Relapse is common after discontinuation of treatment.
 - Acyclovir 800 mg PO 5 times per day for 2 weeks; famciclovir and valacyclovir may be considered.
 - Topical tretinoin (Retin-A) 0.025-0.05% solution, podophyllin 25% in tincture of benzoin, and other treatments also have been used.

- For relapse of severe OHL, consider maintenance therapy with high-dose acyclovir, famciclovir, or valacyclovir.
- For severe symptomatic cases, surgical treatment (e.g., cryosurgery, excision) may provide temporary resolution.
- Candidiasis may be present concurrently; treat candidiasis if it is present (see chapter *Candidiasis, Oral and Esophageal*).

Patient Education

- Advise patients that OHL rarely is a problem in itself, but may be a marker of HIV progression.
- Encourage patients to start antiretroviral therapy.
- Advise patients to contact their care providers if new symptoms develop.
- Instruct patients to comply with regular dental and medical care regimens.

Necrotizing Ulcerative Periodontitis and Gingivitis

Background

Necrotizing ulcerating periodontitis (NUP) is a marker of severe immunosuppression that affects gingival tissues (gums) and extends to the underlying bone or periodontium. It may or may not be distinct from necrotizing ulcerative gingivitis (NUG), which is considered to be confined to the gingiva. This discussion will focus primarily on NUP, but the microbial profiles and treatment recommendations for these two periodontal diseases are similar.

NUP in HIV-infected individuals is believed to be an endogenous infection that progresses to necrosis of the gingiva. Pathogens may include anaerobic bacteria and fungi. NUP usually presents as “blunting” or ulceration of the interdental papillae, but rapidly progresses to destruction of underlying alveolar bone. It usually is associated with severe pain and spontaneous bleeding. Several case reports have described extensive destruction leading to exfoliation of teeth within 3-6 months of onset, with sequestration of necrotic alveolar bone and necrotic involvement of the adjacent mandible and maxilla. Patients may present with concomitant malnutrition resulting from inability to take food by mouth. The prevalence of NUP in the HIV-infected population has been reported as 0-5%. NUP is the most serious form of periodontal disease associated with HIV.

S: Subjective

The patient complains of painful, spontaneously bleeding gums, diminished or metallic taste, bad breath, or loose teeth (with a prevalence toward anterior teeth and first molars). “Deep jaw pain” is a common complaint and may reflect extension to adjacent mucosa.

O: Objective

Examine the oral cavity carefully. NUP and NUG present with fiery red, ulcerated gingival tissues, and grayish exudate. Teeth may be very loose or missing and there will be a fetid odor from the mouth. The ulcerated tissues can extend past the attached gingiva to the adjacent mucosa. Necrosis of adjacent bone also is common.

A: Assessment

The differential diagnosis includes other causes of gingival ulceration, such as herpes simplex

virus, herpes zoster, and cytomegalovirus. (See relevant chapters on these conditions.)

P: Plan Treatment

Treatment usually is divided into the acute phase and the maintenance phase. The primary concern in the acute phase is pain control. For the maintenance phase, treatment is directed toward reducing the burden of potential pathogens, preventing further tissue destruction, and promoting healing.

- For uncomplicated NUP or NUG, the primary care provider should prescribe an antimicrobial rinse (see below), antibiotic therapy (see below), medications for pain management, and nutritional supplementation; the patient should be referred to a dental health care professional.
- Chlorhexidine gluconate rinse (0.12%) twice daily after brushing and flossing (an alcohol-free preparation is preferred).

- Antibiotic therapy (preferably narrow spectrum, to leave gram-positive aerobic flora unperturbed).
- Metronidazole is the drug of choice, 500 mg PO BID for 7-10 days.
- If the patient cannot tolerate metronidazole: clindamycin 150 mg QID or amoxicillin-clavulanate (Augmentin) 875 mg PO BID for 7-10 days, if no hypersensitivity or allergy to either drug exists.
- Refer to a dentist for the following:
 - Removal of plaque and debris from the site of infection and inflammation.
 - Debridement of necrotic hard and soft tissues, with a 0.12% chlorhexidine gluconate or povidone-iodine lavage.
 - Regular deep cleaning.

Patient Education

- Advise the patient of the following: Good oral hygiene is critical for arresting gingival infection and tooth loss. Avoid smoking and try to eliminate emotional stress. When primary stabilization is achieved, resume daily brushing and flossing after every meal. This may be difficult during the acute phase, but it is very important to keep the mouth as clean as possible. Nutrition education and supplements (liquid diet, plus vitamins/minerals) are recommended.
- Frequent professional cleaning (every 3 months) may be needed during the maintenance phase.
- Patients taking metronidazole should not drink alcohol for at least 24-48 hours after taking the last dose, in order to avoid severe nausea and vomiting from a disulfiram-like reaction.
- Instruct patients not to drink or eat for 30 minutes after rinsing with chlorhexidine.

- HIV (and hepatitis C) may (rarely) be transmitted from bleeding gums during “deep kissing” or other activities (oral-genital contact). Advise patients/clients to avoid exposing partners to HIV by taking all necessary precautions, including abstinence from risky activities until this condition is healed and stable (no oozing of oral fluids).

Web-Based Resources

Background

The care and management of HIV-infected patients is a rapidly evolving field. Keeping up to date with clinical information about HIV care has in the past required attendance at national and international conferences. With the increasing availability of the Internet, clinicians and patients are able to access the most current advances through Web coverage, without requiring travel or time away from work.

The challenge of using Internet resources is in determining which websites are accurate and current. Check for dates of authorship, the credentials of the site sponsors and authors, and how well supported any recommendations or analysis may be. Be aware of any possible commercial bias. Finally, it is important to remember that information on these sites does not replace clinical judgment or consultation with HIV experts.

Listed below is a selection of useful and accurate Internet sites. Many of these websites also link out to additional information resources, and many allow users to subscribe to receive updates via email. Many providers find it helpful to review sites geared toward patients, in order to maintain familiarity with patients' concerns and patient-based information resources.

Resources for Clinicians

- **AIDSInfo** (aidsinfo.nih.gov)
Official repository for HIV/AIDS information from the U.S. Public Health Service. Content includes national clinical trial information, drug and vaccine overviews, fact sheets for patients, and a clinical guidelines portal that includes the following:
 - Adult and Adolescent ARV Guidelines
 - Adult and Adolescent OI Prevention and Treatment Guidelines
 - Perinatal Guidelines
 - Pediatric ARV Guidelines
 - Pediatric OI Prevention and Treatment Guidelines
 - Guidelines on Care for HIV-Infected Residents Displaced from Disaster Areas
 - Preexposure Prophylaxis (PrEP) Guidelines
 - Occupational Postexposure Prophylaxis (PEP) Guidelines
 - Nonoccupational Postexposure Prophylaxis (nPEP) Guidelines
 - Recommendations for Hormonal Contraception
 - HIV Counseling, Testing, and Referral Guidelines
 - Guidelines on Incorporating HIV Prevention into Medical Care
- **TARGET Center** (careacttarget.org)
The central source of Ryan White training and technical assistance, including clinical care resources funded by HRSA's HIV/AIDS Bureau.
- **AIDS Education and Training Centers National Resource Center** (www.aidsetc.org)
Clinical training resources, including curricula, self-study, and slide sets, including slides for all national guidelines.

- **National HIV/AIDS Clinicians' Consultation Center** (www.nccc.ucsf.edu)
An AIDS Education and Training Centers clinical resource for health care professionals, with contact information for the Warmline, PEpline, and Perinatal HIV Hotline.
- **Aidsmap** (www.aidsmap.com)
London-based HIV/AIDS news and treatment information site. Patient information is written at both lower and higher literacy levels. International focus.
- **Clinical Care Options for HIV** (clinicaloptions.com)
Continuing Medical Education (CME) materials related to HIV/AIDS, including conference reviews.
- **HIV InSite** (hivinsite.ucsf.edu)
Major HIV/AIDS portal from the University of California San Francisco. Includes *HIV InSite Knowledge Base*, updated ARV information, including an ARV interactions database, global country profiles, and links out to other useful sites.
- **HIV Drug Resistance Database** (hivdb.stanford.edu)
Information on resistance mutations to antiretroviral medications from Stanford University.
- **HIV Web Study** (depts.washington.edu/hiv aids)
Northwest AETC, University of Washington. Dozens of online clinical cases featuring downloadable tables, charts, and images.
- **International Training and Education Center on HIV** (www.go2itech.org)
The international AETC. Website features extensive database of international HIV/AIDS training materials.
- **International Antiviral Society-USA** (www.iasusa.org)
ARV resistance mutations charts and "Cases on the Web" online CME courses.
- **Journal Watch: HIV/AIDS Clinical Care** (www.jwatch.org/hiv-aids-clinical-care)
From the publishers of the New England Journal of Medicine, Journal Watch features updates and analysis online or via a weekly email newsletter.
- **Medscape HIV/AIDS Topic Area** (www.medscape.com/hiv?src=pdown)
CME materials related to HIV/AIDS, including conference coverage, news, and special features.
- **VA National HIV/AIDS Program** (www.hiv.va.gov)
Comprehensive information portal for providers. Also has a section for veterans and patients.
- **Women, Children, and HIV** (www.womenchildrenhiv.org)
Expert-selected, evidence-based information on prevention of mother-to-child transmission of HIV, care of women and children with HIV, and related topics.

Resources for Patients and the Community

- **AIDS.gov** (aids.gov)
AIDS.gov provides access to Federal HIV/AIDS information through a variety of new media channels, and supports the use of new media tools by Federal and community partners to improve domestic HIV programs serving minority and other communities most at-risk of, or living with, HIV.
- **AIDS.org** (www.aids.org)
Online home of AIDS Treatment News.
- **AIDS InfoNet** (www.aidsinfonet.org)
Comprehensive collection of fact sheets on clinical topics, available in English and Spanish, in print-friendly and downloadable formats. Regularly updated.
- **AIDSmeds** (aidsmeds.com)
Information regarding HIV-related medications for patients, including drug interactions calculator.
- **AIDS Project Los Angeles** (www.apla.org)
Fact sheets, newsletters, and program information. Some information in Spanish.
- **The Body** (www.thebody.com)
Major HIV information resource geared toward patients and the community.
- **Gay Men's Health Crisis** (www.gmhc.org)
Patient and program information from one of the oldest community organizations. Some information in Spanish.
- **Project Inform** (www.projectinform.org)
Comprehensive information and advocacy information geared toward individuals infected and affected by HIV.
- **San Francisco AIDS Foundation** (www.sfaf.org)
AIDS 101, BETA treatment newsletter, and prevention and program information. Some information in Spanish.
- **The Well Project** (www.thewellproject.org/en_US)
Health resources for women diagnosed with HIV and AIDS.

Sulfa Desensitization

Background

Trimethoprim-sulfamethoxazole (TMP-SMX), also known as Septra, Bactrim, and cotrimoxazole, is a key antibiotic for prophylaxis and treatment of several HIV-related illnesses. It is the most effective prophylaxis and the first-line treatment for *Pneumocystis jiroveci* pneumonia (PCP). In addition, it is effective in preventing toxoplasmosis encephalitis in severely immunocompromised patients who have evidence of previous exposure (see chapter *Opportunistic Infection Prophylaxis*), and it is effective against certain bacterial infections. TMP-SMX is quite inexpensive, which is a rarity in the field of HIV treatment. Because of its effectiveness and availability, it is used widely throughout the world. However, adverse reactions to TMP-SMX and other sulfa drugs occur in a high proportion of HIV-infected patients (roughly 25%), and such reactions may limit treatment options.

Desensitization to TMP-SMX should be considered when there are no reasonable or available alternatives and the patient has not experienced severe reactions (e.g., Stevens-Johnson syndrome or toxic epidermal necrolysis) to sulfa drugs. Several methods of desensitizing patients with previous reactions to TMP-SMX have been tried. These methods vary in starting dosage and length of dosage escalation, but success rates are around 80% in most cases and may be higher in patients with CD4 counts of <200 cells/ μ L.

S: Subjective

The patient reports a previous adverse reaction to sulfa drugs, such as erythema, pruritus, or rash. The patient has no history of anaphylaxis, Stevens-Johnson syndrome, or toxic epidermal necrolysis, and no reaction involving vesiculation, desquamation, ulceration, exfoliative dermatitis, etc.

O: Objective

CD4 count <200 cells/ μ L, or other important indication for TMP-SMX.

A: Assessment

Reaction to sulfa, possibly reversible with desensitization protocol.

P: Plan

Begin 9- to 13-day desensitization protocol, starting with pediatric oral suspension, which contains 40 mg of TMP and 200 mg of SMX per 5 mL (1 teaspoon). Gradually increase the dosage according to the protocol.

If there is any concern about the severity of a previous reaction, have the patient take the initial morning dose in the clinic so that the patient may be monitored for 3-4 hours before going home. (This assumes that emergency treatment, including IV access materials, IV fluids, epinephrine, antihistamines, and steroids, are readily available.)

Many experts recommend treatment with an antihistamine medication starting 1 day before initiation of the desensitization regimen and continuing daily until the dosage escalation is completed.

More rapid desensitization protocols are available (see “References,” below) for patients urgently needing treatment with TMP-SMX.

Desensitization Regimen

Use commercially available pediatric suspension (containing TMP 8 mg and SMX 40 mg per mL [40 mg/200 mg per 5 mL]), followed by double-strength tablets, as follows:

Table 1. Sulfa Desensitization Regimen

Days	Dosage (TMP/SMX)	Volume or Tablet
1-3	8 mg/40 mg	1 mL
4-6	16 mg/80 mg	2 mL
7-9	40 mg/200 mg	5 mL (or 1/2 single-strength tablet)
9-12	80 mg/400 mg	1/2 double-strength tablet (or 1 single-strength tablet)
13 and thereafter	160 mg/800 mg	1 double-strength tablet
Note: These day ranges are approximate; patients can be advanced more quickly or more slowly, depending on their reactions to the dosages. In the event of mild reaction: If the patient experiences a mild reaction or itching (i.e., mild morbilliform rash without fever, systemic symptoms, or mucosal involvement), the dosage can be reduced to the last tolerated step or continued at the same dosage for an additional day, while simultaneously treating the rash or reaction. Antihistamines or antipyretics may be used to treat symptoms of mild reactions. If the reaction diminishes, the patient may advance to the next dosage (consider more gradual increase of dosages); if the reaction worsens or if systemic symptoms develop, TMP-SMX should be discontinued. In the event of severe reaction: The desensitization regimen should be discontinued and the patient should be treated appropriately for the reaction.		

Patient Education

For home desensitization regimen

- Explain the benefits of using TMP-SMX. Be sure the patient understands and is able to follow these instructions:
 - The patient should measure the dose carefully and take it each morning, followed by a glass (6-8 oz) of water. (The patient should do a demonstration, if possible, using an oral syringe that will be used for the actual measuring at home.)
- TMP-SMX can cause severe illness unless close attention is paid to any problems that may occur. It is extremely important for the patient to check his/her body temperature each afternoon. If the temperature is more than 100.5°F by mouth, the patient should stop taking the drug and contact the clinic. Note: If shaking chills occur, the body temperature should be checked as soon as the shaking stops, and the patient should contact the clinic.
- If the patient develops a rash, blisters on the skin or in the mouth, or vomiting, he or she should stop taking TMP-SMX and go the clinic or emergency room immediately. The skin should be checked each evening, and any time itching occurs.
- If mild itching or a faint rash occurs, diphenhydramine (Benadryl) 25-50 mg PO can be taken Q4H as needed. If itching or rash persists, continue with the same dosage for an additional day; the patient should contact the clinic if there are questions or concerns.
- The patient should contact the clinic for alternative dosage instructions in the event of persistent itching without rash.
- Other adverse events should be reported immediately.

For all desensitized patients

- Desensitization may be effective only as long as the allergic individual is continuously exposed to the drug. After desensitization is complete, continue with the daily dosage. If the drug is stopped (even for a few days), the entire regimen may have to be repeated, as patients may have a recurrence of the adverse reaction.

Antiretrovirals Available in the United States and Mexico

Brand and Generic Names of ARVs in the United States and Mexico

This chart was developed to facilitate continuity of care for people living with HIV who may receive care in both the United States and Mexico. Although most HIV medications are available in both countries, some are sold under different brand names.

Antirretrovirales Disponibles en los Estados Unidos		Antiretrovirals Available in Mexico	
Generic	Brand Name	Genérico	Nombre Comercial
Nucleoside/Nucleotide Analogues (NRTIs)		Inhibidores de la Transcriptasa Reversa Análogos a Nucleósidos (ITRAN)	
Abacavir*	Ziagen	Abacavir*	Ziagenavir
Didanosine*	Videx	Didanosina*	Videx
Emtricitabine	Emtriva	Emtricitabina*	Emtriva
Lamivudine*	Epivir	Lamivudina*	Epivir/3TC
Stavudine*	Zerit	Estavudina*	Zerit
Tenofovir	Viread	Tenofovir	Viread
Zidovudine*	Retrovir	Zidovudina*	Retrovir
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)		Inhibidores de la Transcriptasa Reversa No Nucleósidos (ITRNN)	
Delavirdine	Rescriptor	No disponible/not available	
Efavirenz	Sustiva	Efavirenz	Stocrin
Etravirine	Intelence	Etravirina	Etravirina
Nevirapine*	Viramune	Nevirapina*	Viramune
Rilpivirine	Edurant	No disponible/not available	
Protease Inhibitors (PIs)		Inhibidores de Proteasa (IP)	
Atazanavir	Reyataz	Atazanavir	Reyataz
Darunavir	Prezista	Darunavir*	Prezista
Fosamprenavir	Lexiva	Fosamprenavir	Telzir
Indinavir	Crixivan	Indinavir	Crixivan
Lopinavir/Ritonavir	Kaletra	Lopinavir/Ritonavir	Kaletra
Nelfinavir	Viracept	Fuera de mercado/off market	
Ritonavir	Norvir	Ritonavir	Norvir
Saquinavir (hard-gel caps)	Invirase	Saquinavir (cápsula de gel duro)	Invirase
Tipranavir	Aptivus	Tipranavir	Aptivus

Antirretrovirales Disponibles en los Estados Unidos		Antiretrovirals Available in Mexico	
Generic	Brand Name	Genérico	Nombre Comercial
Chemokine Coreceptor Antagonists		Inhibidores de Acoplamiento	
Maraviroc	Selzentry	Maraviroc	Celsentri
Fusion Inhibitors		Inhibidores de Fusion	
Enfuvirtide (T20)	Fuzeon	Enfuvirtida*	Fuzeon
Integrase Inhibitors		Inhibidores de Integrasa	
Dolutegravir	Tivicay	No disponible/not available	
Elvitegravir	**	No disponible/not available	
Raltegravir	Isentress	Raltegravir	Isentress
Fixed-Dose Combinations		Combinaciones en Tableta Única	
Efavirenz + tenofovir + emtricitabine	Atripla	Efavirenz + tenofovir + emtricitabina	Atripla
Lamivudine + zidovudine*	Combivir	Lamivudina + zidovudina	Combivir
Rilpivirine + tenofovir + emtricitabine	Complera	No disponible/not available	
Abacavir + lamivudine	Epzicom	Abacavir + lamivudina	Kivexa
Elvitegravir + cobicistat + tenofovir + emtricitabine	Stribild	No disponible/not available	
Zidovudine + lamivudine + abacavir	Trizivir	Zidovudina + lamivudina + abacavir	Trizivir
Tenofovir + emtricitabine	Truvada	Tenofovir + emtricitabina	Truvada

* Available as generic/Disponible en forma genérica

** Available only in fixed-dose combination (Stribild)

Table 5a. Antiretroviral Regimens Recommended for Treatment-Naïve Patients

Preferred Regimens (Regimens with optimal and durable efficacy, favorable tolerability and toxicity profile, and ease of use) The preferred regimens for non-pregnant patients are arranged by chronological order of FDA approval of components other than nucleosides and, thus, by duration of clinical experience.		
NNRTI-based Regimens - EFV/TDF/FTC (AI) PI-based Regimens (in alphabetical order) - ATV/r + TDF/FTC (AI) - DRV/r (once daily) + TDF/FTC (AI) INSTI-based Regimen (in order of drug approval) - RAL + TDF/FTC (AI) - EVG/COBI/TDF/FTC (AI) - DTG + ABC/3TC (AI) - DTG + TDF/FTC (AI) Preferred Regimen¹ for Pregnant Women - LPV/r (twice daily) + ZDV/3TC¹ (AI)	Comments EFV: - Teratogenic in nonhuman primates. A regimen that does not include EFV should be strongly considered in women who are planning to become pregnant or who are sexually active and not using effective contraception. TDF: - Should be used with caution in patients with renal insufficiency. ATV/r: - Should not be used in patients who require >20 mg omeprazole equivalent per day. Refer to Table 15a for dosing recommendations regarding interactions between ATV/r and acid-lowering agents.	EVG/COBI/TDF/FTC: - Should not be started in patients with an estimated CrCl <70 mL/min, and should be changed to an alternative regimen if the CrCl falls below 50 mL/min - Should not be used with other ARV drugs or with nephrotoxic drugs - COBI is a potent CYP 3A inhibitor. It can increase the concentration of other drugs metabolized by this pathway. Refer to Tables 15d and 16c for drug interaction information on concomitantly administered drugs. Once-daily LPV/r is not recommended in pregnant women.
Alternative Regimens (Regimens that are effective and tolerable but have potential disadvantages compared with preferred regimens. An alternative regimen may be the preferred regimen for some patients.)		
NNRTI-based Regimens (in alphabetical order) - EFV + ABC/3TC (BI) - RPV/TDF/FTC (BI) - RPV + ABC/3TC (BIII) PI-based Regimens (in alphabetical order) - ATV/r + ABC/3TC (BI) - DRV/r + ABC/3TC (BIII) - FPV/r (once or twice daily) + ABC/3TC or TDF/FTC (BI) - LPV/r (once or twice daily) + ABC/3TC or TDF/FTC (BI) INSTI-based Regimen - RAL + ABC/3TC (BIII)	Comments RPV: - Not recommended in patients with pretreatment HIV RNA >100,000 copies/mL - Higher rate of virologic failures reported in patients with pre-ART CD4 count of <200 cells/μL who are treated with RPV + 2 NRTIs - Contraindicated for use with protein pump inhibitors (PPIs)	ABC: - Should not be used in patients who test positive for HLA-B*5701 - Use with caution in patients with high risk of cardiovascular disease or with pretreatment HIV-RNA >100,000 copies/mL (see text)

Note: 3TC may substitute for FTC or vice versa.

¹ For more detailed recommendations on antiretroviral use in an HIV-infected pregnant woman, refer to *Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States*. Available at aidsinfo.nih.gov/guidelines. Accessed December 1, 2013.

Abbreviations:

INSTI = integrase strand transfer inhibitor
 NNRTI = non-nucleoside reverse transcriptase inhibitor
 NRTI = nucleos(t)ide reverse transcriptase inhibitor
 PI = protease inhibitor

ABC = abacavir
 ATV = atazanavir
 3TC = lamivudine
 COBI = cobicistat
 ddI = didanosine
 DRV = darunavir

DTG = dolutegravir
 EFV = efavirenz
 EVG = elvitegravir
 FPV = fosamprenavir
 FTC = emtricitabine
 LPV = lopinavir

NVP = nevirapine
 r = low dose ritonavir
 RAL = raltegravir
 SQV = saquinavir
 TDF = tenofovir
 ZDV = zidovudine

Table 5b. Other Antiretroviral Regimens for Treatment-Naive Patients

Regimens that may be selected for some patients but are less satisfactory than preferred or alternative regimens listed in Table 5a.	
NNRTI-based Regimens • EFV + ZDV/3TC • NVP + (ABC/3TC or TDF/FTC or ZDV/3TC) • RPV + ZDV/3TC PI-based Regimens • (ATV or ATV/r or DRV/r or FPV/r or LPV/r or SQV/r) + ADV/3TC • ATV + ABC/3TC • SQV/r + (ABC/3TC or TDF/FTC) INSTI-based Regimen • RAL + ZDV/3TC CCR5 Antagonist-Based Regimens • MVC + (ABC/3TC or TDF/FTC or ZDV/3TC)	Comments NVP: • Should not be used in patients with moderate to severe hepatic impairment (Child-Pugh B or C).¹ • Should not be used in women with pre-ART CD4 counts of >250 cells/μL or in men with pre-ART CD4 counts of >400 cells/μL. • Use with caution when coadministered with ABC; both NVP and ABC can cause HSR within the first few weeks after initiation of therapy. ZDV: • Can cause bone marrow suppression, myopathy, lipoatrophy, and rarely, lactic acidosis with hepatic steatosis. ATV/r: • Generally preferred over unboosted ATV. MVC • Perform tropism testing before initiation of therapy; may be considered for patients who have only CCR5-tropic virus. SQV/r: • Not recommended for patients with: • Pretreatment QT interval >450 msec • Refractory hypokalemia or hypomagnesemia • Concomitant therapy with other drugs that prolong QT interval • Complete AV block

Note: 3TC may substitute for FTC or vice versa.

¹ Refer to Appendix B, Table 7 for the criteria for Child-Pugh classification.

Abbreviations: 3TC = lamivudine; ABC = abacavir; ATV = atazanavir; ATV/r = atazanavir/ritonavir; AV = atrioventricular; COBI = cobicistat; ddl = didanosine; DRV = darunavir; DRV/r = darunavir/ritonavir; DTG = dolutegravir; ECG = electrocardiogram; EFV = efavirenz; EVG = elvitegravir; FPV = fosamprenavir; FPV/r = fosamprenavir/ritonavir; FTC = emtricitabine; INSTI = integrase strand transfer inhibitor; msec = millisecond; MVC = maraviroc; NNRTI = non-nucleoside reverse transcriptase inhibitor; NVP = nevirapine; PI = protease inhibitor; RAL = raltegravir; RTV = ritonavir; SQV = saquinavir; SQV/r = saquinavir/ritonavir; TDF = tenofovir; ZDV = zidovudine

Table 6. Advantages and Disadvantages of Antiretroviral Components Recommended as Initial Antiretroviral Therapy

ARV Agent(s)	Advantages	Disadvantages
Nonnucleoside Reverse Transcriptase Inhibitors (in alphabetical order)		
	NNRTI Class Advantages: Long half-lives	NNRTI Class Disadvantages: - Greater risk of resistance at the time of treatment failure than with PIs - Potential for cross-resistance - Skin rash - Potential for CYP450 drug interactions (see Tables 14, 15b, and 16b) - Transmitted resistance more common than with PIs
EFV	- Virologic responses noninferior or superior to most comparators to date - Once-daily dosing - Coformulated with TDF/FTC	- Neuropsychiatric side effects - Teratogenic in nonhuman primates. Several cases of neural tube defect in infants born to women who were exposed to EFV in the first trimester of pregnancy reported. EFV use should be avoided in women with potential for pregnancy and is contraindicated in the first trimester. - Dyslipidemia
NVP	- No food requirement - Fewer lipid effects than EFV - Once-daily dosing with extended-release tablet formulation	- Higher incidence of rash, including rare but serious hypersensitivity reactions (Stevens-Johnson syndrome or toxic epidermal necrolysis), than with other NNRTIs - Higher incidence of hepatotoxicity, including serious and even fatal cases of hepatic necrosis, than with other NNRTIs - Contraindicated in patients with moderate or severe (Child-Pugh B or C) hepatic impairment - Some data suggest that ARV-naïve patients with high pre-NVP CD4 counts (>250 cells/μL for females, >400 cells/μL for males) are at higher risk of symptomatic hepatic events. NVP is not recommended in these patients unless benefit clearly outweighs risk. - Early virologic failure of NVP + TDF (FTC or 3TC) in small clinical trials
RVP	- Once-daily dosing - Coformulated with TDF/FTC - Smaller pill size than coformulated TDF/FTC/EFV or TDF/FTC/EVG/COBI - Compared with EFV: - Fewer discontinuations for central nervous system adverse effects - Fewer lipid effects - Fewer rashes - Smaller pill size	- Not recommended for use in patients with pre-ART HIV RNA >100,000 copies/mL because the rate of virologic failures is higher in these patients - Higher rate of virologic failures observed in patients with pre-ART CD4 count of <200 cells/μL - More NNRTI-, TDF-, and 3TC-associated mutations at virological failure than with regimen containing EFV + two NRTIs - Meal requirement - Absorption depends on lower gastric pH. (See Table 15a for detailed information regarding interactions with H2 antagonists and antacids.) - Contraindicated with PPIs - RPV-associated depression reported - Use RPV with caution when coadministered with a drug having known risk of torsades de pointes.

ARV Agent(s)	Advantages	Disadvantages
Protease Inhibitors (in alphabetical order)		
	PI Class Advantages: - Higher genetic barrier to resistance than NNRTIs and RAL - PI resistance at the time of treatment failure uncommon with RTV-boosted PIs	PI Class Disadvantages: - Metabolic complications such as dyslipidemia, insulin resistance, and hepatotoxicity - Gastrointestinal adverse effects - CYP3A4 inhibitors and substrates: potential for drug interactions (more pronounced with RTV-based regimens) (See Tables 14 and 15a.)
ATV (un-boosted)	- Fewer adverse effects on lipids than other PIs - Once-daily dosing - Low pill burden - Good gastrointestinal tolerability - Signature mutation (I50L) not associated with broad PI cross-resistance	- Indirect hyperbilirubinemia sometimes leading to jaundice or scleral icterus - PR interval prolongation: generally inconsequential unless ATV combined with another drug with similar effect - Unboosted ATV should not be coadministered with TDF, EFV, or NVP (see ATV/r). - Nephrolithiasis, cholelithiasis - Skin rash - Food requirement - Absorption depends on food and low gastric pH (See Table 15a for detailed information regarding interactions with H2 antagonists, antacids, and PPIs.)
ATV/r	- RTV boosting: higher trough ATV concentration and greater antiviral effect - Once-daily dosing - Low pill burden	- More adverse effects on lipids than unboosted ATV - More hyperbilirubinemia and jaundice than unboosted ATV - Food requirement - Absorption depends on food and low gastric pH (See Table 15a for interactions with H2 antagonists, antacids, and PPIs) - RTV boosting is required with TDF and EFV. With EFV, use ATV 400 mg and RTV 100 mg, once daily (PI-naïve patients only). - Should not be coadministered with NVP. - Nephrolithiasis, cholelithiasis
DRV/r	- Once-daily dosing - Potent virologic efficacy	- Skin rash - Food requirement
FPV/r	- Twice-daily dosing resulted in efficacy comparable to LPV/r - Once-daily dosing possible with RTV 100 mg or 200 mg daily - No food effect	- Skin rash - Hyperlipidemia - Once-daily dosing results in lower amprenavir concentrations than twice-daily dosing - For FPV 1,400 mg + RTV 200 mg: requires 200 mg of ritonavir and no coformulation - Fewer data on FPV 1,400 mg + RTV 100 mg dose than on DRV/r and ATV/r

ARV Agent(s)	Advantages	Disadvantages
Protease Inhibitors (in alphabetical order) <i>continued</i>		
LPV/r	• Coformulated • No food requirement • Greater CD4 T-cell count increase than with EFV-based regimens	• Requires 200 mg per day of RTV • Lower drug exposure in pregnant women – may need dosage increase in third trimester • Once-daily dosing not recommended in pregnant women • Once-daily dosing results in lower trough concentration than twice-daily dosing • Possible higher risk of myocardial infarction associated with cumulative use of LPV/r • PR and QT interval prolongation have been reported. Use with caution in patients at risk of cardiac conduction abnormalities or receiving other drugs with similar effect.
SQV/r	• Similar efficacy but less hyperlipidemia than with LPV/r	• Highest pill burden among available PI regimens (6 pills per day) • Requires 200 mg of RTV • Food requirement • PR and/or QT interval prolongations in a healthy volunteer study • Pretreatment ECG recommended • SQV/r is not recommended for patients with any of the following conditions: • Congenital or acquired QT prolongation • Pretreatment ECG >450 msec • On concomitant therapy with other drugs that prolong QT interval • Complete atrioventricular block without implanted pacemakers • Risk of complete atrioventricular block

ARV Agent(s)	Advantages	Disadvantages
Integrase Strand Transfer Inhibitors (in alphabetical order)		
DTG	- Once daily dosing if no resistance to integrase inhibitors - Virologic response noninferior to RAL, superior to DTV/r and EFV	- Inhibits tubular secretion of creatinine and can decrease CrCL without affecting renal glomerular function - May cause headache or sleep disturbance
EVG	- Coformulation with COBI/TDF/FTC - Once-daily dosing - Noninferior to EFV/TDF/FTC and ATV/r + TDF/FTC	- COBI is a potent CYP3A4 inhibitor, which can result in significant interactions with CYP3A substrates. - COBI inhibits active tubular secretion of creatinine and can decrease CrCl without affecting renal glomerular function. - Has potential for new onset or worsening off renal impairment - Only recommended for patients with baseline CrCl >70 mL/min; therapy should be discontinued if CrCl decreased to <50 mL/min - Lower genetic barrier to resistance than with boosted PI-based regimens - Food requirement
RAL	- Virologic response noninferior to EFV - Fewer drug-related adverse events and lipid changes than with EFV - No food effect - Fewer drug-drug interactions than with EVG/COBI/TDF/FTC-, PI-, NNRTI- MVC-based regimens	- Twice-daily dosing - Lower genetic barrier to resistance than with boosted PI-based regimens - Increase in creatine kinase, myopathy, and rhabdomyolysis have been reported - Rare cases of severe hypersensitivity reactions (including Stevens-Johnson syndrome and toxic epidermal necrolysis) have been reported
CCR5 Antagonist		
MVC	- Virologic response noninferior to EFV in post-hoc analysis of MERIT study (See text.) - Fewer adverse effects than EFV	- Requires viral tropism testing before initiation of therapy, which results in additional cost and possible delay in initiation of therapy - In the MERIT study, more MVC-treated than EFV-treated patients discontinued therapy owing to lack of efficacy - Less long-term experience in ART-naïve patients than with boosted PI- or NNRTI-based regimens - Limited experience with dual NRTIs other than ZDV/3TC - Twice-daily dosing - CYP 3A4 substrate: dosing depends on presence or absence of concomitant CYP3A4 inducer(s) or inhibitor(s)

ARV Agent(s)	Advantages	Disadvantages
Dual-Nucleoside Reverse Transcriptase Inhibitor Pairs (in alphabetical order)		
ABC/3TC	• Virologic response noninferior to ZDV/3TC • Better CD4 T-cell count responses than with ZDV/3TC • Once-daily dosing • Coformulation • No food effect • No cumulative TAM-mediated resistance	• Potential for abacavir hypersensitivity reaction in patients with HLA-B*5701 • Inferior virologic responses when compared with TDF/FTC in patients with baseline HIV RNA >100,000 copies/mL in ACTG 5202 study; however, this was not seen in the HEAT study • Some observational cohort studies show increased potential for cardiovascular events, especially in patients with cardiovascular risk factors
TDF/FTC	• Better virologic responses than with ABC/3TC in patients with baseline HIV RNA >100,000 copies/mL in ACTG 5202 study; however, this was not seen in the HEAT study • Active against HBV; recommended dual-NRTI for HBV/HIV coinfection • Once-daily dosing • No food effect • Coformulated (TDF/FTC, EFV/TDF/FTC, EVG/COBI/TDF/FTC, and RPV/TDF/FTC) • No cumulative TAM-mediated resistance	• Potential for renal impairment, including proximal tubulopathy and chronic renal insufficiency • Early virologic failure of NVP + TDF + (FTC or 3TC) in small clinical trials • Potential for decrease in bone mineral density
ZDV/3TC	• Coformulated (ZDV/3TC and ZDV/3TC/ABC) • No food effect (although better tolerated with food) • Preferred dual NRTI in pregnant women	• Bone marrow suppression, especially anemia and neutropenia • Gastrointestinal intolerance, headache • Mitochondrial toxicity, including lipoatrophy, lactic acidosis, hepatic steatosis • Compared with TDF/FTC, inferior in combination with EFV • Less CD4 increase compared with ABC/3TC • Twice-daily dosing

Abbreviations: /r = ritonavir boosted; 3TC = lamivudine; ABC = abacavir; ART = antiretroviral therapy; ARV = antiretroviral; ATV = atazanavir; COBI = cobicistat; CrCl = creatinine clearance; CYP = cytochrome P; d4T = stavudine; ddI = didanosine; DRV = darunavir; DTG = dolutegravir; ECG = electrocardiogram; EFV = efavirenz; EVG = elvitegravir; FPV = fosamprenavir; FTC = emtricitabine; HPV = hepatitis B virus; LPV = lopinavir; MVC = maraviroc; NNRTI = nonnucleoside reverse transcriptase inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; NVP = nevirapine; PI = protease inhibitor; PPI = proton pump inhibitor; RAL = raltegravir; RPV = rilpivirine; RTV = ritonavir; SQV = saquinavir; TAM = thymidine analogue mutation; TDF = tenofovir; ZDV = zidovudine

EXHIBIT K

Providing Gender-Affirming Care to People with HIV

2022 National Ryan White Conference on HIV Care and Treatment

August 25, 2022

Dana Hines, PhD, RN

Nurse Consultant, Division of Community HIV/AIDS Programs (DCHAP)

HIV/AIDS Bureau (HAB)

Vision: Healthy Communities, Healthy People

Health Resources and Services Administration (HRSA)

Overview

Supports more than 90 programs that provide health care to people who are geographically isolated, economically or medically challenged

HRSA does this through grants and cooperative agreements to more than 3,000 awardees, including community and faith-based organizations, colleges and universities, hospitals, state, local, and tribal governments, and private entities

Every year, HRSA programs serve tens of millions of people, including people with HIV/AIDS, pregnant women, mothers and their families, and those otherwise unable to access quality health care

HRSA's HIV/AIDS Bureau Vision and Mission

Vision

Optimal HIV care and treatment for all to end the HIV epidemic in the U.S.

Mission

Provide leadership and resources to advance HIV care and treatment to improve health outcomes and reduce health disparities for people with HIV and affected communities.

HRSA's Ryan White HIV/AIDS Program (RWHAP) Overview

- Provides a comprehensive system of HIV primary medical care, medications, and essential support services for low-income people with HIV.
- Funds grants to states, cities, counties, and local community-based organizations to improve health outcome and reduce HIV transmission.
 - Recipients determine service delivery and funding priorities based on local needs and planning process.
- Provided services to nearly 562,000 people in 2020—more than half of all people with diagnosed HIV in the United States.
- 89.4% of RWHAP clients receiving HIV medical care were virally suppressed in 2020, exceeding national average of 65.5%ⁱ.

i. Centers for Disease Control and Prevention. Core indicators for monitoring the Ending the HIV Epidemic initiative (early release): National HIV Surveillance System data reported through December 2020; and pre-exposure prophylaxis (PrEP) data reported through September 2020. HIV Surveillance Data Tables [Table 5a] 2021;2(No. 2). <http://www.cdc.gov/hiv/library/reports/surveillance-data-tables/vol-2-no-2/index.html>. Published March 2021.

Objectives

- Understand and define the unique gender affirming care and treatment needs of transgender people with HIV
- Help better articulate the principles of gender affirming care
- Identify Ryan White HIV/AIDS Program and other services that can be used to provide gender affirming care to transgender people with HIV

Gender Affirming Care in the RWHAP Program Letter

- Reaffirms the importance of providing culturally-affirming health care and social services to the transgender community
- Letter is *not* new policy or approach to the services delivered by the RWHAP
- Accessible via:
<https://hab.hrsa.gov/sites/default/files/hab/About/RyanWhite/gender-affirming-care-in-the-rwhap.pdf>

DEPARTMENT OF HEALTH & HUMAN SERVICES

Health Resources and Services
Administration

Rockville, MD 20857
HIV/AIDS Bureau

December 16, 2021

Dear Ryan White HIV/AIDS Program Colleagues,

Ensuring that transgender people with HIV have access to care, treatment and support services that improve their health and decrease risk of morbidity and mortality related to HIV is a priority for the Health Resources Services Administration's (HRSA) HIV/AIDS Bureau (HAB). Of the more than half a million people served by the Ryan White HIV/AIDS Program (RWHAP) 2.1 percent, approximately 11,600, are transgender.¹ Providing gender-affirming care is an important strategy to effectively address the health and medical needs of transgender people with HIV. HRSA HAB strongly encourages RWHAP service providers to harness and mobilize the existing RWHAP infrastructure and services to support gender-affirming services within allowable RWHAP parameters.

Gender-affirming care and treatment services are described in the *HHS Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents Living with HIV* (Guidelines).² According to the Guidelines, gender affirmation describes processes whereby a person receives social recognition, value, and support for their gender identity and expression. Gender affirmation is often described across several dimensions, including: social (e.g., social support and acceptance, use of pronouns, names, or clothing that align with their gender identity); medical (e.g., use of hormones or surgery); legal (e.g., legal name change or changing gender markers on identity documents); and psychological (e.g., the degree of self-acceptance and comfort with their gender identity).

RWHAP funds may be used to support gender affirming care across various HRSA RWHAP core medical and support service categories as outlined in *Policy Clarification Notice #16-02 Ryan White HIV/AIDS Program Services: Eligible Individuals & Allowable Uses of Funds*.³ Many RWHAP AIDS Drug Assistance Programs (ADAPs) provide access to gender-affirming

Ryan White HIV/AIDS Program

Gender Diverse People with HIV

- Transgender and non-binary people bear a **disproportionate burden of HIV**.
- Encounter a number of social and structural barriers to HIV care.
- Gender affirming care and inclusive environments of care play a key role in entry and engagement in HIV care.

Gender affirmation:

- ✓ Improves engagement in care
- ✓ Improves viral suppression
- ✓ Improves adherence to ART
- ✓ Improves mental health outcomes and well being

Examples of Gender-Affirming Care in the RWHAP

Training on cultural humility, cultural sensitivity, and inclusive environments of care

Behavioral & Mental Health Services

Housing & Case Management

Access to gender affirming hormone therapy

Purchase and maintenance of private health insurance, Medicaid and Medicare coverage

Activities that support patient centered, trauma informed, and inclusive environments of care

Gender Affirming Care Activities in the RWHAP

- Updated language in the RWHAP Part D NOFO FY22
- Considering supplemental RWHAP Part D FY23 funding for gender affirming care innovation.
- Gender affirming care presentations at the 2022 NRWC.
- Collaborating with other federal partners to integrate and consolidate gender-affirming care resources and leverage expertise across various agencies.

Transgender Clients served by the RWHAP

Clients Served by the Ryan White HIV/AIDS Program, by Gender, 2020—United States and 3 Territories^a

^a Guam, Puerto Rico, and the U.S. Virgin Islands.

Transgender Clients Served by the Ryan White HIV/AIDS Program, by Gender Identity, 2020—United States and 3 Territories^a

Sexual Orientation and Gender Identity are Not the Same

- All people have a sexual orientation and gender identity
 - How people identify can change
 - Terminology varies
- Gender Identity $\neq$ Sexual Orientation

Sex Assigned at Birth

- Female
- Male
- Intersex

Gender Identity and Gender Expression

- Gender identity
 - A person's inner sense of being a girl/woman, boy/man, both, beyond, or having no gender
 - All people have a gender identity
- Gender expression
 - How one presents themselves through their behavior, mannerisms, speech patterns, dress, and hairstyles
 - May be on a continuum

A complete glossary of terms is available at <https://www.lgbtqiahealtheducation.org/publication/lgbtqia-glossary-of-terms-for-health-care-teams/>

Gender Identity Terminology

- Transgender: gender identity beyond societal expectations related to sex assigned at birth
- Binary terminology
 - Transgender woman, trans woman
 - Transgender man, trans man
- Non-binary
 - Genderqueer person, gender fluid person
- Trans masculine, Trans feminine
- Gender identity is increasingly described as being on a continuum

Understanding Gender Transition/Affirmation

- The process of changing from living and being perceived as the gender traditionally associated with the sex assigned at birth (e.g., F or M) to living and being perceived as the individual sees and understands themselves.
 - Social affirmation
 - Legal/document changes
 - Hormone therapy
 - Surgical affirmation

Sexual Orientation

- Sexual orientation: how a person experiences their physical, emotional and romantic attachments to others
- Desire
- Behavior
 - Risk of sexually transmitted infections is related to behavior, not identity
- Identity
 - e.g., gay, straight, lesbian, bisexual, queer, asexual, pansexual

Dimensions of Sexual Orientation:

What Does 'Q' Stand For?

- 'Q' may reflect someone who is 'questioning' their gender identity or sexual orientation.
- 'Q' may stand for 'queer,' a way some people identify to state they are not straight or cisgender. It is now also a term of self-identification for many transgender and gender diverse people. The term queer is particularly commonly used by younger people, and also by people of all ages.

Gender Minority Stress Framework

NATIONAL

Perspective

Strategies to Mitigate Clinician Implicit Bias Against Sexual and Gender Minority Patients

Michal J. McDowell, M.D., M.P.H., Hilary Goldhammer, S.M., Jennifer E. Potter, M.D.,
Alex S. Keuroghlian, M.D., M.P.H.

Background: *Implicit bias is an ingrained, unconscious cultural stereotype that can negatively affect a person's interactions with members of stigmatized groups, including sexual and gender minorities. Clinician implicit biases may negatively impact the quality of patient care.*
Methods: *This article uses 4 case scenarios to illustrate how implicit bias among psychiatrists and other clinicians can affect patient-clinician communication and diminish the quality of health care provided to sexual and*

gender minority people. We offer strategies for clinicians to recognize, challenge, and address implicit bias.
Discussion: *Through continuing education, self-reflection, and practice, psychiatrists and other clinicians can improve communication and foster more affirming care experiences for their sexual and gender minority patients, with the goal of addressing and ultimately eliminating sexual and gender minority health disparities.*

(*Psychosomatics* 2020; ■■■ ■)

Key words: sexual minority, gender minority, implicit bias, unconscious bias, LGBT, communication.

Health Disparities: U.S. Transgender Survey

- 39% of respondents experienced **serious psychological distress** in the month prior (compared to 5% of the U.S. population)
- 40% had **lifetime suicide attempt** (compared to 4.6% of US population)
- In the preceding 12 months:
 - 48% had seriously thought about suicide
 - 24% made a plan to kill themselves
 - 7% had attempted suicide
- Of the 40% who attempted suicide at one point in their lives:
 - 34% had first attempt by age 13
 - 92% had first attempt by age 25

Affirming Gender Identity of Patients With Serious Mental Illness

William B. Smith, M.D., Hilary Goldhammer, S.M., Alex S. Keuroghlian, M.D., M.P.H.

Transgender people who experience serious mental illness represent a uniquely vulnerable population. Because of limited research, however, recommendations for treating this population are scarce. In this article, the authors describe the challenge of recognizing gender dysphoria in people with serious mental illness. They then discuss why existing evidence and clinical experience support provision of gender-affirming

medical and surgical treatments for transgender people who have serious mental illness and also demonstrate capacity to make informed medical decisions. More research is needed to develop evidence-based treatments and programs for transgender people with serious mental illness.

Psychiatric Services 2018; 0:1–3; doi: 10.1176/appi.ps.201802022

PERSPECTIVES

Distinguishing and Addressing Gender Minority Stress and Borderline Personality Symptoms

Hilary Goldhammer, SM, Cary Crall, MD, and Alex S. Keuroghlian, MD, MPH

Abstract: As transgender and gender-diverse people are gaining increased visibility in clinical settings, clinicians are requesting better guidance on providing affirming care to improve the mental health and well-being of these patients. In particular, more direction is needed on whether, when, and how to diagnose and treat borderline personality disorder among gender minorities, partially in response to beliefs among some mental health clinicians that a gender minority identity may be a manifestation of identity diffusion. In this Perspectives article, we argue that gender minority identity, even when fluid, is rarely a sign of identity diffusion. By taking a careful history of a patient's gender identity development, the clinician can clarify and gain more conviction regarding the presence of a patient's gender minority identity. Moreover, multiple stigma-related stressors experienced by gender minorities may produce symptoms and behaviors that can mimic or be consistent with certain diagnostic criteria for borderline personality disorder. We therefore conclude with recommendations for adopting a gender-affirming framework to treat borderline personality symptoms when present among gender minority patients, with implications for future research and practice.

Keywords: borderline personality disorder, gender dysphoria, gender identity, gender minority, transgender

Screening, Counseling, and Shared Decision Making for Alcohol Use with Transgender and Gender-Diverse Populations

Jacob Arellano-Anderson, BS¹ and Alex S. Keuroghlian, MD, MPH¹⁻³

Abstract

At-risk alcohol use occurs among transgender and gender-diverse (TGD) populations, yet current alcohol use screening tools and guidelines do not distinguish between sex- and gender-related characteristics, having been developed without accounting for natal sex-based physiology, effects of gender-affirming medical care, and gendered drinking behavior among TGD people. More research on how sex- and gender-related factors independently influence alcohol use can help validate gender-inclusive screening protocols and develop evidence-based guidelines meaningful for people of all genders. In the interim, clinicians must be mindful of gender diversity and engage in transparent, collaborative discussions when screening for and counseling about alcohol use.

Keywords: alcohol, counseling, gender identity, nonbinary, screening, transgender

ABSTRACT

Transgender and gender-diverse people face multiple barriers to accessing appropriate health care, including denial of service, harassment, and lack of clinician knowledge. This article presents a blueprint for planning and implementing a transgender health program within a primary care practice in order to enhance the capacity of the health care system to meet the medical and mental health needs of this underserved population. The steps described, with emphasis on elements specific to transgender care, include conducting a community needs assessment, gaining commitment from leadership and staff, choosing a service model and treatment protocols, defining staff roles, and creating a welcoming environment.

Figure 1. Suggested components of a comprehensive transgender health program.

STI = sexually transmitted infection.

ANNALS OF
FAMILY MEDICINE

Role of Providers in Gender Affirmation Process

- Fostering gender identity exploration, discovery and affirmation
- Presenting appropriate medical and non-medical strategies for gender affirmation
- Assistance in making fully informed decisions regarding personalized gender affirmation process:
 - relevant options
 - risks/benefits
 - evaluate capacity for medical decision making/informed consent
 - arranging suitable referrals to care

Pronouns

People may have a range of pronouns, including she/her/hers and he/him/his, as well as less-common pronouns such as they/them/theirs and ze/hir/hirs (pronounced zee/hear/hears).

Subjective	Objective	Possessive	Examples
He	Him	His	He is in the waiting room. The doctor is ready to see him. That chart is his.
She	Her	Hers	She is in the waiting room. The doctor is ready to see her. That chart is hers.
They	Them	Theirs	They are in the waiting room. The doctor is ready to see them. That chart is theirs.
Ze	Hir	Hirs	Ze is in the waiting room. The doctor is ready to see hir. That chart is hirs.

Collecting Data on Gender Identity

NATIONAL
RYAN WHITE
CONFERENCE
ON HIV CARE & TREATMENT

- What name do you go by?
- What name is on your insurance records?
- What are your pronouns (e.g., she/her, he/him, they/them)?
- What is your current gender identity?
- What sex were you assigned at birth?

Anticipating and Managing Expectations

- Transgender and gender diverse people have a history of experiencing stigma and discrimination in diverse settings
- Don't be surprised if a mistake results in a patient becoming upset
- Don't personalize the reaction
- Apologizing when patients become upset, even if what was said was well-intentioned, can help defuse a difficult situation and re-establish a constructive dialogue

Avoiding Assumptions

- You cannot assume someone's gender identity based on how they look or sound.
- To avoid assuming gender identity:
 - *Instead of:* "How may I help you, Ma'am/Sir?"
 - *Say:* "How may I help you?"
 - *Instead of:* "He/She is here for his/her appointment."
 - *Say:* "The patient is here in the waiting room."

Keeping Up with Terminology

- Obvious “don’ts” include
 - Use of any disrespectful language
 - Gossiping about a person’s appearance or behavior
 - Saying things about someone not necessary for their care:
 - “You look great, you look like a real woman/real man!”

Avoid these Outdated Terms (in English)	Consider these Terms Instead
Homosexual	Gay, lesbian, bisexual, or LGBTQIA+
Transvestite; Transgendered	Transgender
Sexual preference; Lifestyle choice	Sexual orientation
Sex Change	Gender-affirming care

Inclusive Registration and Medical History Forms

NATIONAL
RYAN WHITE
CONFERENCE
ON HIV CARE & TREATMENT

Avoid these terms...	Replace with...
Mother/Father	Parent/Guardian
Husband/Wife	Spouse/Partner(s)
Marital Status	Relationship Status
Family History	Blood Relatives
Nursing Mother	Currently Nursing
Female Only/Male Only	Allow patients to choose <i>not applicable</i>.

Focus on Forms and Policy:

Intersectionality

Regional considerations with patients living on both sides of the Mexican-American border

- Collaborations: El Rio x Mexican Consulate and El Rio x Mexican Secretariat of Health (CAPASITS)
- Barriers: Immigration status, language, cultural and religious beliefs
- Crossing border to access medications and care, bidirectional
- Opportunities: Navigation to medical home and other services

Intersectionality

NATIONAL
RYAN WHITE
CONFERENCE
ON HIV CARE & TREATMENT

Local indigenous communities

- Native American culture x western culture and religion
- Urban vs tribal residents
- Case 1: Tohono O’Odham Nation: gender non-conforming presentation and roles, “addition” of other
- Case 2: Pascua Yaqui: Tribal nurse navigator, patient rights
- Case 3: Variability of cultural beliefs across tribes

Gender affirming care as primary care

- Gender affirming care:
 - Primary care
 - Case 1: Gender affirming care is part of primary care.^{1,2} Smoking cessation, estradiol, identifying with gender-affirmed body
 - Improves care related to HIV:
 - Case 2: Gender affirming hormone therapy may improve HIV viral suppression.³ Taking antiretrovirals for HIV management and estradiol
 - Life-saving care
 - Case 3: Transgender suicide attempt rate has been cited at 41%, with notable improvements in psychological functioning, depression with gender-affirming hormone therapy.^{4,5} New diagnosis of HIV and restarting of gender affirming hormone therapy.

Executive Summary

The United States (US) Department of Health and Human Services (HHS); the Centers for Disease Control and Prevention (CDC) National Center for HIV, Viral Hepatitis, Sexually Transmitted Diseases (STDs), and Tuberculosis (TB) Prevention (NCHHSTP); and the Health Resources and Services Administration (HRSA) HIV/AIDS Bureau (HAB) convened a meeting of the CDC/HRSA Advisory Committee on HIV, Hepatitis, and STD Prevention and Treatment (CHAC) on April 26-28, 2022.

CDC and HRSA Welcome and Updates

The meeting began with detailed updates from CDC and HRSA. The CDC update highlighted a number of important areas of interest from the NCHHSTP HIV, STD, viral hepatitis, and school/adolescent health programs including: a brief update on the continuing impact of COVID-19; NCHHSTP's equity initiative and strategic plan; harm reduction and Syringe Services Programs; discussion of mental health concerns in youth; Ending the HIV Epidemic (EHE) update; discussion on updated hepatitis B vaccination and screening and testing recommendations; and integrating STI and HIV services to address the syndemic. Highlights from the HRSA/HAB presentation included the introduction of a new Administrator, launch of a new Ryan White website, release of the National HIV/AIDS Strategy (2022–2025) in December 2021, and policy and data updates. CHAC members discussed recent policy changes and their potential impacts on LGBTQ (lesbian, gay, bisexual, transgender, and questioning) youth's access to information, resources, and equitable care.

Strategizing an Approach to Providing Comprehensive STI Services

During this panel, CHAC heard from programs in Mississippi, New York, and Minnesota that highlighted innovative strategies they are employing to increase access to testing and comprehensive STI services. These strategies included using the school space to increase access to health services for young people, leveraging technology, and the effort to align that with the COVID-19 pandemic response to: 1) innovate and modernize the public health infrastructure, which can serve as a good model moving forward in jurisdictions; and 2) determine how to secure and sustain funding to support these efforts moving forward in a post-COVID world.

Leveraging Policy to Advance HIV, VH, and STI Priorities

This panel focused on utilizing policy as a public health intervention as an approach to solving expansive issues in public health. The National Viral Hepatitis Roundtable presented on the state of Medicaid access with respect to Hepatitis C. The California Department of Public Health (CDPH) Office of AIDS provided an update on Senate Bill (SB) 159 pertaining to HIV pre-exposure and post-exposure prophylaxis (PrEP & PEP) for California pharmacists and the STD Control Branch presented on leveraging policy changes for STI and VH prevention, testing, and treatment. The Louisiana Office of Public Health STD/HIV/Hepatitis Program described Louisiana's *Hepatitis C Elimination Plan: 2019-2024*. The Transitions Clinic Network described issues pertaining to the Medicaid Inmate Exclusion Policy (MIEP) which reduces barriers to care for post-incarceration, reintegrating individuals.

Turning the Tide on Self-Testing and Sample Collection

This special presentation focused on self-testing and sample collection, highlighting the pipeline and approval process for self-collection kits. CHAC heard data on how impactful self-collection kits could be on communities that historically have not utilized traditional brick-and-mortar structures. The availability of self-collection kits has been demonstrated to increase testing practices in a number of communities. Discussion focused on how the Food and Drug

Administration (FDA) views HIV versus HCV and manufacturers' willingness to produce self-testing kits and seek FDA approval. Additionally, CHAC members discussed the differences in the criteria used for regulatory authorization of collection kits/methods domestically versus internationally and the potential for the review and revision of FDA process to increase access to and use of self-test kits.

Applied Syndemic Approach to HIV, VH, and STIs: Focusing on People

This panel focused on implementation of programmatic syndemic approaches, which underscored the need to take a "whole person" approach in terms of the issues that influence an individual's ability to access the resources that are being put forward, utilize them effectively, and achieve successful health outcomes. The New Mexico Department of Health (NMDOH) described its comprehensive harm reduction program focused on meeting people where they are to support HCV treatment and syphilis services. The North Dakota State Correctional Health Authority emphasized that corrections health is an important part of public health and represents a vulnerable and underserved population and can be an ideal setting for delivering comprehensive services. The San Francisco Unified School District (SFUSD) described policies and mandates, community partnerships, resources, training, and initiatives that help support comprehensive sexual health services to SFUSD youth. Finally, CDC's Division of HIV Prevention (DHP) provided an update focused on advancing syndemic approaches through cluster detection and response, emphasizing that cluster detection and response can guide tailored implementation of proven treatment and prevention strategies for HIV and other syndemic conditions where transmission is occurring most rapidly.

Telehealth/Telemedicine Working Group (WG)

The Telehealth/Telemedicine WG put forth several recommendations focused on enhancing routine screening through virtual services for all populations, health equity's relationship to telehealth service provision, and deployment of the Tele-PrEP initiative for Federally Qualified Health Centers (FHQCs).

Presidential Advisory Council on HIV/AIDS (PACHA)

CHAC was provided an update on PACHA's 73rd full council meeting that was convened virtually on March 14-15, 2022. This presentation emphasized the importance of hearing the voices of the community that will help guide PACHA in moving forward in terms of making recommendations to support EHE and in implementing the National HIV/AIDS Strategy (NHAS).

Business Session

The Business Session focused on CHAC actions and proposed future agenda topics. The next CHAC meeting is scheduled for November 1-3, 2022.

Future Agenda Topics Proposed

- Gender-affirming care, coverage, and outcomes
- Barriers to providing PrEP for uninsured and under-insured individuals
- Lessons that can be learned from the global setting (e.g., task-sharing to enhance the workforce, availability of self-testing and self-collection of specimens, et cetera)
- Issues specific to pregnancy (e.g., perinatal transmission of HIV, HCV, HBV, and congenital syphilis; underuse of PrEP in at-risk pregnant women; mental health; intimate partner violence; breast and chest feeding; et cetera)
- The effects of COVID-19 in a variety of areas (e.g., healthcare overall, HIV, persons ≥50 years of age, disparities, and comorbidities post-COVID, et cetera)

CHAC Actions

During this meeting, CHAC members voted unanimously to:

- Adopt the November 2021 CHAC meeting minutes, with no edits proposed.
 - Send the letter of recommendations presented by the Telehealth WG to the HHS Secretary, with a minor revision of repositioning the health equity recommendation as the first bullet.
 - Develop and send a letter to the HHS Secretary regarding LGBTQ youth.
 - Create a Self-Collection Self-Testing WG to consider issues related to self-testing, potentially including: 1) Differences in FDA risk classification of HCV and HIV; 2) Criteria required and data available for the FDA approval process; and 3) Downregulation to class II diagnostics. In addition, this WG will draft a letter to be presented to CHAC for a potential vote during the November 2022 meeting.
 - Establish a Workforce WG to liaise with PACHA on their efforts, to discuss the main issues CHAC is to consider on workforce including exploring the role of other professionals and community health workers (CHWs) in this space, and to discuss topics to potentially inform a panel for the November 2022 CHAC meeting.
-

**US DEPARTMENT OF HEALTH AND HUMAN SERVICES
CENTERS FOR DISEASE CONTROL AND PREVENTION
HEALTH RESOURCES AND SERVICES ADMINISTRATION
CDC/HRSA Advisory Committee on
HIV, Viral Hepatitis, and STD Prevention and Treatment
April 26-28, 2022**

Minutes of the Meeting

The United States (US) Department of Health and Human Services (HHS); the Centers for Disease Control and Prevention (CDC) National Center for HIV, Viral Hepatitis, Sexually Transmitted Diseases (STDs), and Tuberculosis (TB) Prevention (NCHHSTP); and the Health Resources and Services Administration (HRSA) HIV/AIDS Bureau (HAB) convened a meeting of the CDC/HRSA Advisory Committee on HIV, Hepatitis, and STD Prevention and Treatment (CHAC) on April 26-28, 2022.

The CHAC is a committee chartered under the Federal Advisory Committee Act (FACA) to advise the Secretary of HHS, Director of CDC, and Administrator of HRSA on objectives, strategies, policies, and priorities for HIV, viral hepatitis, and STD prevention and treatment efforts for the nation. Information for the public to attend the CHAC meeting virtually was published in the *Federal Register*, in accordance with FACA rules and regulations. All sessions of the meeting were open to the public. Please see Appendix A for Membership Attendance.

Day 1: Opening of the Meeting and Roll Call

Marah E. Condit, MS

Public Health Analyst, Advisory Committee Management Lead
Office of Policy, Planning, and Partnerships
National Center for HIV, Viral Hepatitis, STD, and TB Prevention
Centers for Disease Control and Prevention

Ms. Condit welcomed participants to the CHAC meeting, called the proceedings to order at 11:00 AM Eastern Time (ET), reviewed ground rules, and provided instructions for discussion periods. She indicated that members of the public would have an opportunity to provide oral comments at 3:30 PM ET during the second day, and that public comments would not be accepted at any other point during the meeting.

Jonathan Mermin, MD, MPH (RADM, USPHS)

Director, National Center for HIV, Viral Hepatitis, STD and TB Prevention
Centers for Disease Control and Prevention
CHAC Designated Federal Officer
Centers for Disease Control and Prevention

On behalf of CDC and HRSA, Dr. Mermin welcomed those present and reminded everyone that CHAC meetings are open to the public and that all comments made during the proceedings are a matter of public record. Members should be mindful of potential conflicts of interest (COIs) identified by the Committee Management Office (CMO) and recuse themselves from voting or participating in any discussions for which they could be conflicted. He then conducted a roll call to determine the CHAC voting and *Ex-Officio* members who were in attendance and establish quorum. Quorum was maintained during all 3 days of the meeting.

Conflict of Interest Disclosures

CHAC Voting Member Institution/Organization	Disclosure of Conflicts
Jean R. Anderson, MD Johns Hopkins Medical Institutions	Stocks: Apple, Amazon, Cisco, Alphabet, Splunk Research Funding: Merck, Gilead
Wendy Armstrong, MD Emory University School of Medicine	Research Funding: HRSA/Ryan White Parts A, B, D that supports part of her salary as well
Jodie Dionne-Odom, MD, MSPH University of Alabama, Birmingham	Research Funding: NIH
Shannon Brown Dowler, MD North Carolina Medicaid	None
Daniel Driffin, MPH D3 Consulting	None
Travis Gayles, MD, PhD Hazel Health	Self-recusal for Telehealth related topics
Meredith Greene, MD University of California, San Francisco	Research Funding: Gilead, NIH Works in a Ryan White-funded clinic
Vincent Guilamo-Ramos, PhD, MPH, LCSW, RN, ANP-BC, PMHNP-BC, AAHIVS, FAAN Duke University	Research Funding: NIH, ACF
Kali Lindsey amfAR, Foundation for AIDS Research	None
Christine Markham, PhD University of Texas Houston	Research Funding: NIH, ACF, OMH
Shruti Mehta, PhD, MPH Johns Hopkins Bloomberg School of Public Health	Research Funding: NIH, USAID Materials Support For Research Studies: Abbott
Johanne Morne, MSED AIDS Institute, New York State Department of Health	Research Funding: CDC and HRSA/Ryan White HIV/AIDS Program
Kneeshe Parkinson Washington University/Project ARK	Research Funding: HRSA/Ryan White HIV/AIDS Program Parts A, B, C, and D
Robert Riester Denver Element	Research Funding: CDC and HRSA/Ryan White HIV/AIDS Program, Part A
Leandro Rodriguez, MBA Latino Commission on AIDS	Research Funding: HRSA/Ryan White HIV/AIDS Program, CDC, SAMHSA, Gilead, ViiV
Samuel So, MD Stanford University	Research Funding: CDC, NIH

Ex-Officio members in attendance included Dr. Pradip Akolkar of the Food and Drug Administration (FDA), Dr. Maureen Goodenow of the National Institutes of Health (NIH), Dr. Neerja Gandotra of the Substance Abuse and Mental Health Services Administration (SAMHSA), Ms. Kaye Hayes of the HHS Office of HIV/AIDS and Infections Disease Policy (OIDP), Mr. Rick Haverkate of the Indian Health Service (IHS), and Dr. Richard Wild of the Centers for Medicare and Medicaid Services (CMS). Liaison member Dr. Ada Steward of the

Presidential Advisory Council on HIV/AIDS (PACHA Liaison Representative) organization, Eau Claire Cooperative Health Centers, receives Ryan White Funding Parts B and D.

Dr. Mermin confirmed that a quorum of 22 was achieved and that CHAC could move forward with conducting its business on April 26, 2022.

Welcome and Agenda Review

Travis Gayles, MD, PhD

CHAC Co-Chair, CDC Appointee

Jean Anderson, MD

CHAC Co-Chair, HRSA Appointee

Dr. Gayles and Anderson welcomed everyone to the April 26-28, 2021 CHAC meeting. Dr. Gayles thanked CHAC members, federal officials, CDC and HRSA staff, and the general public for their attendance and commitment. He expressed particular gratitude to Dr. Stewart for her efforts to promote vaccination in the pediatric population, as well as her commitment across the full breadth of public health issues. He reviewed the agenda for the day, pointing out that it highlighted the continued need to be nimble and versatile in the ever-changing post-COVID world with the increased attention on public health issues and budget demands and supplies. He observed that many of the topics to be discussed during this meeting demonstrated how CHAC must continue to evolve in terms of considering what should be included in a comprehensive STI testing program in 2022, determining the types of policies that need to be put into place to impact service delivery in a more meaningful way, and examining how federal policies might influence the delivery of those services. As always, they looked forward to great presentations, robust discussions, and tangible action items.

CDC DFO Welcome and Updates

NCHHSTP Update

Jonathan Mermin, MD, MPH (RADM, USPHS)

Director, National Center for HIV, Viral Hepatitis, STD and TB Prevention

Centers for Disease Control and Prevention

CHAC Designated Federal Officer

Dr. Mermin welcomed new CHAC Voting Members, Mr. Kali Lindsey and Dr. Christine Markham. He also welcomed Dr. Maureen Goodenow, Director of NIH's Office of AIDS Research, who is replacing Dr. Paul Gaist as the NIH *Ex-Officio* member.

To update CHAC correspondence, responses were sent on March 7, 2022, for the HIV and HCV classification letter; the Viral Hepatitis Workgroup (WG) letter; the Youth Engagement letter; and an interim response to the Perinatal Infection WG letter. CDC and HRSA are working on a detailed response currently and hope to have that finalized in the next couple of months.

In terms of COVID-19 pandemic, the number of deaths officially attributed to COVID-19 is close to 1 million in the US and there have been over 80 million total cases. Although mortality and hospitalizations decreased with the decreasing incidence of COVID-19 in the early part of 2022, cases and hospitalizations increased as the new subvariant began to spread. Challenges continue for all of public health and clinical care, as well as policies and other aspects of trying to keep America healthy in an environment where there are various other pressures

simultaneously. NCHHSTP continues to have multiple deployments for the COVID-19 response, with over 700 employees deployed since the beginning of the epidemic, over 1600 cumulative deployments, 53 people currently deployed, and 17 staff soon to deploy. NCHHSTP also is taking responsibility for several aspects of the incident management structure as CDC begins to reorganize its response to COVID-19, with the understanding that this is going to be a long-term effort.

NCHHSTP's Equity Initiative Strategy launched in 2021. This long-term strategy is intended to help achieve workplace equity and eliminate health disparities by addressing racism and other systems of oppression that hinder the center's mission. An implementation plan was developed that outlines the first steps of this process, though NCHHSTP already has been implementing many of the strategies. The overall goal is to help integrate health equity and equity in the workplace as core activities to which NCHHSTP is committed. NCHHSTP is focused on pervasive disparities associated with HIV, viral hepatitis, STDs, and TB, as well as adolescent health. The Equity Initiative involves all aspects of the center, with each division developing action plans that they have been implementing for some time.

An assessment was completed of external work for improving public health, internal workforce, organizational change, and analysis. Based on the analysis of the workforce, over 50% of NCHHSTP's staff are racial/ethnic minorities and close to 70% are women. The proportion of racial/ethnic minorities has increased at least 20% over the past decade. NCHHSTP also was the first group at CDC to conduct a survey of staff regarding sexual orientation and gender identity. Approximately 18% of NCHHSTP staff identified as LGBTQ (lesbian, gay, bisexual, transgender, questioning), with that proportion being the same in lower and higher General Schedule (GS) levels. NCHHSTP is committed to continue to perform these demographic analyses, develop fact sheets, and improve the inclusiveness of the day-to-day experience of staff within the center.

Part of the Equity Initiative is the development of an external public health dashboard that assesses the overarching measures of inequity in the diseases under NCHHSTP's purview. There are relative comparative measures and absolute measures, which follow current scientific practices for analyzing inequities. While these measures vary for each condition and population, the center is committed to reducing health inequity.

CDC's cross cutting strategic plan to reduce the infectious disease consequences among people who use drugs is complete. The mission is to decrease morbidity, mortality, and incidence of infectious diseases associated with injection drug use, as well as stigma experienced by people who use drugs. Several strategic priorities have been identified, including expanding the infrastructure of syringe services programs (SSPs) nationwide and integrating SSPs into the public health system, and establishing coordinated surveillance, monitoring, and program implementation. "Strengthening Syringe Services Programs" Notice of Funding Opportunity (NOFO) was issued recently that will expand SSP and support a network of SSPs across the country.

Additionally, this year CDC is implementing the 6th surveillance cycle among people who use drugs via the National HIV Behavioral Surveillance or NHBS which monitors prevalence and trends of HIV infection, risk behaviors, and prevention services among populations at increased risk for HIV, across 20-23 cities in the US. CDC is also launching the Microinfluencing project with the CDC Foundation and the Public Good Projects. This is a pilot to engage social media influencers to grow support for SSPs starting in West Virginia and other jurisdictions across the country. The campaign launched mid-April called "Appalachian Influencers," recruiting both paid

and volunteer influencers to begin posting messages, focusing on 4 audiences including law enforcement, health care, faith leaders, and community leaders.

Similar to what has been experienced in other infections, tuberculosis (TB) cases decreased in 2020 for a variety of reasons that are still under exploration and increased by 9% in 2021, however, not to the levels of 2019. Factors likely contributing to the observed decline include delayed or missed TB diagnosis due to disruptions in health care access, underdiagnosis, or a true decline from the reduced TB transmission due to pandemic mitigation efforts and fewer new arrivals from high TB incidence countries. TB incidence in the US continues to decrease over time, but not at the pace that would be necessary to achieve TB elimination goals.

Division of Adolescent and School Health (DASH) Update

Kathleen Ethier, PhD

Director, Division of Adolescent and School Health
National Center for HIV, Viral Hepatitis, STD and TB Prevention
Centers for Disease Control and Prevention

Dr. Ethier reminded everyone that DASH has been presenting to CHAC for a number of years about what has been observed through the Youth Risk Behavior Survey (YRBS) regarding the health and wellbeing of young people in the country. New data recently were released that were collected through the Adolescent Behaviors and Experiences Survey (ABES), a version of the YRBS that was implemented in Spring 2021. Students were recruited through schools, same as is done for the YRBS, but they were able to complete the survey online instead of in a classroom. This engagement allowed sample students who were learning virtually, as well as those who were learning in-person in school to participate.

These data reveal the magnitude of challenges that youth are experiencing, particularly related to mental health, experiences of abuse in the home during the pandemic, experience of racism in schools, and a variety of other issues. There is a continuing mental health crisis among youth, which was seen prior to the pandemic, particularly among female students and students who identify as being LGBTQ. These data show 26% of students who identify as LGBTQ attempted suicide in the year prior to the data collection during the pandemic and more than 50% of all students experienced emotional abuse in the home (e.g., verbal abuse by a parent or other adult), speaking to the level of stress experienced by students and families. Among respondents, 64% of Asian students and 55% of Black and Multiracial students reported having experienced racism in school not related to the pandemic.

Youth who identify as LGBTQ have been disproportionately impacted by the pandemic, experiencing higher levels of poor mental health, more than 3 times the likelihood to have attempted suicide in the past year, and more emotional abuse at home during the pandemic compared to their heterosexual peers. This data shows that access to schools and other places in the community where students can be supported is critical and was limited due to the pandemic. One of the hopeful findings was that connectedness mitigated mental health issues. Students who reported that they felt connected were less likely to experience mental health problems and were less likely to consider or attempt suicide. At the same time, students who identify as LGBTQ and students who experienced racism were less likely to feel connected to others at school. This sets up a challenge for those who work in schools in how to make schools safer and more supportive, particularly for those youth.

CDC's "What Works in Schools" approach improves adolescent health and wellbeing. This approach includes quality sex education, systems to connect youth to services, and a set of activities around improving school connectedness and providing support for LGBTQ students. In schools implementing this approach within CDC-funded districts, students were less likely to have ever had sex, have 4 or more sexual partners, be currently sexually active, miss school because of safety concerns, be forced to have sex, and/or use marijuana.¹ Sexual assault is known to be a predictor of lifelong trauma as well as posing STD and HIV risks.

Schools that put a set of policies and practices in place to support LGBTQ students such as identifying safe spaces, having professional development for educators, and having anti-harassment policies that are enforced leads to improvements in mental health outcomes and reductions in suicidal thoughts and behaviors. Improvements are observed in all students including LGBTQ in schools that put these policies and practices in place. The reverse is also the case—that when these policies and practices are not in place, mental health problems are exacerbated for students who identify as LGBTQ and also for heterosexual students. This has significant implications for the currently state of schools across the country. As schools are made less toxic for the most vulnerable students, schools are made less toxic for everyone and the reverse is also the case.²

Division of HIV Prevention (DHP) Update

Demetre Daskaliakis, MD, MPH

Director, Division of HIV Prevention
National Center for HIV, Viral Hepatitis, STD and TB Prevention
Centers for Disease Control and Prevention

Dr. Daskaliakis reminded everyone that has CDC requested \$310 million in the FY23 President's Budget in order to continue its focus on the 4 pillars of EHE, as well as to amplify these efforts by investing in key strategies to advance health equity. Some of the highlights are to focus efforts on increasing access to testing by scaling up self-testing, and to think specifically about the use of self-testing in high impact settings such as community-based organizations (CBOs), LGBTQ-focused clinics, correctional facilities, and SSPs. Syndemic approaches would be expanded to create efficiencies and broaden the reach to many key populations. Lessons learned during the COVID-19 pandemic will be assessed to identify ways to better improve capacity in small priority population-focused CBOs to increase the benefit of EHE prevention and care services. The focus on PrEP uptake would continue to be promoted and delivered, including a newly available injectable PrEP and working on increasing delivery of tele-PrEP. This funding also would support expanding implementation of innovative status neutral approaches to care delivery by providing peer-to-peer training and implementation support to health departments that currently are not providing such services. This all part of EHE and is one of the 5 equity interventions and is part of the focus to increase the reach of HIV prevention and care services to Black, Brown, and LGBTQ people as well as other priority populations.

¹ Robin L, Timpe Z, Suarez NA, Li J, Barrios L, Ethier KA. Local Education Agency Impact on School Environments to Reduce Health Risk Behaviors and Experiences Among High School Students. *J Adolesc Health*. 2022 Feb;70(2):313-321. doi: 10.1016/j.jadohealth.2021.08.004.

² Centers for Disease Control and Prevention, National Youth Risk Behavior Survey (YRBS), 2015 & 2017; Centers for Disease Control and Prevention, School Health Profiles (Profiles), 2014 & 2016

DHP is in the midst of a renaissance of community engagement with a focus on 3 types of engagement:

1. Information gathering, an example of which is a refresh of the domestic HIV program strategic plan
2. Topic-specific discussion, examples of which are cluster detection and response and status neutral approaches
3. Ongoing community-centered engagement. Community-centered engagement began in March when regional Town Halls were convened to educate, encourage, and focus on empowering local community implementation of the EHE Initiative. The goal is to work together to understand and address longstanding inequities and strategies that can be used to further nuance addressing those inequities.

At the beginning of April, CDC funded 36 CBO grantees in 18 states with \$400,000 in funding per grantee to focus on HIV prevention with young men of color who have sex with men and young transgender persons of color.³ Since the last group of grantees, 6 more organizations were identified, and each received an increased funding level. CDC also recently announced and received applications for a funding opportunity⁴ to support organizations that work in transgender clinics and partner with CBOs that focus on transgender populations to develop community-to-clinic models to integrate status-neutral HIV prevention and care services where people seek gender-affirming care. This takes advantage of navigation and other strategies that are designed to increase knowledge, confidence, and use of PrEP and other interventions.

One of the great innovations that came out of the COVID-19 pandemic was the self-testing program, which is being expanded and will be funded over the next 5 years to distribute 150,000 self-tests per year. Conversely, there were significant interruptions in care services due to the pandemic that have made surveillance data harder to interpret and more complex. The HIV Surveillance Data Tables will be released when the full reports are available and the commentary is able to guide how this is interpreted. Because of the disruptions, there are some derived estimates (incidence, knowledge of status, prevalence) that will not be possible to produce for 2020. Work is underway to update data collection to better capture these data, for which approval is expected by the end of 2022 from the Office of Management and Budget (OMB) and collection will begin in early 2023.

Division of Viral Hepatitis (DVH) Update

Carolyn Wester, MD MPH

Director, Division of Viral Hepatitis
National Center for HIV, Viral Hepatitis, STD and TB Prevention
Centers for Disease Control and Prevention

Dr. Wester shared some of the work that the DVH has accomplished recently to address health disparities in viral hepatitis (VH). VH elimination has moved from risk-based to universal recommendations among adults. In November 2021, the Advisory Committee on Immunization Practices (ACIP) voted unanimously to update the hepatitis B vaccination recommendations to include the following recommendations:

1. All adults 19-59 years and adults ≥ 60 with risk factors should receive hepatitis B vaccines
2. Adults ≥ 60 without known risk factors may receive hepatitis B vaccines

³ <https://www.cdc.gov/hiv/funding/announcements/ps22-2203/index.html>

⁴ <https://www.cdc.gov/hiv/funding/announcements/ps22-2209/index.html>

CDC formally published these guidelines in the *Morbidity and Mortality Weekly Report (MMWR)* on April 1, 2022.⁵ The move away from risk-based recommendations will help reduce health disparities by eliminating the need for patients disclose potentially stigmatizing risk factors and also provide healthcare providers with a simplified vaccine decision-making process.

As reported during previous CHAC meetings, CDC is currently updating its hepatitis B screening recommendations from risk-based to universal recommendations as well. This will complement the vaccination approach, as well as the hepatitis C and HIV screening guidelines among adults. The proposed updated recommendations are 2-fold. The first recommendation is that screening be performed at least once in a lifetime for all adults ≥ 18 years of age and the second is to expand existing risk-based testing recommendations for ongoing testing for additional groups, including people who are currently or formerly incarcerated people with a history of STIs, and people with a history of hepatitis C virus infection. These recommendations are currently available on the *Federal Register*⁶ for public comments, which closes on June 3, 2022. Formal publication of this update is anticipated later in the year.

The prevalence of hepatitis C is increasing among reproduction aged individuals and pregnant persons, with approximately 6% of perinatally exposed children becoming infected.⁷ Of the recommendations currently available, the most consistent is to test exposed children with a hepatitis C antibody test at or after 18 months of age. There is no clear guidance regarding hepatitis C RNA testing beginning at 2 months of age despite the fact that this testing may possibly decrease loss to follow-up and misidentification. CDC is working to develop evidence-based hepatitis C testing recommendations for perinatally exposed children to ensure that exposed infants and children are appropriately tested and linked to care and curative treatments. Peer review and public comments for these recommendations are expected to take place in Fall 2022, with publication anticipated in early 2023.

Viral hepatitis cannot be eliminated without also addressing the challenges posed by the national opioid crisis. People who inject drugs (PWID) are at high risk for viral hepatitis, HIV, and other infections. They also experience unique barriers to testing and treatments. Harm reduction service programs are a proven effective component of community-based programs to prevent the spread of infectious consequences from injection drug use. In 2019, the DVH established the National Harm Reduction Technical Assistance Center (NHRTAC) to strengthen the capacity of SSPs.⁸ DVH first partnered with the National Alliance of State and Territorial AIDS Directors (NASTAD) to build the infrastructure of this center. As the program grew, partnerships were expanded to include the National Harm Reduction Coalition (NHRC) and the University of Washington. Now in Year 3, the center has broadened involvement of the NHRTAC to include CDC's Injury Center and SAMHSA and National Association of County and City Health Officials (NACCHO) and 6 additional TA-providing organizations are joining for bridging expanded expertise and offering harm reduction from health departments and recovery communities, as well as experts from SAMHSA's Addiction and Prevention Technical Training Centers.

As part of the effort to build up comprehensive programs to support the needs of PWID, CDC released a NOFO in March 2002, Strengthening Syringe Services Programs (CDC-RFA-PS22-2208), with 2 key components that will increase access to harm reduction services for PWID. Component 1 will support the development of a national network of SSPs to facilitate

⁵ <https://stacks.cdc.gov/view/cdc/115806>

⁶ <https://www.federalregister.gov/d/2022-07050>

⁷ Centers for Disease Control and Prevention. 2019 Viral Hepatitis Surveillance Report. <https://www.cdc.gov/hepatitis/statistics/SurveillanceRpts.htm>

⁸ harmreductionhelp.cdc.gov

communication among SSPs and other harm reduction programs and health organizations trusted by the PWID community and improve data about SSPs by conducting an annual national survey of SSPs to document capacity, needs, access, and service gaps. Component 2 will increase support and resources to SSPs for implementation of these programs, including syringe distribution and disposal, testing, treatment, and prevention of the infectious complications of infections of injection drug use. This program will enhance and expand harm reduction services leading to reductions in new viral hepatitis infections.

In conclusion, the DVH will continue to promote innovative and holistic approaches to reduce health disparities and meet the needs of people living with or vulnerable to viral hepatitis.

Division of STD Prevention (DSTDP) Update

Leandro Mena, MD, MPH, FIDSA

Director, Division of Viral Hepatitis

National Center for HIV, Viral Hepatitis, STD and TB Prevention

Centers for Disease Control and Prevention

Dr. Mena reported that DSTDP is in the process of developing a new division strategic plan for 2022-2025. This effort will include alignment with the Sexually Transmitted Infections National Strategic Plan for the United States | 2021–2025.⁹ The new proposed goals will be to:

1. Prevent new STIs
2. Improve the health of people by reducing adverse (harmful) outcomes of STIs
3. Accelerate progress in STI research, technology, and innovation
4. Reduce STI-related health disparities and health inequities
5. Achieve integrated, coordinated efforts that address the STI epidemic

The new plan is projected to be finalized in early Fall 2022. DSTDP envisions a whole nation response to preventing and controlling STIs in the US that goes beyond disease to address the health and wellbeing of the individual, recognizing that this will require support of partners and collaborators.

The National Strategic Plan and the DSTDP strategy call for reductions in disparities and health inequities. This key approach will be reflected in NOFOs and activities to ensure that there is high population-level impact. The strengthening of STD prevention and control for health departments has had a tremendous response, with an additional \$200 million going to recipients each year for the next 5 years for which there is an emphasis on expansion of the workforce and to strengthen disease outbreak and response capacity by bringing on an additional 1800 staff members. DSTDP continues to strengthen its supplemental surveillance projects, including strengthening US surveillance of drug-resistant gonorrhea with the use of whole genome sequencing (WGS) to better understand the epidemiology of gonorrhea. Investments are being made in innovation, particularly in syphilis diagnostics and in training of Disease Intervention Specialists (DIS). Some of these innovations and trainings will be funded from the \$1.13 billion that was allocated to DSTDP last year through the America Rescue Plan Act.

⁹ <https://www.hhs.gov/sites/default/files/STI-National-Strategic-Plan-2021-2025.pdf>

The 2020 STD Surveillance Report¹⁰ was released in early April 2022 along with preliminary 2021 syphilis data. In 2020, there were increases in gonorrhea, syphilis, and congenital syphilis. Increases are being seen in syphilis and congenital syphilis for 2021 as well. Conversely, there was a 12.7% decline in cases of chlamydia from 2019. This decline is likely due to decreasing STD screening and diagnosis during the pandemic rather than a reduction in new infections since chlamydia is usually asymptomatic. While syphilis cases are increasing, they do present an opportunity for HIV prevention. Since 2015, the number of primary and secondary syphilis cases reported among HIV-negative MSM has surpassed the number of cases reported among HIV-positive MSM. While overall cases reported among HIV-positive MSM may be leveling off, there are no signs of syphilis slowing down among heterosexuals. Reported cases of primary and secondary syphilis cases increased 420% among women from 2011-2022. The intersection of HIV and syphilis presents a clear opportunity in which syndemic approaches can be beneficial to addressing these infections, as well as the conditions that contribute to their occurrence.

Along with the new plans, some key actions DSTDP is taking include identifying opportunities for collaboration and integration of services, increasing access to stigma-free healthcare, expanding partner services and DIS programs, improving STI diagnostics and therapeutics, and enhancing surveillance systems to inform public health actions and better understand root causes of increasing STIs at the national and local levels. For each of these activities, DSTDP is committed to a process that prioritizes access to and extension of services that address disparities and inequities. Social health services can be a gateway for overall health and wellness. DSTDP will move from a disease-focused approach to a social health promotion and wellbeing framework.

HRSA DFO Welcome and Update

Laura Cheever, MD, ScM

Associate Administrator, HIV/AIDS Bureau
Health Resources and Services Administration
CHAC Designated Federal Officer

Dr. Laura Cheever extended her welcome to new CHAC Voting Members, Mr. Lindsey and Dr. Markham. She also welcomed new NIH *Ex-Officio* member, Dr. Goodenow, and expressed her gratitude to Dr. Gaist for his years of service to CHAC as the NIH *Ex-Officio* member.

Dr. Cheever announced that Carole Johnson was named the HRSA Administrator in January 2022. Before coming to HRSA, Ms. Johnson served as the Testing Coordinator on the White House COVID-19 Response Team. She also served as the Commissioner of the New Jersey Department of Human Services, leading the state's largest agency and providing healthcare and social services to 1 in 5 New Jerseyans. During her tenure as Commissioner, the Department expanded Medicaid coverage of mental health and substance use disorder (SUD) services, created new Medicaid benefits to improve maternal health outcomes, and integrated Medicaid into the newly launched state-based Affordable Care Act (ACA) marketplace. Ms. Johnson served for more than 5 years as the Domestic Policy Council public health lead in the Obama White House, working on the Ebola and Zika responses, implementation of the ACA, and combatting the opioid epidemic. In addition to several key positions on Capitol Hill, Ms. Johnson was Policy Director for the Alliance of Community Health Plans, Program Officer with the Pew Charitable Trust health program, and Senior Government Relations Manager with the American Heart Association (AHA). Dr. Cheever welcomed Ms. Johnson back to HRSA where

¹⁰ <https://www.cdc.gov/std/statistics/2020/default.htm>

she previously worked in workforce policy, and she thanked Diana Espinosa for leading the agency as the Acting Administrator for the last year and a half. HRSA is fortunate to have someone with Ms. Johnson's experience and deep knowledge of HRSA's programs, as well as her passion about health equity in the work the agency does.

HRSA's HAB vision is optimal HIV care and treatment for all to end the HIV epidemic in the US. The mission is to provide leadership and resources to advance HIV care and treatment to improve health outcomes and reduce health disparities for people with HIV and affected communities. Health equity is a core concept of the RWHAP, which has been working many years to reduce disparities. It is very exciting to have a new environment in which health equity is in the forefront across the entire federal government.

HRSA is excited that the HAB website has been officially relaunched with a new look and the new URL of <https://ryanwhite.hrsa.gov/>, which should help people searching for information on the Ryan White HIV/AIDS Program (RWHAP). The website navigation has been updated and the content has been reorganized to help visitors find information and resources more efficiently.

Since the last CHAC meeting on December 1, 2021, the *National HIV/AIDS Strategy (NHAS, the Strategy)*¹¹ was released and provides stakeholders across the nation with a roadmap to accelerate efforts to end the HIV epidemic in the US by 2030. In order to guide the nation toward realizing the vision, the strategy includes 4 overall goals, which are to:

1. Prevent new HIV infections
2. Improve HIV-related health outcomes of people with HIV
3. Reduce HIV-related disparities and health inequities
4. Achieve integrated, coordinated efforts that address the HIV epidemic among all partners and stakeholders

The strategy has been used across HRSA and government to help focus efforts and refine the work that is being done in this area.

HRSA is developing an NHAS Implementation Plan that outlines specific actions to achieve the Strategy's goals and objectives. Representatives from across HAB and HRSA have been working to identify strategic policies, programmatic activities, and initiatives to leverage support of the goals, objectives, and strategies outlined in the plan as part of the Strategy implementation. Partnering across the federal agencies is a very important part of this step in the work. HRSA has actively engaged CDC, Administration for Community Living (ACL), Housing and Urban Development (HUD), and others in thinking about the work that needs to be done in order to achieve the goals. Given the Strategy's whole of society approach, HAB leadership conducted a series of listening sessions to engage directly with the RWHAP stakeholder community to hear thoughts and ideas on ways HRSA can support the goals and objectives outlined in the NHAS in the effort toward EHE. Key stakeholder groups included patient advocacy organizations, HIV provider organizations, constituency-based organizations, and coalition groups. Dr. Cheever expressed gratitude for the contributions of the many divisions and offices that took part in this collaborative effort, including HRSA's regional offices and CDC that were part of all sessions.

¹¹ <https://hivgov-prod-v3.s3.amazonaws.com/s3fs-public/NHAS-2022-2025.pdf>

The NHAS also calls for the development of a quality of life (QOL) indicator. The White House Office of National AIDS Policy (ONAP) asked CDC and HRSA to Co-Chair a federal WG to make recommendations. The WG's charge from the White House was to use existing federal datasets that include measures of QOL or measures that can assist in gauging QOL. ONAP held a community listening session to receive input on these datasets. The WG was asked to complete its work by May 2021. QOL has been part of the fabric of the RWHAP over many years. In the absence of a method to measure QOL, HRSA has been addressing it through various domains, such as housing instability, employment, and food insecurity. Critical thought also is being given to domains around health, wellbeing, and psychological factors and work has begun on a framework to conceptualize the efforts and identify work that still needs to be undertaken.

HAB has a relatively new and productive partnership with ACL. ACL's mission is to foster safe, high quality health care for the aging population. This is particularly important for the RWHAP where many clients are aging with HIV. In 2020, about 48% of clients in the RWHAP were over 50 years of age. The goal of this partnerships is to work together to share resources among recipients and cultivate partnerships with other federal and non-federal partners. HAB and ACL have collaborated on several webinars to share information about the RWHAP and to hear from ACL about their programs and services. HAB and ACL also have teamed up with training for ACL grantees and Ryan White recipients on the Older Americans Act (OAA) and Area Agency on Aging (AAA). There is a tremendous amount of expertise in the community on aging, which should be leveraged in the efforts to expand the work in the RWHAP in order to improve services for older people with HIV quickly.

HAB also has a longstanding committed partnerships with HUD. HAB is currently assessing how the RWHAP can better address the housing needs of people with HIV. Because HAB is not primarily a housing provider, they are grateful for the partnership with HUD. The focus traditionally has been on the federal Housing Opportunities for People with AIDS (HOWPA) program. HAB also is working to expand its efforts with HUD beyond the HOWPA program and to continue to work together to address the needs of RWHAP clients. HAB and HUD will continue to partner on educational events at the intersection of housing and HIV and other opportunities broadly across HUD programming.

The 2022 National Ryan White Conference (NRWC) on HIV Care & Treatment will be convened August 23-26, 2022. Dr. Cheever thanked the RWHAP community providers, recipients, and partner organizations who submitted a total of nearly 400 abstracts for consideration in the 2022 conference. Abstract approvals were sent out the week of April 12, 2022. In light of the constantly evolving COVID-19 pandemic, HAB has made the decision to host the 2022 NRWC virtually. This is a shift from the initially proposed hybrid format that included both virtual and in-person components. The conference dates will remain the same, but times will be adjusted to accommodate the different time zones. Recognizing the unpredictability of the COVID-19 pandemic over the last several years, HAB holds true to its commitment to providers, recipients, stakeholders, partner organizations, planning council members, and more than the half million people they serve every day to reduce any risk of potential COVID-19 transmission. All of the recipients, providers, stakeholders, and people with HIV who are a part of the RWHAP will have an opportunity to attend the conference and not be taken away from the communities HAB serves. This means that the RWHAP part-specific caps that were applied to the hybrid format no longer apply. The virtual format will utilize the same platform as the 2020 conference that had incredible engagement during the chat as sessions were occurring. All breakout sessions will be pre-recorded.

Turning to policy updates, transgender people with HIV continue to be a priority for HAB. There are tremendous disparities for this particular population. In December 2021, HAB released a letter to RWHAP service providers reaffirming the importance of providing culturally-affirming health care and social services to the transgender community as a key component of improving the lives of transgender people with HIV and eliminating health disparities. The letter is not a new policy or approach to the services delivered by the RWHAP, but builds upon HAB-funded initiatives that support patient-centered, trauma-informed, and inclusive environments of healthcare for people with HIV to help reduce medical mistrust and other barriers to adherence from transgender populations.¹²

To highlight a few RWHAP updates, 2 new Executive Summary documents have been published that are on the RWHAP website. The first is a high-level summary of what was learned during the 2021 EHE in the US listening sessions with public health leaders and communities mentioned earlier. This document discusses the key themes from those sessions and provides a high-level look at how HAB is moving forward to build on what has been learned. The second Executive Summary is based on the telehealth white paper that shares how RWHAP have been leveraging telehealth during the COVID-19 pandemic. Both of these publications should be useful to RWHAP.¹³

Moving to data updates, all states showed improvements in viral suppression among RWHAP clients by state from 2010 to 2020. However, some states continue to have room for improvement—particularly in the Southeast US. Also notable was a significant improvement in viral suppression in 2020 even though at that time, states and recipients were responding to the COVID-19 pandemic. Among key populations served by the RWHAP, viral suppression of all RWHAP clients was 69.5% in 2010 and 89.4% in 2020. The improvement in suppression occurred across all key populations. However, it is important to note that challenges remain in achieving viral suppression for certain populations. Most notably in 2020, there were disparities in viral suppression overall for African Americans and Blacks at 86.7%, transgender clients of 84.5%, youth 12-24 years of age at 81.5%, and clients with unstable housing at 76%. This illustrates that more work needs to be done.

Viral suppression increased for all RWHAP clients nationally by about 19.9 percentage points from 2010-2019. Key populations had even greater improvements in viral suppression. For example, viral suppression increased by 23.4 percentage points among African Americans. This demonstrates that while disparities remain, the disparity gap has been decreased. Among youth transgender populations and people who are homeless, larger disparities remain with significant work to do.

The inaugural *2020 HRSA HAB Ending the HIV Epidemic in the U.S. Data Report* was released and is posted on the HRSA HAB website. This is the first publication to highlight data submitted through the EHE Triannual Module data system. This module collected aggregate-level data 3 times a year on the number of new and existing clients receiving services and the number of clients prescribed antiretroviral therapy from EHE-funded providers. EHE recipients, sub-recipients, and stakeholders have been doing important work in response to the COVID-19 public health emergency to meet the needs of clients during that emergency while simultaneously doing incredible work in this new EHE Initiative that launched in March 2020 simultaneously with the COVID-19 pandemic nationally and submitting high-quality, complete EHE triannual data to HRSA HAB.

¹² <https://ryanwhite.hrsa.gov/sites/default/files/ryanwhite/hiv-care/gender-affirming-care-rwhap.pdf>

¹³ <https://targethiv.org/library/innovation-rwhap-telehealth>

Many EHE recipients used their EHE funding to expand and innovate the delivery of existing RWHAP service categories. For example, RWHAP EHE recipients focused on what could safely be accomplished during the pandemic such as emphasizing self-care within the community, leveraging virtual spaces, and staggering or scaling back activities in order to provide them safely. Recipients also introduced flexibilities that prioritize health and safety, such as offering telehealth and remote work for staff, contactless prescription delivery, e-prescribing, providing 90-day supplies of antiretrovirals, and delivering socially distant case management and navigation—something most providers had not done previously.

EHE recipients scaled up services to address new activities or activities where there was greater demand, such as transportation, rental assistance, emergency financial assistance, and food or delivered meals. Recipients also worked to streamline the client experience, including consolidating services in clinics and creating policies and procedures to simplify future client interactions. Beyond EHE, recipients were able to leverage their existing RWHAP knowledge, partnerships, experiences, and resources so their jurisdictions could respond to the COVID-19 pandemic. It is amazing what recipients have been able to achieve throughout this pandemic.

CHAC Member Discussion On CDC & HRSA Updates

The following questions, observations, and suggestions were raised:

- Dr. Gayles observed that all of the teams demonstrated the ability to be flexible in pivoting to new ways to deliver services to meet the needs of those who utilize CDC and HRSA services. Mental health crisis in children was significant before COVID-19 and is further exacerbated. This is a key moment in terms of responding to this need in terms of building infrastructure. Equity remains important as disparities continue to be seen in incidence across populations and continued gaps in access to services such as PrEP. There are exciting new funding opportunities from CDC and HRSA and continued inclusion of the SDOH and the impact that those play on service delivery. It also was affirming to hear the continuing commitment from both agencies in providing affirming services to different communities, given the political environment in many places across the country that potentially affect the way services are delivered. Given the increased attention on mental health in young people and the impact that mental health issues can play on risk-taking behaviors, he inquired as to how services are being implemented across the board in various divisions in thinking about rolling out new projects.
- Dr. Ethier said that from a school health perspective, DASH has layered in additional resources received from Coronavirus Aid, Relief, and Economic Security (CARES) Act dollars to transition some of the school services into the virtual setting and to help support the infrastructure that already had been created to connect youth to sexual health services and to mental health services. Schools received an influx of funds and an array of additional resources, but it is not clear whether they were able to use those funds effectively toward these efforts. There have been discussions with partner organizations to establish services outside of schools and determine the best way to connect with school districts. As often is the case with community-based services, a 2-pronged approach is needed. Something is needed to motivate the school district to create infrastructure to connect to services in the community, but that is not sufficient. It is also important to make a connection to the community to help them establish connections in schools. They have consistently seen that it is not going to be possible to “mental health professional” our way out of this. There are not sufficient trained mental health providers to be able to deal with the influx. Mental health services are just not available for adolescents. This also speaks to the pipeline issues. In

order to convince providers to train or retrain to work with youth, the mental health professional pipeline has to be made possible, affordable, and attractive.

- Based on the data Dr. Cheever presented, Mr. Driffin noted that close to 90% of people living with HIV return back to care. He wondered whether the data team would pose additional inquiries to determine why those individuals decided to stop care and ultimately return to care during the pandemic or connected to EHE activities, and how those findings could be incorporated into better healthcare delivery for people living HIV.
- Dr. Cheever indicated that they are not collecting this from the recipients. The reporting is kept high-level because of the burden on recipients. Many EHE programs do inquire about what keeps people out of care so that they can better respond in the future. A challenge over time has been the difficulty in finding people who are out of care, understanding who they are and the challenges they face. Dr. Cheever will take this idea back to the Project Officers.
- Dr. Mermin observed that the viral load suppression data highlighted by Dr. Cheever showed remarkable increases in viral load suppression with a 30-point absolute increase in 10 years and an almost elimination of racial and ethnic disparities in viral suppression. He wondered what the most important factors were that led to that increase, as well as how to get to the next 10% to achieve 100%. He also requested an update on the HRSA-initiated hepatitis C program that screened, diagnosed, and cured people in RWHAP of hepatitis C.
- Dr. Cheever noted that HAB has been focused on data quality and quality improvement. There have been several large collaboratives with hundreds of thousands of patients in which individual recipients assess their data and then experts, including people with lived experience, to help figure out what works through a quality improvement rapid cycle. A number of these over the years have been successful and the rates of improvement in these initiatives have been remarkable. That is why they are adamant about developing best practices communication so people can demonstrate improvements by publishing what works in this key population so others are able to replicate. There is some improvement with easier drugs to take, but overall improvement is due partly to specific quality improvement activities. The hepatitis C chart abstraction work slowed down during the pandemic because it is difficult to collect data at the national level, especially regarding treatment and sustained viral response. HAB has a chart abstraction contract through which these data were going to be collected in individual clinics, but that was delayed significantly by the pandemic. All they have at this point are anecdotal inputs.
- Given that many cities are experiencing increasing problems with homeless populations, Dr. So inquired as to whether CDC has programs to try to improve prevention, testing, and treatment for HIV and hepatitis in homeless populations and whether SSPs across the country are experiencing any pushback by states.
- Dr. Mermin indicated that there is a lot of interest in homeless populations at CDC. They have been engaging with HOPWA and HUD in general, and DDID has taken on a role of looking across the agency to determine whether there are ways to work at the more fundamental social determinants side. Housing and homelessness affect almost all aspects of public health, so CDC is increasingly trying to work in that field. In terms of SSPs, it is a project that takes concerted effort and continual monitoring and support over time. In some places, SSPs have been initiated and expanded and sometimes there is not a lot of pushback. SSPs become normalized with engagement with the community and law

enforcement, and when there is supportive legislation in the state or local areas that enable SSPs to continue over time. There are other places where SSPs are going well and then there is pushback for a variety of reasons (e.g., political conflict in the community, certain events that result in loss of trust with law enforcement or politicians, et cetera). There are a lot of services that cannot be offered now due to minimal resources, lack of technical capacity, and or lack of infrastructure.

- Dr. Daskalakis added that really great work is occurring with HUD beyond HOPWA in a more status-neutral space. One exciting area is the work with HOPWA to think about housing as an outbreak intervention which is moving in a great direction. They are looking at ways testing interventions can be deployed specifically in those environments as social determinants are also being addressed. DHP's most recent NOFO for young MSM and transgender women of color has a component that asks the grantees to select areas of social determinants to pursue, one of which is housing.
- Dr. Wester added that people who use drugs, injection and non-injection, and people experiencing homelessness are some of the populations most heavily impacted by the multistate outbreaks of hepatitis A, which now include 37 states and over 44,000 cases. The TA efforts that have been provided to states and other jurisdictions experiencing that have made a lot of inroads into those communities.
- Dr. Anderson emphasized how impressive the increases in viral load suppression and reduction in disparities were that Dr. Cheever presented. She asked how DASH plans to follow up on the data regarding mental health issues among adolescents, particularly the data on LGBTQ adolescents and the outsized concerns in these issues. This includes more than individuals who are HIV-affected. She asked whether the data on LGBTQ includes transgender and lesbian, gay, bisexual or if they were separated out. The issues are probably slightly different.
- Dr. Ethier indicated that for the ABES data, they were not able to include a question on transgender identify. At this point, that question is on the state optional list. However, they were able to include the transgender identify question on the ballot process for the questions to be included in the 2023 YRBS. They are optimistic that this question will be included on the national survey. Hopefully for the next CHAC meeting, she will be able to provide an update on some of the improvements they will be able to make for the 2023 survey. ABES was done in Spring 2021 and the regular YRBS was moved to Fall 2021. Approximately 30 states and locals included the transgender identify question on the state YRBS. This allows them to group those data together to look in more depth at those students.
- Mr. Lindsey noted that substance use is an area that has not had as much data to contribute to prevention efforts and healthcare engagement efforts, and that he was happy to hear about the marijuana data in Dr. Ethier's presentation. Particularly given the increase in stimulant use over the past couple of years due to isolation and other social dynamics that have arisen, especially in urban communities. He wondered if they have been able to or plan to collect those data.

- Dr. Ethier indicated that they do assess stimulant use as one of the substances. They did not find an impact of the program on stimulant use, but that could be because it was relatively low for young people—at least when those data have been collected. Prior to the pandemic, all substance use apart from alcohol and marijuana had been decreasing. They have not collected opioid data for long enough to know whether there has been an increase or decrease.
- Dr. Daskalakis added that the National HIV Behavioral Surveillance (NHBS) survey is able to tease out stimulant use, which is something that DHP is following.
- Dr. Cheever added that they are taking a deeper dive into SUD and what people are actively using in their chart abstraction survey, so that will be a topic every other year.
- With the current political climate regarding LGBTQ in Florida, Dr. So asked Dr. Ethier whether she is worried about the coming year in terms of how much progress can be made. Already there are mental health issues. He wondered whether the politicians know how much harm they are doing. He also asked whether it would be appropriate for them to raise this concern through a CHAC statement, perhaps.
- Dr. Ethier responded that as a federal employee, she was unable to comment on any particular state law or policy. She said that she is extremely concerned about whether the gains made over time in implementing the policies and practices that she mentioned are effective for all youth with respect to mental health and wellbeing. In 2018, close to 80% of schools had safe spaces for LGBTQ students, more than 90% had anti-harassment laws, and about 75% had professional development on inclusivity for teachers. That had improved dramatically over time, but now changes have been made to directly take some of those important practices out of schools. She is extremely worried about the mental health crisis for young people. Taking away those supports will be threatening not only for LGBTQ students, but also for other students. As she mentioned earlier, making schools more toxic for anyone makes them more toxic for all students.
- In terms of whether there is something CHAC can do, Drs. Gayles and Anderson will discuss this offline and will get back to the group about what is/is not within CHAC's purview as a committee.
- Mr. Riester noted that a bill recently passed the House that would criminalize certain amounts of fentanyl, which could increase the number of people who are incarcerated and also would require mandated substance use counseling. There is a very large problem with fentanyl across the country, so this is something to think about in the future. Regarding mental health status and LGBTQ youth, he asked whether there is a correlation to visibility, inclusion, awareness, and/or a specific geographic prevalence.
- Dr. Ethier responded that the ABES data is nationally representative, so it does not tie back to specific geographic areas. They do not ask about visibility, inclusion, and awareness in this survey. Therefore, they do not know whether the more "out" someone is increases the reaction and stigma associated with their identity. However, this is a very important question. It might be possible to look at some of these difference by state in the 2021 YRBS data. This did come up to some extent with regard to parental abuse questions related to

issues around whether healthcare providers and school personnel are required to report back to parents if they have conversations with young people about their sexual identity. They do not ask these questions, but it is difficult to imagine that there is not some aspect of being out to one's family and then experiencing abuse, otherwise they would not see the difference between students who identify as heterosexual and those who identify as LGBTQ.

- Dr. Markham added that as a youth sexual health researcher in Texas, she echoed Dr. Ethier's concerns. They hear a lot from school-based personnel and clinicians that the climate in Texas is definitely a concern in terms of the mental health of youth and also their families trying to be supportive of them. With the abuse cases and reporting cases, it is getting quite dire. Whatever CHAC might be able to do, she would love to be part of that. She also expressed interest in information about additional initiatives for provider training, influences, and other programs to address rises in congenital syphilis, for which Texas may be #1. There also is an overlap with teen STI rates in Texas.

Panel 1: Strategizing an Approach to Providing Comprehensive STI Services

Moderator: Robert McDonald, MD, MPH, LCRD, USPHS; Medical Officer, Division of STD Prevention, NCHHSTP, CDC

Addressing STIs in Mississippi

Thomas E. Dobbs, MD

State Health Officer

Mississippi Department of Health

Dr. Dobbs first shared a photograph from an 1881 photograph atlas on cutaneous syphilis to illustrate that history is reality and that a lot of work remains to be done. For instance, based on the 2020 published STD rates, Mississippi ranked first in chlamydia per capita by a substantial margin of almost 100/100,000 population higher than Louisiana, ranked second highest for gonorrhea, and tied for first place in primary and secondary syphilis rates. This is the worst STI performance he has seen during his tenure at the State of Mississippi. While that is awful and embarrassing, there are interventions for improvement.

There has been a transition in the landscape of care. The health department and its STD clinics traditionally have been thought of as a go-to location for STD treatment and diagnostics in Mississippi. However, data by ordering facility type in 2020 showed that the majority of STD cases were being identified primarily in private physician offices and other health clinics. Some reasons for this are the general transition away from public health services for clinical care and funding issues. Compared to 10 years ago, they have half of the nurses they had in 2010. They have less nurses now in 2022 than in 2019—even with the COVID-19 pandemic funds. While there is a paucity of providers in general, nurses are responsible for much of the frontline work in STI treatment. If the Mississippi Department of Health is addressing only 10% of the pie, they are missing 90% of the opportunity and must rethink how to address STIs in Mississippi.

To demonstrate a parallel lesson, the fertility rate in Mississippi has been declining gradually since 2001 other than an interesting increase from 2006 to 2008 that was observed across the country for unknown reasons. There also has been a decline in teen births in Mississippi, with the exception of an increase in 2007. Although fertility and teen birth rates have been

decreasing, the health department has been losing ground in providing reproductive health services. This suggests that there are solutions to the problem that transcend what a county health department or STD division can do, but depending upon third parties who do not have the same authorities or a more holistic view of STI intervention also raises a number of challenges in addressing STIs and HIV.

Community health centers offer an opportunity for interventions in Mississippi where there are 11 Federally Qualified Health Centers (FQHCs) that operate 69 school-based clinics. This presents an excellent opportunity to provide sexual health resources to young people who are at risk. The majority of chlamydia and gonorrhea cases occur among older teens and young adults in their early 20s. While there are only 69 school-based clinics currently, there are 530 high schools in Mississippi. This means that there are many uncovered locations that could be served.

As pointed out in Healthy People 2020, one of the correlates associated with STD transmission is social determinants of health (SDOH). Mississippi Department of Health has struggled to expand its role beyond just STDs. While they can get shots in people's arms, test for chlamydia, et cetera, they must address SDOH—most of which pertains to racial and ethnic disparities. Otherwise, they will continue to try to “bail water from a sinking ship.” The majority of STD cases are now among African Americans, which are a minority population. SDOH issues must be addressed to get ahead of the problem. These include racial and ethnic disparities, structural issues (including structural racism), poverty and marginalization, access to healthcare, substance abuse, stigma pertaining to sexuality and secrecy and/or HIV transmission, risky sexual network, and so forth.

Most adults and the vast majority of children in Mississippi have health insurance. However, about 24% of adults are uninsured. Mississippi adults 19-25 years of age represent a high-risk group who do not have access to care and impoverished communities are over-represented. There are multiple difficulties in Mississippi. They do not have contact tracing and treatment, especially within private clinic settings. If someone is diagnosed within the health department, they will be given a referral card. While Mississippi does not yet have partner expedited therapy, an effort to offer this option is underway. The private clinic setting does not have the same public health focus that county health departments and STD-focused clinics have. Stigma and reluctance to discuss sexual health among patients and providers is a major problem, especially in the era of a 15-minute medical visit—10 minutes of which are spent on a computer. Ensuring that clinicians are up front diagnosing people with STIs and that there is access to care are critical issues. Mississippi is a non-expansion state with no anticipation of that changing in the near future. This state also has a very high poverty rate, is a rural location, and has a low provider to population ratio. People with STIs or symptoms do not want to go to a local clinic for various reasons, which results in major delays in care.

There are many potential opportunities, such as using some of the lessons learned from the COVID-19 pandemic to move forward. COVID-19 provided an opportunity to build remarkable new partnerships that included making remarkable inroads with the Spanish-speaking community, faith communities, local leaders, and others. These partnerships should be fostered and translated into successes in sexual health and STI prevention, treatment, and diagnosis. Continued work must be done to advance partner expedited therapy, though it is going to be challenging to move that outside of the health department to places where the majority of people are being seen. Mississippi plans to perform targeted contact tracing. For a small state with a shrinking workforce and 30,000 cases of chlamydia, comprehensive contact tracing poses a major challenge, but an effort must be made to try to interrupt some high-risk sexual networks.

Telehealth offers a major opportunity. While Mississippi Department of Health already offers universal PrEP through free telehealth, it is currently underutilized. It also is important to break down silos such that all services are providing comprehensive care that are not focused only on STIs or HIV. Mississippi has a major challenge within its epidemiology infrastructure and is underfunding its workforce. Mississippi has one epidemiologist for HIV/STDs. The state also is traditionally unfriendly to government employees and tries to keep the wages artificially low. Hence, people who complete top-notch training programs are not flocking to the Mississippi workforce. Despite the challenges, Mississippi will continue to seek opportunities for improvement.

Innovative Models to Support New York City (NYC) Sexual Health Clinics

Joaquin Aracena, MA

Assistant Commissioner, Division of Disease Control
New York City Department of Health and Mental Hygiene

Christine M. Borges, MPH

Director of Program Implementation and Evaluation
New York City Department of Health and Mental Hygiene

Dr. Aracena described innovative models that the NYC Department of Health and Mental Hygiene (NYC Health) have incorporated during the COVID-19 pandemic to reach and continue to serve New Yorkers with sexual health services. NYC Department of Health went through a reorganization during the pandemic, so the Bureau of STI no longer exists and the clinics have been folded into the Bureau of Public Health Clinics (BPHC). Bringing innovative services to the community was done through innovative approaches such as telemedicine, an STI Hotline, STI Quickie, and a COVID-19 Pivoting Model.

The BPHC was created on July 1, 2021 and oversees the health department's clinics that offer direct services to New Yorkers. This includes 8 Sexual Health Clinics (SHCs), 4 Tuberculosis Chest Centers, and 9 COVID Express Testing and Vaccination Clinics. The rationale behind this reorganization was that under centralized clinical operations, they are in a better position as a bureau and agency to achieve their goals to integrate services where common interventions are effective; create new pathways to expand services, especially telehealth services that are new for NYC Health; implement innovative approaches; and improve resilience to budget challenges.

Pre-pandemic in 2017, NYC Health serviced close to 80,000 patients. Among them, 53% are MSM and 47% percent are men who have sex with women (MSW). The 4 clinics operating in 2021 saw less than 50,000 patients, the demographics continued to narrow, and they were still reaching similar populations. Interestingly, there was an increase in MSW presenting for services or who received services via telemedicine. In terms of the SHCs' annual volume, there was a peak in 2019 and a major decline in 2020 during the height of the COVID-19 pandemic. Clinic visits and telemedicine visits began trending back up in 2021. In terms of efforts to reduce sexual health disparities, the clinics offer same-day HIV testing and PrEP and post-exposure prophylaxis (PEP) and PrEP Jumpstart. Other services include STI screening and treatment, condoms, partner services, emergency contraception, QuickStart contraception, crisis counseling, and substance use services.

In terms of the impact of COVID-19 on SHCs, the BPHC is within the Division of Disease Control. Therefore, many NYC Health staff were deployed to the pandemic response and 7 of 8 clinics had to be closed as part of the deployment and lockdown. The Chelsea clinic in Manhattan remained open and NYC Health quickly had to identify a model on how to continue to serve New Yorkers during this time in the absence of the clinics. The telemedicine operation was launched by the end of March 2020 to provide all EHE services. Not only were they able to assess individuals during this time, but also they were able to prescribe. They quickly published an RFP to contract with a pharmacy to deliver medications to individuals' homes at no cost to the patient. An additional layer was added to the pharmacy delivery that included home HIV test kits.

In May 2020, they were able to reopen the Fort Greene Clinic with limited services, given that many staff were still deployed to the COVID response. In June 2020, express visits resumed, and long-acting reversible contraception (LARC) services resumed at one clinic. Express visits and LARC services resumed in the 4 currently operating SHCs in July 2020. The Jamaica clinic reopened in July 2020 with limited services and telemedicine was expanded as staff came off of deployment. By August 2020, COVID Express Clinics were opened in SHCs and Tele-PrEP began. They had about 12 weeks to convert spaces that were not previously laboratories into laboratories to be able to respond to COVID testing. Morrisania opened in November 2020 for limited services, so now there is representation in 4 of 5 boroughs. They do not have a presence in Staten Island. In July 2020, they were able to pivot one of the instruments being used for COVID testing to be able to do STI testing in parallel.

Telemedicine services included management of positive/abnormal STI tests results, with HIV treatment initiation for those diagnosed with HIV who wished to start HIV treatment for the first time; consultation for PrEP initiation for NYC residents ≥ 13 years of age, including daily PrEP and PrEP on demand; medical evaluation for those who think they have signs or symptoms of HIV; medical evaluation for those who might have or have been exposed to a HIV; contraception services, including emergency contraception and consultations for other contraceptive methods (e.g., pills, ring, patch, shot, LARC); and prescriptions for STI treatment and HIV home test kits. To highlight telemed trends, there was an increase in the volume of calls during the peak of the pandemic. However, this declined when clinics began to reopen and it was possible to work with community partners to link individuals to services. There were 523 Tele-PrEP visits in 2021. Among these, 376 (72%) patients visited a SHC post-telehealth visit within 14 days of the telehealth visit and 332 (88%) patients received PrEP medication on the day of their visit.

Services offered at STI Quickie Clinics include provision of services such that individuals are in and out of a clinic within a cycle time of under 30 minutes compared to 1.5 hours in regular SHC. Services offered include HIV testing with 1-minute results; and CT/NG testing with 24-hour or less results; syphilis serology testing and hepatitis serology testing for HEP A-B-C with results in 3-5 days. There continues to be an increase in STI Quickie Clinic visits that now reach capacity each day. The positivity rate of either gonorrhea or chlamydia is over 13%, which provides an opportunity to test/diagnose someone who is asymptomatic and engage in conversations with them on PrEP and additional services they may need. BPHC now operates 8 Covid Express clinics across Bronx, Brooklyn, Manhattan, and Queens within existing SHCs.

To highlight some expansion plans, STI Quickie Services will be scaled up in the outer boroughs with Fort Greene anticipated to come online in Summer 2022. A patient-facing scheduling platform will be implemented. A PrEP Continuity Clinic will open in Summer 2022. There are plans to build up an Emergency Response Unit to allow for pivoting between COVID

Express Clinics and STI services as needed, and future reagent cartridges will be explored for implementation as they are FDA-approved.

Minnesota Community Care

Erica Drake APRN, CNP

Medical Director, Health Start Clinics-School Based Health Clinics
Minnesota Community Care

Sandy Naughton, BA, CCE

Health Education, Health Start Clinics-School Based Health Clinics
Minnesota Community Care

Ms. Drake and Ms. Naughton described Minnesota Community Care's Health Start Clinics-School Based Health Clinics in St. Paul Public Schools (SPPS) and their comprehensive STI outreach. The Health Start School-Based Clinics began as a maternal and child health (MCH) organization housed in a hospital across the street from a high school. They realized quickly that teens, especially pregnant teens, were not keeping their appointments, even though the organization and school were across the street from each other. They were then given space within the school and now have 10 school-based clinics. Young people who have access to school-based care have much better health outcomes, and the mantra at the time was to make those clinics acceptable, accessible, and available and they still view their provision of services this way.

The clinics are designed with an integrated team approach that includes an Advanced Practice Provider, Mental Health Provider, Health Educator, Registered Dietician, Medical Assistant, and Clinic Coordinator. One of the school-based clinics is open to adolescents 13-22 years of age regardless of ability to pay. Confidential care is provided under the Minnesota Minors Consent Law, without notification to adolescents' families. Given that the Health Start School-Based Clinics can help to provide this care for free, it overcomes a barrier in other types of clinics that may bill insurance and send home an explanation of benefits (EOB). The 10 clinics within the SPPS see an average 4,000 unique patients a year between the 4 disciplines and have a total of approximately 25,000 visits.

In addition to the 4,000 students seen in the clinics, about 100,000 students are seen through classroom visits provided all year. They are often invited to Health and Social Studies classes to talk about a variety of topics (e.g., hygiene, risk reduction, risk management et cetera). Each year, CRUSH (Community, Restoring, Urban Youth, Sexual, Health),¹⁴ a partnership of youth serving organizations and community members, holds a statewide STI Day in June. CRUSH focuses only on chlamydia and gonorrhea on the day that youth come in. During the summer, 3 clinics are kept open so that young people never lose their access to health care. Even though the focus is on chlamydia and gonorrhea on the testing day, adolescents are invited back for a fuller panel of testing. On the CRUSH testing day, clinics can see as many as 50 to 70 young people in this stigma-free situation. When this began, the idea was to do testing for students who felt they might need testing. That felt very stigmatizing, so now it is presented as visiting the clinic to talk about staying safe for life.

¹⁴ <https://www.health.state.mn.us/diseases/chlamydia/crush.html>

This teen-friendly, stigma-free introduction to the clinics that focuses on outreach into the classrooms and beyond the clinic walls, offers walk-in testing and basic sexual health screening, and makes it fun and exciting (e.g., decorate the clinic, play music, have a raffle for attendees, provide treats, incentives, et cetera). These testing days are the first time some young people visit the clinic. This is the first time that they have visited the clinic, so there is visibility. While this was the first clinic to open in a school building, there are now thousands of school clinics. This is a wonderful way to provide adolescent healthcare. The SPPS school-based clinics are holistic in that they teach, test, and treat in a stigma-free manner. A longer screening form has been shortened just for CRUSH STI Day. Every adolescent who attends completes the screening form, which helps to determine what kind of care they need and provides contact information so that they can be reached for follow-up care if needed. They do make it clear that adolescents do not have to have had sex to attend a CRUSH STI Day, because it also includes education and outreach.

For ease of flow, only a urine screen is done for chlamydia and gonorrhea. The screening tool is used to schedule further education and screening for additional STI testing, including blood draws and throat and rectal screening. Condoms are provided to all students and as noted, the clinics can provide care for all students regardless of parental consent under the Minnesota Minor Consent law. The clinics within SPPS require parental consent for all services except reproductive healthcare. Clinic staff can help uninsured students apply for the Minnesota Family Planning Program (MFPP)¹⁵ to help assist with reimbursement rates for the services the clinic is able to provide.

The last CRUSH STI Day event was in Spring 2019 because SPPS did not return students to in-person education until the middle of April 2021. CRUSH STI Day 2022 is now being kicked off. During these events, approximately 400 teens are seen and about half of them are screened based on their sexual history and risk factors. There is about a 10% positivity rate.

CHAC Member Discussion on Panel 1

To focus the discussion, Dr. Anderson reminded CHAC members of the advice related to this topic that was requested from CDC/HRSA and asked them to be thinking about action items CHAC might address and vote on later in the business section related to these questions:

1. How can CDC/HRSA support the expansion of STI care to include ART and PrEP services in clinical care sites and service areas?
2. How can CDC/HRSA support the integration of comprehensive care into school health clinics?
3. How do we equip school districts with a means to improve the linkage of healthcare in communities?
4. What else does CDC/HRSA need to consider when expanding STI care?

The following questions, observations, and suggestions were raised:

- Dr. Gayles noted that during COVID times, health department directors often have been met with surprise and confusion from political and community leaders for not having tons of contact tracers or a sophisticated surveillance system to follow COVID cases, which health department directors frequently pointed out that this was a side effect of years of budget cuts due to under development/underfunding of public health infrastructure. He asked how NYC was able to leverage CARES Act funding to support their rebranding and if they were

¹⁵ https://www.dhs.state.mn.us/dhs16_137813

able to identify new potential funding streams for other public health programs to support their work.

- Mr. Aracena indicated that there was a lot of cross-collaboration among agencies and hospitals throughout the city leveraging any current infrastructure.
- Dr. Dowler reported that North Carolina also is a non-expansion state, and they experienced a lot of the same issues as Mississippi. She has worked very hard over the last couple of years to expand PrEP access within the Medicaid family planning benefits. While this is a much smaller benefit, she encouraged Mississippi to reach out to their Medicaid partners. North Carolina was able to get everything within that program except for the drug, which can be obtained through HRSA's program to make it reimbursable for folks and to encourage health departments and FQHCs to reach out to that population that is essentially uninsured. An important part of North Carolina's initiative was that men need family planning as well.
- Dr. Dobbs indicated that Mississippi does have a full benefit for a family planning waiver for PrEP and they pay for the medicine as well. The problem is that it is underused.
- In terms of EOBs, Dr. Dowler indicated that North Carolina has viewed the EOBs being suppressed as a requirement for any Medicaid Claim. Particularly for managed care companies, EOBs cannot go out to the homes because North Carolina Medicaid does not want that to be a barrier for care. They want school-based health clinics or health departments to bill Medicaid as a payer source whenever possible so they can save their dollars for the uninsured. Some areas of the country experience barriers with school boards as well.
- Ms. Drake clarified that the public assistance program does not send home EOB, but private insurance does. Minnesota has only a handful of Planned Parenthood and other types of clinics left since so many have been closed over the last 10 years. Adolescents without access to school-based clinics suffer even more without access to other types of clinics. They are able to have a pharmacy in their school-based clinics through their 340B funding that permits them to provide various types of oral contraceptives, and they work with their obstetrics team to get IUDs placed.
- In terms of CHAC's role on advising CDC and HRSA, Dr. Greene inquired as to how the committee could support expansion and perhaps advise on how federal support could help with the interplay with local or state policies that are more restrictive. Given that the workforce is a challenge across all sectors right now, she also wondered what would help to increase the workforce or work in Mississippi or other areas that perhaps are not as desirable.
- Dr. Dobbs said that while he knew it was a pipe dream, the most beautiful thing that happened during COVID-19 was the HRSA portal. People used that like it was a de facto way for things to happen. His dream would be to have a HRSA portal for these other needs. In a non-expansion state, there are still major financial barriers for people to get access even to FQHCs. People who are undocumented are really in trouble because they do not have proof of income and are paying market rates for healthcare in a community health center. It would be helpful to find a way to have no cost visits for community health centers. The health department is the only place with no cost care, except for a few free clinics that do not provide reproductive health services. A lot of activities must happen, but there often are not enough people to get to the desired depth. Part of the issue pertains to deciding

what to do and handing off other activities to partners who are better suited for them. The issues with the epidemiology component involve low pay and the need to create a training program locally since people in Mississippi tend to stay there. Some strides have been made in pay, but now they do not have enough human resources (HR) staff to bring on new people. It is literally like trying to build a sandcastle in a hurricane.

- Dr. So commended NYC Health for thinking about expanding the usage of the laboratory capacity they built for COVID-19 to test for other diseases. He asked whether hepatitis A, B, and C testing is offered to all the patients who have no history of previous testing, infections, and/or who have not been vaccinated. CDC recently published a study that showed that in addition to the current recommendation, offering people a one-time hepatitis B test also would identify an estimated 1000 people every year who acquire hepatitis B from sexual activities and will save vaccine doses if they already have been infected or have immunity.
- Mr. Aracena said it was based on certain categories originally. Recently, they began offering testing and vaccination to all patients.
- Mr. Lindsey pointed out that while there is discussion about “risky sexual networks” and “social sexual networks” in the HIV area, he had not heard that as much in terms of STIs. He wondered whether there were opportunities to evolve the language to talk about “open sexual networks” instead of “risky sexual networks” in the future in terms of engaging communities in thinking about getting tested for STIs. He asked whether prophylactic interventions are a dead conversation in terms of STIs, even after the success of COVID-19 vaccines and some promising thoughts about the potential for an mRNA HIV vaccine. Consideration also should be given to work that is being done at the global level and whether that might make sense for local communities, such as the Dean Street Clinic in Atlanta that used some of the resources from the EHE planning. There are a lot of advantages to 24/7 online access to schedule STI screening and treatment, order HIV self-tests, order condoms and lubricants, obtain information to connect with health literacy training online or in-person, et cetera.
- Dr. Dobbs noted that Mississippi is making an effort to implement interventions in the community at the highest impact points. Part of that involves targeted contacts investigation and work with community partners to find the engagements that can pay the most dividends. When there are many bottlenecks, it creates “inverse energy” and more bottlenecks. Mississippi cannot even do GIS mapping because they cannot assemble staff. There is a lot of infrastructure to build out, but this is hard, laborious, boring, and no one wants to fund generalized infrastructure that is self-sustaining and builds on each piece.
- Mr. Aracena noted that like the Dean Street Clinic, the Quickie model was born out of being so busy during that pandemic that there were no opportunities for static. They were able to innovate and continue to evolve to try to stay ahead of the curve of not just the pandemic, but also in order not to lose sight of EHE as well. They were fortunate at NYC Health to have one STI Quickie model at Chelsea that they were quickly able to mirror and convert to a COVID-19 express testing model, which gave them the opportunity to expand out and extend their vision. It would have taken decades to stand up laboratories at all of the SHCs. Due to the pandemic, all sites have them. Now it is a matter of finding the funding to be able to turn them on and pivot them to extend the service.

- Dr. Gayles emphasized that with the pandemic funding streams drying up, consideration must be given on how to sustain the work that everyone has put in place. This is likely to be an ongoing conversation. As Mr. Lindsey raised earlier, what happened to creative science and technology to improve and prevent STDs and HIV (e.g., better diagnostics, point-of-care self-tests, better vaccines and more of them for a lot of infections, better treatments, et cetera)? These are all areas that respective parts of NCHHSTP have been exploring in terms of their role in moving these efforts forward, including working with NIH, FDA, and industry partners. This is a nascent topic that is ripe for growth, and it is possible that in the next CHAC or the one after that, it may be possible to talk more practically about what can be done about it. CDC is going to be funding new diagnostic research into syphilis testing.
- Dr. Mermin observed that telemedicine is a great opportunity to provide services and reduce inequities. One of the biggest obstacles for Tele-PrEP is the diagnostics. That is also true for STD diagnosis. There are good scientific data showing that the OraQuick® HIV test is insensitive compared to other tests in early infection and that it can be problematic particularly in regard to PrEP. Some anecdotal cases have reported several months before seroconversion with OraQuick®. He asked whether NYC Health has capacity to use surveillance and/or other data sources to look back at all of the people who participated in Tele-PrEP and use some form of person years of PrEP use and then HIV seroconversion rates. If it is low, that could be very useful for other jurisdictions that are considering this kind of programming and it could be compared to people who are taking PrEP in-person.
- Mr. Aracena clarified that their Tele-PrEP was more of a consult in which everything would be started for the individual, but it would not be initiated until the first day at the clinic. The at-home test kits were provided with a prescription for any STI treatment. They are still considering ways to evolve their Tele-PrEP initiative.
- Ms. Borges added that they did perform a surveillance match with their colleagues in HIV to assess HIV seroconversion.
- Dr. Anderson observed that the presentations offered nice snapshots of the urban, rural, and school-based settings. She asked whether the individuals presenting the Quickie Clinics differ from those who are accessing different services, and whether they were advertised differently. She asked to what extent each group was using peers or community-based workers in all settings, which could be enormously helpful in extending health services, reducing stigma, education, and using a task-sharing and task-shifting model.
- Mr. Aracena indicated that the demographics of the people accessing the Quickie and COVID Express services were very similar. When they expand to Fort Greene in the summer, they will be able to do further comparisons. NYC Health funds a lot of community organizations, FQHCs, and various institutions, so there is a lot of cross collaboration in NYC and they also have CBO liaisons within the BPHC who work closely with community partners. During this pandemic, they have been able to expand their reach and collaboration in different settings that they did not work closely with previously, so they want to continue to leverage those partnerships going forward as they begin to pivot their instruments as well.
- Ms. Naughton indicated that Minnesota Community Care was partnering with a college in St. Paul on a Youth Advisory Board (YAB) that was taking off and doing well until COVID hit, so it all has been very distanced. Before COVID, they had representatives in each of the schools working with these college students who helped develop materials that are used in

the clinics, as well as advising them on activities they can host, distance learning, et cetera. They plan to continue this YAB work as COVID restrictions are lifting.

- Dr. Anderson asked whether anyone was using Peer Navigators (PN) as part of a telehealth system for education, counseling, linkage to care, et cetera.
- Ms. Naughton said that they have done a great deal of peer education around issues of sexual safety, especially in terms of HIV. They have not done this in telehealth, partly because of the need to be careful about not providing incorrect information. In previous peer education, a professional staff member went with peer educators to assist them with answering questions.
- Dr. Akolkar asked if/how compliance is being monitored of those people who are receiving PrEP via telehealth.
- Dr. Dobbs said it is early and they do not have enough data to support it, but it is challenging for them to keep folks on PrEP regardless. Telehealth is no different.
- Ms. Borges said that in New York they are not currently retaining patients who they start on PrEP. They start it and then refer to a community provider. The most they do is make sure the patient attends the appointment made for them. They are given a prescription for the first month, except during COVID-19 it was 3 months because it was a lot harder to get a quick appointment in most places. Once they are connected to their community provider, they are no longer a patient.
- In terms of funding streams, Dr. Mermin pointed out that they are interested in becoming as efficient as possible with providing holistic services to certain people and in certain venues. That applies to STIs at STI clinics, community health clinics, or student health clinics. Yet the funding streams tend to come from multiple sources. With that in mind, he asked what could be done better.
- Dr. Dobbs suggested finding a clearer way to braid funding. Project Officers see things very black and white, it is almost impossible to blend multiple streams of funding.
- Ms. Naughton added that something that makes school-based clinics work so well and have such good outcomes is that the team is very integrated. That is always hard to find support for, especially considering the effects of SDOH on every kind of behavior and health outcome. They are very attached to their integrated program and when they have had a chance to do that in their larger ambulatory care sites, they find better outcomes as well.
- Mr. Aracena noted that because things are so selective in these buckets, they have to continuously seek additional funding to complete the wheel on the vision and the pathway they are trying to reach.
- Ms. Borges agreed, emphasizing that they all do their best to piece together different funding sources. That can be complicated in terms of reporting and justifying/explaining to Project Officers the best they can.

- Dr. Gayles asked Ms. Drake and Ms. Naughton to speak more about having achieved a higher level of integration of services in the school-based program comparable to community services and to share more about how within that integration, how they have tapped into the community resources to improve and enhance linkage to care services and any particular best practices that could be scaled up into a community model that CDC and HRSA could support.
- Ms. Naughton indicated that within their own system, they have a very comprehensive health history and they are very careful about linking within their own system to all the disciplines and they have developed community resources that go beyond what they can do within their clinics, which are widely available to everyone within their full organization. That is a constant build and a constant nurturing of those resources.
- Ms. Drake added that having the services that are most needed for adolescents within the school-based program results in easy access to care (mental health, nutrition, therapist for counseling, et cetera) and students do not have to leave school to go outside for services. While the mental health team is able to bill and get reimbursed, health educators and registered dietitians cannot except through private insurance. There is a lot of frustration with medical assistance and public funding in terms of not getting reimbursement for those services. Seeking funding for these services is a never-ending process.
- Mr. Lindsey asked whether the NCHHSTP retired program coordination and service integration (PCSI) in the reorganization.
- Dr. Mermin indicated that PCSI is not retired and is a core part of the center's strategy. They prioritized certain aspects of PCSI that they thought would make the biggest difference, but then COVID hit, and people were shifted in general. They have a new reinvigorated conceptual framework that initially was called PCSI 2.0, but now they are thinking of pulling in the conceptual framework of syndemics because it is very similar but more cutting-edge and pulls in a slightly different concept of population health and holistically valuing people, groups of people, and populations. PCSI was focused more on structured service provision. There is a lot of support from the Division Directors, but NCHHSTP recognizes the difficulty in identifying the specific interventions, research areas, programmatic areas, and policy areas that will make the biggest difference. That was part of the reason he asked the question about just funding streams, because that comes up a lot and has been insoluble at times. Congress allocates funds by diseases and conditions, but public health thinks about health by individuals, populations, and sometimes geography. COVID showed the importance of the skills, energy, and smarts of DISs. The new resources CDC has for DISs which Dr. Mena discussed is a comprehensive approach to COVID, infectious diseases, and STIs. Regardless of size, most health departments focus on at least HIV and STDs and sometimes venture into hepatitis and TB. They might be able to build on that.
- Dr. Anderson encouraged everyone to think about the advice that has been requested from CHAC by CDC and HRSA and potential motion, action items, suggested WGs, et cetera that they might discuss during the business meeting.
- Dr. Dowler emphasized the importance of standardizing payment for testing more broadly. Right now, this is very limited. She is in a state with 100 counties and every health department has its own funding stream that is different from the one next, none of which is patient-centered. A gold standard is needed for screening availability and provision of tests

for everybody regardless of where the testing is done (e.g., home, laboratory, clinic), geographies, political issues, or financial status.

- Dr. Gayles summarized that this panel discussion highlighted significant continued funding needs, the need to be flexible and nimble in services provision, reimbursement issues, the need to define what is included in a post-COVID approach, et cetera. Just as a zip code should not determine life expectancy, it also should not determine what type of STI services, testing, et cetera are available. Consideration should be given to the potential impact on the incidence of new cases that could be arrested and curved if services were readily available.

Panel 2: Leveraging Policy to Advance HIV, VH, and STI Priorities

Moderator: Michael Williams, MPH; Office of Policy, Planning, and Partnerships, NCHHSPT, CD

Hepatitis C: State of Medicaid Access

Adrienne Simmons, PharmD, MS, BCPS, AAHIVP
Director of Programs National Viral Hepatitis Roundtable

Julia Harvey, JD
Clinical Fellow, Center for Health Law and Policy Innovation
Harvard Law School

Dr. Simmons and Ms. Harvey provided an overview of a 5-year project called *Hepatitis C: State of Medicaid Access*,¹⁶ recent progress and the current state of hepatitis C treatment access in Medicaid programs; remaining barriers to care; and next steps for this project. To provide a brief history of hepatitis C treatment access in Medicaid, the first direct-acting antiviral (DAA) Sovaldi came to market in 2013. It was commonly known as the “thousand dollars a day pill.” Due to the high cost of treatment, most payers imposed restrictions on access to treatment. In 2014, a group of researchers published a preliminary review of Medicaid coverage policies, which showed that restrictions to hepatitis C treatment were common and commonly enforced by prior authorizations. In 2015, CMS issued guidance to states that Medicaid must cover medically necessary DAAs in the hope that Medicaid programs would voluntarily loosen their restrictions. Following little voluntary progress, in 2016 Washington Medicaid was sued for requiring severe liver damage in order to access hepatitis C treatment. In 2017, the Center for Health Law and Policy Innovation (CHLPI) and the National Viral Hepatitis Roundtable (NVHR) launched *Hepatitis C: State of Medicaid Access*, which detailed Medicaid restrictions by state.

At its core, the *Hepatitis C: State of Medicaid Access* project was developed in direct response to treatment restrictions occurring in the Medicaid Program. The project conducts individual state-by-state assessments of treatment access policy and tracks national trends in treatment access over time. This project is meant to serve as a resource to state officials and advocates to help provide a comparative lens across Medicaid programs as to the state of hepatitis C treatment access, and to identify clear opportunities for policy improvement within state Medicaid programs. Historically, this project has tracked 3 primary types of treatment restrictions in hepatitis C treatment Medicaid programs. The first type is restrictions based on fibrosis score or the amount of liver damage a patient would have to have before they were eligible for treatment. The second type is restrictions based on patient abstinence from alcohol

¹⁶ www.stateofhepc.org

and drugs, most often implemented as a required sobriety period of 1, 3, or 6 months to access treatment. The third type is restrictions based on which providers are eligible to prescribe treatment. In some cases, states would narrow the pool of providers eligible to prescribe (e.g., hepatologist, gastroenterologist, infectious disease doctors). These restrictions have been tracked because federal agencies and courts have declared that they are incompatible with federal law, and it is known that these types of restrictions have had severe impacts on individuals who are trying to access care who otherwise certainly would benefit from treatment.

In terms of progress over the last 5 years, there continue to be severe restrictions and states that have been hard-hit by hepatitis C. In terms of prior authorization (PA), 12 states now allow access to hepatitis C treatment without requiring a PA for most patients. Those states include: Washington, Louisiana, New York, California, Indiana, Wisconsin, Missouri, Michigan, Rhode Island, Virginia, Alaska, and Massachusetts. Oregon will soon be the 13 state to join this list. The majority (67%) of these states removed PA without using a subscription or what is called a “Netflix model.” This is a tremendous improvement that will help streamline access to treatment by eliminating burdensome paperwork.

Moving to fibrosis, the most progress made to date has been removing this barrier, with 33 states having either eliminated or reduced their fibrosis restrictions. Only 2 states have restrictions remaining. Regarding sobriety, many states have required patients to abstain from substances or alcohol for a specific period of time before approving hepatitis C treatment despite injection drug use driving new infections. Fortunately, 29 states have loosened their sobriety restrictions and the majority of states no longer require a minimum period of abstinence. While many improvements have been seen with restrictions related to substance use, this remains the most widespread barrier of the barriers that are currently tracked. Important improvements have been seen in removing prescriber restrictions, with 28 states having scaled back on prescriber restrictions. However, barriers remain in 18 states that require specialist involvement to prescribe hepatitis C treatment and 1 state that requires prescriptions to be written by a specialist.

Despite the progress that has been made in terms of access to hepatitis C treatment within Medicaid programs, it also is known that fibrosis, sobriety, and caregiver restrictions are not the complete universe of barriers to hepatitis C treatment. Over the last few months, in an effort to understand what some of these barriers are and specifically how they impact patients, the project team has been soliciting input from patients, providers, policy-makers, and others with the goal of understanding how to improve tracking and reporting out on state Medicaid programs to best meet the needs of individuals seeking access to hepatitis C treatment. Over the last few months, the team hosted a public listening session, disseminated a public survey, and convened a provider-led steering committee to identify the most pressing barriers. In terms of the breakdown of the 275 individuals who participated in the survey, the majority (~52%) of responses were from providers and other members of the healthcare team, followed by government staff (~23%), advocates (~11%), individuals personally impacted by hepatitis C and others (~6%).

What was learned from these conversations was that there are many key barriers to hepatitis C treatment and access beyond what has been tracked to date. Many of these have not previously been comprehensively tracked across Medicaid programs. This is not a complete list of everything that was identified, but barriers include the PA process, chronic infection diagnosis, time-based laboratory values, genotype reporting requirements, adherence assessments, retreatment restrictions, specialty pharmacy requirements, and differences in requirements between Medicaid fee-for-service and managed care. Responders indicated that all of these really play a role in meaningfully inhibiting access.

In terms of the impact of these barriers, they have heard anecdotally and objectively that these barriers result in delays, denials, and interruptions to care and ultimately impede the ability to eliminate hepatitis C by 2030, particularly among communities who are disproportionately impacted by hepatitis C. Rhode Island estimated that PA can take between 45 to 120 minutes per patient, not including time addressing denials and appeals. Patients are frequently lost to follow-up due to administrative barriers at every step of this process. The following quotes from the survey describe the impact of these barriers:

“In my state, there is actually investigation into adherence for other medications for the patient. For instance, if a person has picked up their diabetes meds late before, [Medicaid] will deny [hepatitis C] treatment.”

“The burdens include the wasteful cost of repeat labs and negative impact on patients regarding cost and access to transportation. Genotype results have a long turnaround time, sometimes creating delays.”

“Some of the specialty pharmacies have requirements to speak with the patient before mailing the medication. It becomes a barrier, and possibly even a delay in treatment.”

The impact of these barriers also is evident in data recently published by CDC, which shows that the number of people who initiated hepatitis C treatment in the US declined from 2015 to 2020.¹⁷ The National Academies of Sciences, Engineering, and Medicine (NASEM) has estimated that at least 260,000 people must be treated each year to eliminate hepatitis C by 2030. However, only 120,000 people on average are treated each year and that number continues to decline in the context of the COVID-19 pandemic.

In terms of next steps, the project team is currently in the process of updating *Hepatitis C: State of Medicaid Access* project to reflect what has been learned about these other barriers to care and to include many of them in the assessment process moving forward. Based on the stakeholder input received, the state evaluation criteria have been updated and the project team is in deep data collection mode. The release of the updated report cards and full report is targeted for late May 2022.

Senate Bill 159 (SB 159) HIV PrEP & PEP For California Pharmacists Leveraging Policy Changes for STI and VH Prevention, Testing, and Treatment

Marisa Ramos, PhD

Chief, Office of AIDS

California Department of Public Health

Dr. Ramos presented on Senate Bill 159 (SB 159), HIV Pre-Exposure and Post-Exposure Prophylaxis (PrEP & PEP) For California Pharmacists. As a reminder, oral PrEP is a once-a-day pill (Truvada/Descovy) that can reduce a person’s risk of acquiring HIV by up to 99% from sexual contact. Among individuals who inject drugs, there is a 70% reduction in acquisition of HIV. PrEP provides maximum protection when taken daily for 7 days after engaging in anal sex and 20 days for vaginal sex or injection drug use. It is important to note that while an injectable version of PrEP given once every 8 weeks has been approved by the FDA, it is not relevant for SB159. Pep is a regimen to reduce the risk of contracting HIV after an exposure. PEP is the

¹⁷ Eyasu H Teshale, MD, Henry Roberts, PhD, Neil Gupta, MD, MPH, Ruth Jiles, MS, MPH, PhD, Characteristics of persons treated for hepatitis C using national pharmacy claims data, United States, 2014–2020, Clinical Infectious Diseases, 2022; ciac139, <https://doi.org/10.1093/cid/ciac139>

“Plan B” of HIV that reduces the risk of contracting HIV if taken in the 72-hour window from the moment of possible exposure. PEP is most effective when started as soon as possible and typically consists of Truvada or Descovy plus another agent, which is usually an HIV integrase inhibitor. Unlike PrEP, PEP is a complete antiretroviral regimen against HIV. Once prescribed, it must be taken for 28 days.

SB 159 was introduced by State Senator Weiner and was signed into law on October 7, 2019. SB 159 provides authority for pharmacists to determine if patients meet clinical criteria for PEP or PrEP and allows them to furnish 30 or 60 days of PrEP once every 2 years or furnish 28 days of PEP. The pharmacist must inform the patient’s primary care provider (PCP) or provide the patient with a similar report to give to their provider themselves. The law also requires that before providing PrEP or PEP, pharmacists have to complete training that is approved by the California Board of Pharmacy or that is delivered by an accredited provider. Free training is available.¹⁸ Participants must pass a quiz with a 70% score, maintain the record of training for 4 years, and retrain every 4 years. There is a website¹⁹ to find pharmacists who are permitted to provide PrEP/PEP and who have signed up for the website. It is important to note that pharmacists are not automatically enrolled in this website.

Patients must meet certain conditions to qualify for pharmacist-furnished PEP. The pharmacist must screen the patient and determine that exposure occurred within the previous 72 hours. The patient must meet the clinical criteria for PEP consistent with CDC guidelines, and there must not have been any signs or symptoms associated with acute HIV. Given that education must be provided, the patient may not waive the consultation with the pharmacist. The pharmacist is required to provide information to the patient’s PCP or provide the patient with a list of where to seek care or start PrEP if they do not have a PCP. PEP initiation should not be delayed for baseline laboratory testing, but the patient should follow-up with a provider for laboratory testing.

To qualify for PrEP, the patient must have a negative HIV test in the previous 7 days (negative antigen/antibody test or negative rapid test) and no signs or symptoms associated with HIV infection. The patient must not be taking any contraindicated medication. As with PEP, the patient must receive education and may not waive the consultation. The patient must consent to follow-up with a PCP for additional prescriptions. The pharmacist must maintain a record of the prescription provided and provide information either to the PCP if the patient has one or provide a list where the patient may seek additional care for PrEP.

In summary, pharmacists have played an important role in HIV prevention for decades. They provide condoms, sterile syringes, and supporting adherence to HIV treatment. The notion behind SB 159 is that pharmacists are uniquely situated to improve access to new preventive tools, PrEP, and PEP—especially for patients who are underserved. There are typically pharmacies within walking distance or nearby. Pharmacists also have relationships with prescribers and can support linkage to care for ongoing PrEP prescriptions, HIV testing, and laboratory monitoring. Financial assistance is available on the PrEP-AP Webpage.²⁰ Evaluation of implementation of this program begins this year to assess use, barriers, and facilitators.

Leveraging Policy Changes for STI and VH Prevention, Testing, and Treatment

Rachel McLean, MPH

Chief, Policy and Viral Hepatitis Prevention
Sexually Transmitted Diseases (STD) Control Branch
California Department of Public Health

Ms. McLean reported on additional policies and laws passed in California, as well as their implications. In terms of background, STD rates increased significantly in California between 1990-2019. As syphilis rates increased among people of childbearing age, congenital syphilis cases increased as well to an alarming 446 cases in 2019. This is included cases of fetal demise and stillbirths, which are preventable and should never have happened. California also bears a significant burden of chronic hepatitis B and C based on the most recent data. From 1989 to 2016, the cumulative total of chronic hepatitis B cases newly reported to CDPH was 287,087. From 1994 to 2018, the cumulative number of chronic hepatitis C cases reported to CDPH was over 700,000. This does not take into account the many people living with hepatitis B or C who remain unaware of their infection, meaning that these are probably under-estimates. STI testing volume decreased during the COVID-19 pandemic, which highlighted the need for alternative testing options.

Within that context, there has been interest in creative strategies that can be used to increase all hepatitis testing. Two bills were signed into law, Senate Bill (SB) 306 (Pan, Chapter 486, Statutes of 2021)²¹ and Assembly Bill (AB) 789 (Low, Chapter 470, Statutes of 2021)²² that healthcare providers (HCP) in California are now required by law to follow. Effective January 2, 2021, California law now requires syphilis screening in pregnancy per CDPH guidelines. This includes third trimester screening in pregnancy. SB 306 also provides liability protections for prescribers and pharmacists dispensing expedited partner therapy (EPT) for chlamydia and gonorrhea. This is very exciting, given that prescriber concerns about liability have been a barrier for a number of years. California also had stricter laws related to the use of Clinical Laboratory Improvement Amendments (CLIA)-waived rapid tests. SB 306 now will allow HIV test counselors who are trained and certified to use CLIA-waived rapid tests. AB 789 requires primary care facilities to screen adults for hepatitis B and C, which was modeled after the law in New York and appears to be the first law that requires screening for both.

SB 306 also requires health plans to cover at-home STD tests, which is particularly important due to the increased use and comfort that arose with home tests for COVID-19 that could help pave the way for at-home tests for other diseases. The SB 306 definition of at-home STD tests is, "A product used for a test recommended by CDC guidelines or USPSTF that has been CLIA-waived, FDA-cleared or -approved, or developed by a laboratory in accordance with established regulations and quality standards, to allow individuals to self-collect specimens for STDs, including HIV, remotely at a location outside of a clinical setting." CDPH has spent a lot of time examining each word in this definition, given that it is somewhat cryptic. It has been reported that FDA is working closely with companies to help them achieve FDA approval standards for at-home tests. The SB 306 at-home STD testing coverage requirement is complicated. Specific coverage requirements vary by payer depending on which state agency regulates their products. Medicaid (Medi-Cal) does not have to reimburse for at-home STD tests until specific billing codes are created, including American Medical Association (AMA) Common Procedural Terminology (CPT) Codes and CMS Healthcare Common Procedure Coding System (HCPCS) Codes.

²¹ SB 306 full text: https://leginfo.ca.gov/faces/billNavClient.xhtml?bill_id=202120220SB306

²² AB 789 full text: https://leginfo.ca.gov/faces/billNavClient.xhtml?bill_id=202120220AB789

In terms of next steps, CDPH is in the process of developing fact sheets to summarize various aspects of SB 306 and AB 789 for dissemination to HCP, payers, local health departments, and CBOs. The fact sheets are now going through the clearance process. They also are monitoring testing company efforts to request new CPT and HCPCS codes that will be needed for at-home test reimbursement. CDPH has a formal evaluation plan in place and is exploring options for how to evaluate the impact of these bills.

Louisiana's HCV Elimination Plan

Anthony James, MS, MA, MSHCM

Deputy Director of Programs
STD/HIV/Hepatitis Program
Louisiana Department of Health

Mr. James reported on the progress that has been made on Louisiana's HVCV Elimination Plan that was launched in July 2019 and is rooted in several strategies. One of the primary strategies is the establishment of an innovative payment model. The plan also seeks to expand provider capacity to treat hepatitis C; educate the public related to the availability of a cure; expand screening and expedite linkage to HCV treatment; strengthen surveillance systems to identify and diagnosis; and link those who are identified to care and treatment as part of Louisiana's "Big Bet." As part of the Big Bet, Louisiana Department of Health (LDH) has undertaken several large-scale projects to improve health conditions within Louisiana. Since the launch of the Big Bet in 2019, a total of 10,759 persons have access to treatment for hepatitis C. That includes 9,302 persons within the Medicaid population and 1,457 persons who are incarcerated.

In terms of the breakdown of characteristics of Louisiana's Medicaid and corrections populations, the majority of folks (60%) who have access within the Medicaid population are male and 40% are female. In the incarcerated population, 96% have been male and only 4% have been female. While there is a fairly good distribution race and ethnicity, approximately 59% of those accessing Medicaid treatment are white and 60% of those within the incarcerated population are Black. It is important to have that historical context to understand that a disproportionate number of persons of color are incarcerated compared to those who identify as White. The largest distribution of those accessing treatment within the Medicaid population are between 30-59 years of age, with a similar trend within the corrections population.

As everyone knows, even the best laid plans have hiccups. Since the launch of the plan in 2019, one of the biggest hiccups has been COVID-19. Being a Southern Gulf state, hurricanes also impact Louisiana significantly. Hurricanes Ida, Laura, and Zeta and an ice storm all had major impact on the Southwestern portion of the state in 2020 and 2021. Prior to this prescription model, about 61 persons on average were accessing a hepatitis C treatment. That number increased significantly to about 390 persons on average. Due to COVID-19 spikes, that average decreased to about 290. It is important to note that for persons on Medicaid, treatment is calculated using DAA claims data. Due to delays in reporting of claims data, numbers from recent months are preliminary and are an undercount.

Since July 15, 2019 over 9,300 persons have accessed treatment for HCV through Medicaid; 9,133 persons have started treatment for HCV through Medicaid for the first time; 7,930 persons who have accessed treatment have completed it; 6,394 persons have accessed treatment because of Medicaid Expansion; 612 providers have written prescriptions for DAAs for the first time; and last HCV RNA was positive for 585 persons who did not complete treatment. In order for all of this to work, it was necessary to examine some policy changes.

Several of those dealt with Medicaid in terms of lifting provider restrictions and the sobriety and fibrosis requirements.

It is important to understand that while over 9,300 individuals have been treated, others have been identified who are currently enrolled within the Medicaid group who are accessing one of the 5 managed care organizations (MCOs), which helps fulfil Medicaid's charge. Close to 16,000 persons with a positive RNA have been identified who are currently enrolled but who have not been treated. In terms of the last 2 years of this iteration of the statewide elimination plan, a lot of energy and attention will be placed on examining this group in more detail and on examining additional strategies that can be put in place to help lead these folks to a cure.

Based on data from July 15, 2019 through August 31, 2021, over 8,100 individuals in Medicaid had started treatment. Of those, over 7,000 (87%) completed treatment and over 5,200 (65%) had sustained virologic response (SVR) testing performed. Of those, approximately 4,700 (90%) achieved SVR and 514 (9.8%) had a failed SVR. Examining the Medicaid population by birth sex, 88% of females who started treatment completed treatment and 87% of the population of who started treatment completed treatment. There was a larger rate of SVR failure within the male population (10.5%) compared to the female population (8.7%).

By race and ethnicity, 93% of American Indian/Alaskan Natives (AI/AN), 87% of Blacks, 83% of Hispanic/Latinx, and 8% of Whites who started treatment have completed treatment. Of those who failed treatment, 10.2% were White, 9.3% were Black, 9.3% were Hispanic/Latinx, and 7.7% were AI/AN. By age, 80% of persons 18-29 years of age, 84% of persons 30-39 years of age, 89% of persons 50-59 years of age, and 88% of persons ≥60 years of age completed treatment and achieved SVR. Among those who experienced failure, the highest failure was among persons 18-29 years of age at 19%, followed by persons 30-39 years of age at 11.6%, persons 40-49 years of age at 9%, persons 50-59 years of age at 8.9%, and persons ≥60 years of age at 6.6%.

Assessing completions and failures by regions helps LHD prioritize regions that may be experiencing more difficult challenges. Also of interest is that 653 providers have prescribed for the first time. Determining where those providers sit within the state and using provider details can help identify and work with the regions with slower increases in new providers prescribing DAAs for the first time. From a regional perspective, Region 9 (13.7%), Region 2 (11.9%), and Region 1 (10.8%) had the highest rates of failure. Regions 4 (6.6%), 5 (6.9%), and 6 (6.5%) are doing somewhat better. Region 7 (3.7%) has had the most success, which is the Shreveport/Monroe area. Among persons who have identified as having an opioid use disorder (OUD), 84.9% have completed treatment versus 93.2% with no OUD. The completion rates for males and females seem to be fairly consistent, while there is slightly variation in terms of race and ethnicity and by age group. There are some variations from a regional perspective as well.

To summarize, Louisiana has made significant progress in addressing that HCV epidemic. If not for COVID-19 and severe weather conditions, it is anticipated that more people would have been treated. Based on data received earlier in the day, the number of individuals accessing treatment from the Medicaid and corrections populations is close to 11,000 combined.

Transitions Clinic Network**Shira Shavit, MD**

Family Physician

Executive Director & Co-founder

Transitions Clinic Network

Dr. Shavit explained that the Transitions Clinic Network (TCN) is a national non-profit organization that supports health system transformation for primary care clinics that are serving communities disproportionately impacted by incarceration. In San Francisco in 2006, TCN developed an evidence-based model of primary care for people returning home from incarceration. All of the community health centers employ CHWs with histories of incarceration within primary care teams to address the health and well-being of people returning from incarceration. To date, they have worked with 48 primary care clinics in 14 states and Puerto Rico.

People who are incarcerated are disproportionately impacted by a variety of chronic medical conditions, HIV, and substance use. People who are incarcerated have 3 times the prevalence of HIV, a much higher prevalence of hepatitis C with rates approaching 30% to 40%, and increased risks of STIs of 30% to 40%. Incarcerated people also have higher rates of chronic medical conditions and high rates of SUD and mental health conditions. With 95% of people returned home, the primary care system is a natural place to think about providing care to these individuals since they have multiple, complex, comorbid conditions. It is important to remember that in terms of cross-sector collaboration and working across systems, the carceral system and the health system have very different cultures and that really dictates a lot of what can be done and how. The punitive aspect of the carceral system sometimes plays out significantly and can impact what is known to be best practice for caring for people in the health system.

While people may not receive great care while they are incarcerated, people's health actually worsens when they are released from incarceration. Their HIV or SUDs may become worse, their viral loads may increase, they are more likely to be hospitalized post-incarceration, and they are more likely to die. A seminal study showed that people were 12 times more likely to die in the first 2 weeks post-incarceration from drug overdose, cardiovascular disease (CVD), suicide, or cancer. While great strides have been made on a policy front via ACA and Medicaid Expansion, many people who previously did not get Medicaid now have Medicaid and are eligible for services upon release. Having that Medicaid card is not always enough to get people in the door to treatment and it does not always translate to increased engagement or use of services.

That is because people face tremendous barriers when they come out of incarceration that are not just about access to care or having insurance. There is little continuity of care between systems. People may not even get medications or if they do, they get a shortened supply of medications that is not enough to bridge them to the health system. They have competing priorities, with all of the SDOHs evident (e.g., housing, employment, food on the table, stigma and mistrust with the health system due to negative experiences prior to incarceration, et cetera). These are Black and Brown communities that have experienced discrimination at the hands of health systems and then have negative experiences in the carceral system, so it is no wonder that they have a healthy mistrust of systems when released. They also face a lot of challenges in navigating complex services and services in the community that may not meet their needs.

The TNC Model of Enhanced Care was created to try to build capacity in the community health side. While it is easy to point the finger at the carceral system as not being a robust health system, the outside health system also was not meeting the needs of people returning home. Services need to be enhanced in community health systems to provide patient-centered services and engage people into care. In collaboration with communities, the TNC Model of Enhanced Care was created. This model is based on existing primary care clinics where each clinic hires CHWs who have experienced incarceration in prison or jail, most of whom have felony convictions. TNC also works with the clinics to ensure that they are providing patient-centered services like treatment of hepatitis C, HIV, OUD, behavioral health conditions, et cetera. They also work with the clinics to build cross-sector collaboration with the criminal legal system, as well as many other systems to address SDOH (e.g., re-entry organizations, community networks, faith-based networks, family systems, behavioral health system, public health system, tertiary care system, housing system, et cetera). This forces clinics to open their walls and be more contiguous with these important systems in supporting the care for people who are coming home.

This model has been successful because it follows what the community dictated as being needed. They have iterated on the model and have studied it, which has shown that this is an evidence-based model of care. Hiring CHW with lived experience in incarceration and embedding them into clinics has reduced urgent care utilization. For instance, a randomized control trial (RCT)²³ was conducted in San Francisco that assessed 200 people with chronic medical conditions or >50 years of age just released from prison. All of them were engaged into care by CHWs with lived experience. They were then randomized to either staying in the TNC or receiving primary care in the remainder of the system. They found that patients in the program had 50% fewer ED visits in the first 12 months post-release, and that having CHWs engaged study participants at much higher rates into primary care than is seen in the community.

Some information has come from unpublished administrative data from one of TNC's programs in Santa Clara County in California that works very closely with their jail.²⁴ Their health system is part of the jail health system as well, so they were able to make appointments in the jail for people pre-release, but only 33% of people were going to their appointments. When CHWs with lived experience go inside and meet people in the jail, the appointment attendance rates increased to 70%. This demonstrates that the CHW component is critical in bridging systems and engaging people in care.

A propensity-matched study²⁵ in Connecticut of enhanced primary care on contact with the criminal justice system among individuals recently released from prison to New Haven compared to individuals who were released to Hartford where there was no transition clinic program. This study found that individuals in the TNC program had fewer preventable hospitalizations and fewer probation and parole violations. They were spending 25 less days re-incarcerated in the first year post-release. The takeaway from this is that when investments are made in the health system to support these populations, costs can be reduced and outcomes can be improved in other sectors.

²³ E.A. Wang, et. al. AJP 2012 Jul 19

²⁴ Data provided by Dr. Ari Kriegsman, Santa Clara Valley Health & Hospital System 2017

²⁵ E.A. Wang, et. al. BMJ Open 2019

The last 2 years have laid the groundwork for the opportunity to build more bridges between carceral systems and health systems. Because of COVID-19, correctional leadership for the first time really understood what it meant to the importance of bridging these systems. Like everything else in the pandemic, many of these disparities and the need to address them became evident. Many of the statewide systems within TCN built stronger bridges with their carceral systems to be able to connect with people pre-release and provide care coordination systematically from those systems back to community health systems, and back to networks of patient-centered services in the community.

The timing of that groundwork has been fortunate in that some major policy shifts are emerging in the country, such as policies to waive the Medicaid inmate exclusion policy. When people are incarcerated, they are excluded from using Medicaid for their routine services. The idea would be to turn on Medicaid 30, 60, 90 days, pre-release from incarceration to allow health systems or other entities in the community to help provide care coordination from one system to the other. Another policy opportunity relates to providing targeted services to people returning home from incarceration. In California, individuals returning from prison or jail are eligible for enhanced care management services, which is a team-based approach to support people in navigation of the health system and around SDOH. Recent legislation that was passed and pending supports the idea of Section 1115 Demonstrations that would allow for states to turn Medicaid on at some point pre-release to bridge the carceral system and the community health system.

On paper this sounds feasible, but it is important to recognize that it requires a lot of system transformation. The primary care system requires tremendous system transformation to successfully care for this population. In the carceral system, there are many barriers to cross-sector collaboration and a lot of transformation is needed there as well. It is important to recognize that some of the barriers are structural. For instance, having 35 prisons across a very large geography could be a major barrier for local entities that support individuals coming out in terms of meeting with patients and supporting them in the transition home. Other barriers that may play a role include the leadership in place, lack of discharge planning services, lack of meaningful health information exchange, absence of timely identification/access to patients, lack of telehealth services, limited access for all types of community service providers, the siloed nature of carceral systems, patient mistrust, and/or isolation from/lack of community partners. Much remains to be done to build better capacity within the carceral system to enable partnerships with health systems.

The TCN has demonstrated that the policy strategy of supporting the integration of CHWs into health systems who have lived experience of incarceration means that these individuals can give back to their communities to make a difference to improve health outcomes, and health systems can contribute to reversing the harms of mass incarceration by providing job opportunities for people who normally are excluded from health systems because of their criminal record. This really is a win-win.

CHAC Member Discussion Panel 2

To focus the discussion, Dr. Anderson reminded CHAC members of the advice related to this topic that was requested from CDC/HRSA and asked them to be thinking about action items CHAC might address and vote on later in the business section related to these questions:

1. What policy changes are needed to improve access to care and prevention services and tools for HIV, other STIs, and viral hepatitis among populations disproportionately affected by these infections?
2. What policy-making partnerships should CDC/HRSA establish or expand to improve care and prevention among these populations?
3. What are the opportunities for CDC/HRSA to inform and collaborate with states on evidence-based policies that establish enabling environments to decrease HIV, other STIs, and VH?

The following questions, observations, and suggestions were raised:

- Regarding non-viral hepatitis and hepatitis C, Dr. Mehta said it is clear that barriers are disproportionately faced by PWID and other marginalized populations. Related to the barriers pertaining to testing, genotyping, and pharmacy pick-ups described, a recently published study demonstrated that in a global population, people with chronic hepatitis C can be treated with minimal initial monitoring and providing all 84 tablets with little in-person contact. The study demonstrated that it was safe and that SVR rates were comparable to other real-world studies of persons with hepatitis C. This is important to think about in terms of policies going forward and data collection on barriers and acceptability of providers on such an approach.
- Dr. Dowler emphasized that getting Medicaid Expansion in every state would be amazing and that establishing CPT and HCPCS codes for at-home testing is critically important in terms of billing and reimbursement. CHAC probably could have some influence on this effort and perhaps could make a recommendation about this.
- Dr. Mermin asked what advice Dr. Simmons and Ms. Harvey could give to CDC and CHAC about how the agencies could help states and local jurisdictions do X, Y, and Z to make a major difference in terms of helping them make the changes recommended.
- Ms. Harvey emphasized that there are many reasons why policies changed over the last 5 to 7 years. For instance, prices have changed, the Center for Health Law and Policy Innovation brought litigation in a lot of states based on the fact that the restrictions were illegal, and there has been a ton of very forceful patient advocacy around these issues. Thinking about the specific questions Dr. Anderson read is that federal guidance in this space would be very valuable. Thinking back to the 2016 Bulletin that was jointly put out in the HIV space around treatment and prevention by CDC, HRSA, and CMS has been an essential tool in some of her other work to help move the needle on Medicaid access. There is an opportunity for a similar initiative in the Hepatitis C space as well.
- Dr. Simmons added that another helpful tool states had over the last few years was the HHS Hepatitis C Medicaid Affinity Group (Affinity Group), which engaged in collaborative efforts between Medicaid, departments of health, corrections, et cetera to discuss innovative payment models. Many have cited this group as a catalyst for demonstrating that evidence-based policy change and evidence-based programming can make major impacts.

- Dr. So noted that it would be beneficial to know how many state Medicaid programs are covering hepatitis C treatment among incarcerated populations, particularly given that over 20% of incarcerated populations are estimated to have hepatitis C. It is clear that evidence-based policy change has made an impact, such as requiring pregnant women to be screened for syphilis, hepatitis B and C screening law, and linkage to care law. He emphasized the need to address health disparities/inequities and incentives/laws for providers to incorporate recommendations from various bodies (CDC, HRSA, USPSTF) into health records, waivers, and screening recommendations/requirements. CDC and HRSA should reach out to electronic medical record (EMR) providers to incorporate recommended screenings, linkage to care, and clinical support/decision tools to ensure that patients are identified and receive appropriate treatment.
- Dr. Anderson agreed that while there may be guidance or policies in place, in hectic daily 10- to 15-minute visits with patients, it is difficult for this to rise to a priority. Also, there may be issues related to lack of knowledge. Having decision aids in the EMR is invaluable.
- In terms of Dr. Shavit's comments about the policy suggestion Dr. Wester made during her presentation about ensuring the best price restrictions in Medicaid do not preclude access of strategies for incarcerated populations at the state or county level justice-involved populations, particularly for hepatitis C treatment and other expensive medications. Louisiana has used 340B pricing, but she asked whether there are any examples of jurisdictions that have successfully been able to put waivers in place for that.
- Dr. Shavit clarified that in the study in which they were assessing cost savings for patients who were receiving care in their program compared to other programs, they did a propensity match for another city in Connecticut and found that they had a reduction in preventable hospitalizations and parole probation violations. The cost savings was primarily on the criminal legal side with 25 days or less incarceration. While she was not specifically talking about pharmaceuticals, investments in Medicaid saves costs in other sectors. No states have successfully waived the Medicaid exclusion policy yet. CMS had a listening session and is developing some guidance based on that. Multiple states have applied, including California, but none have been approved yet to her knowledge. However, it is an emerging opportunity.
- Dr. Wester asked whether there has been any integration of a requirement for hepatitis C screening among pregnant persons. Through claims data, they are seeing about a 30% uptake of hepatitis C screening among pregnant persons and they would like to see that increase quickly.
- Dr. So indicated that the California law is based on recommendations from the USPSTF, which recommends screening for all adults for hepatitis C. Because universal screening has become the law in California, it makes it much easier to implement screening in EMRs. He has been trying to convince Kaiser and other large groups to introduce all of the USPSTF recommendations into EMRs. As of this month, Stanford has incorporated universal hepatitis B and C testing, even though the USPSTF recommendation is not quite universal for hepatitis B.
- Dr. Ramos indicated that they started a pilot project in Orange County, California to provide medication to individuals who are HIV-positive within that county incarceration system. It is paid through the CDPH AIDS Drug Assistance Program (ADAP), which is a mixture of general funds versus HRSA funds. They are currently going through an estimate package.

It looks like they will be able to expand to more counties if they are interested in participating in the program. Some of the more conservative counties were not testing everyone for HIV as they entered some of the jails. To ensure that screening is done, treatment for those found to be positive will be paid for by CDPH versus using the county's general funds. The hope is to expand to at least 6 more counties that have shown interest.

- Dr. Anderson said she was impressed with the recent state laws in California and their innovations have moved this topic along. She observed that one barrier seems to be that there are so many different county and state laws. While it is not clear if/how CDC/HRSA could impact that, perhaps a central compilation of innovative strategies as laws arise could be beneficial. Access to knowledge about innovations in some states might be very appropriate in terms of pushing the discussion forward in other states.
- Mr. Williams indicated that NCHHSTP funded the National Conference of State Legislatures (NCSL) to create a Legislative Data Tracking System.²⁶ That is exactly what the system is designed to do, and the system refreshes every 2 weeks. As states introduce pieces of legislation that fit certain key words across all of these areas, including laws that affect healthy youth and sex education curriculum, these will be displayed. It is easy to ask NCSL to make adjustments to the system to ensure that everything is captured.
- Dr. Dowler pointed out that even when there are laws, they are very hard to track and enforce. She noted that the Guttmacher Institute maintains a good listing.
- Dr. Mermin said he was intrigued by the differential aspects of the pharmacy program for PrEP that Dr. Ramos described. Based on the examples presented, it seems that the emergency aspects of receiving PrEP through pharmacies is harder than receiving PEP. The ongoing benefit of having a pharmacist as a provider is lost if they can give only a starting dose. While receiving a starting dose can be helpful, he wondered why the PrEP restriction of 30-60 days once every 2 years was included and whether it could be changed.
- Dr. Ramos indicated that there is a history. Originally, there was a push from some of the clinics that had a pharmacy within their organization since it would be easy for someone to present, be started on PrEP, and then go next door to see their PCP. While she did not have the data, PrEP has been under-utilized from what she has seen. However, the specialty pharmacies within those clinics would not like it to go away because they can administer and at least start PrEP. Implementation has been slow. The state is seeing more dispensing for PEP than for PrEP. Because of COVID-19, this was averted to do the training that is required.

Wrap Up Day 1

Travis Gayles, MD, PhD
CHAC Co-Chair, CDC Appointee

Jean Anderson, MD
CHAC Co-Chair, HRSA Appointee

Dr. Anderson observed that it had been a tremendous day with a lot of information that began with reports from CDC and HRSA. They heard some statistics on continued increases in syphilis and congenital syphilis, as well as increases in adolescent mental health concerns and

²⁶ <https://www.ncsl.org/research/health/state-public-health-legislation-database.aspx>

the need to find ways to address these. Some of these negative statistics were offset by the data CHAC heard about the dramatic improvement in viral load suppression overall and in key populations; demonstrable reductions in disparities; and very impressive successes reported in CDC-funded programs in schools to decrease risky sex behaviors, safety concerns, and sexual assault. She congratulated CDC and HRSA for their work and deep thinking in terms of integration and collaboration strategies and the use of the syndemic approach to deal with these interrelated problems, which is critical. In the afternoon, they heard about innovative models of care and continued challenges. Some of the innovations and the ability to address challenges are constrained by state- and county-level policies and legislation, funding, and lack of time or knowledge on the part of physicians. They also heard about a lot of flexibility and innovation during the COVID-19 pandemic and in many cases inspired by it. They heard about the role of integration of different relevant infections, as well as issues related to SDOH.

Dr. Gayles expressed his gratitude for the great presentations and for the work everyone does on a daily basis in order to be able to present the data that you provide. He further emphasized the continued notion of evolution in terms of the need to be modern and think outside the box moving forward with regard to funding to sustain programs and to continue to pivot to keep efforts moving. This includes the ability to speak fluently to young people to make sure that they are engaging and they are able to effectively communicate their needs in safe spaces. With regard to engaging in conversations about increasing services that folks need, it is important not to use mental health as a crutch to not do the necessary work to root out racism, systemic issues, bias, transphobia, and all of the other things that significantly influence the potential success of projects in the future in terms of being able to sustain funding and considering the significant variability in terms of the differences in geography and the level of services available. A lot of tremendous work has been done but there are still many headwinds in the way moving forward.

Adjourn

Dr. Mermin officially adjourned the meeting for April 26, 2022 and CHAC stood in recess until 11:00 AM ET on April 27, 2022.

Day 2: Welcome and Roll Call

Jonathan Mermin, MD, MPH (RADM, USPHS)

Director, National Center for HIV, Viral Hepatitis, STD and TB Prevention
Centers for Disease Control and Prevention
CHAC Designated Federal Officer
Centers for Disease Control and Prevention

The proceedings were called to order at 11:00 AM ET. Dr. Mermin welcomed participants to the second day of the CHAC meeting. He conducted a roll call and asked members to disclose any new COIs. COIs did not differ from the previous day and are reflected in the table on page 8 of this document. He confirmed that 21 members were in attendance, which established quorum for the CHAC to conduct its business on April 27, 2022.

Special Presentation: Turning the Tide on Self-Testing and Sample Collection

Moderator: Elizabeth DiNenno PhD; Division of HIV Prevention, NCHHSTP, CDC

FDA Regulation of HIV Self-Testing Devices and Self-Collection Kits for HIV Diagnosis

Julia Lathrop, PhD

Associate Deputy Director
Division of Emerging and Transfusion-Transmitted Diseases
US Food and Drug Administration

To lay the groundwork Dr. Lathrop explained that in vitro diagnostic devices (IVDs) are medical devices per Section 201(h) of the Food, Drug & Cosmetic Act (FD&C Act) [21 CFR 809.3] that defines medical devices as: “Reagents, instruments, and systems used in the diagnosis of disease or other conditions . . . in order to cure, mitigate, treat, or prevent disease intended for use in collection, preparation, and examination of specimens from the human body.” Clearly, self-testing and self-collection kits are considered to be medical devices. As such, they are subject to the provisions of the FD&C Act. It also means that regardless of whether a device is regulated either in the Center for Biologics Evaluation and Research (CBER) or the Center for Devices and Radiological Health (CDRH), it is subject to the provisions of the FD&C Act.

The review of all IVDs, regardless of where they are reviewed or what their use is, is based on the balance of the benefit and risk to the individual and that the data provide a reasonable assurance of safety and effectiveness of the device. A risk for an IVD is providing an incorrect result to the individual. For an HIV diagnostic, that would be a false positive or false negative. Risks from receiving a false negative could be that an individual is denied life-sustaining treatments and could transmit a life-threatening disease. The risk for having an incorrect result, especially a false negative for HIV, is very high. One element of assessing for reasonable assurance of safety and effectiveness and the balance of benefit/risk pertains to whether the device does what it is intended to do.

All IVD reviews begin with a review of the intended use because this is where the determination of the risk lies. Intended use pertains not only to the HIV diagnosis, but also the sample type, population, conditions (e.g., professional use only or self-collection). The risks all lie in the intended use and it is from the intended use that the review logically flows. It is important to keep in mind that one device may have more than one intended use and those uses can have different risks. For example, HIV diagnostics and viral load monitoring have very different risks

associated with incorrect results. The risk involved and what is necessary to mitigate the risk determine whether a device is categorized as a Class I, Class II, or Class III. Colloquially speaking, those mean low, moderate, and high risk, respectively. However, that is not entirely accurate because there can be a high-risk device like an HIV diagnostic that can be safely regulated as a Class II device. FDA is in the process of reclassifying HIV diagnostic supplemental and viral load tests from Class III to Class II. The risks associated with an incorrect result have not changed; these are still high-risk devices. Having approved many devices over many years allows FDA to establish special controls, which are provisions associated with the demonstration of the safe and effective use of the device. Establishment of special controls allows for successful mitigation of the risks in order for FDA to safely review these as Class II devices requiring a PMA. Special controls can be requirements such as performance criteria, post-market reporting, et cetera, that are necessary to provide reasonable assurance of safety and effectiveness of the device. Because reviews are based on intended use, there is no expectation that all Class II devices should have the same special controls since the risks associated with each intended use differ.

Turning specifically to FDA regulation of HIV self-testing devices (HIVST), HIV devices are Class III devices that require approval of a PMA before they can be marketed. There is one approved self-testing device on the market, the OraQuick® HIV self-test approved in 2012. HIVST devices were not included in the reclassification of HIV diagnostic, supplemental, or viral load tests due to a lack of sufficient experience with these devices to write special controls that will safely mitigate the risks so that they can be regulated as Class II devices. FDA does agree wholeheartedly that there is an urgent need to improve access to self-testing for HIV. To that end, FDA is working with manufacturers to consider alternative validation strategies and streamlining of the review and approval process to expedite entry into the market. When the OraQuick® HIV self-test was approved, the process was very laborious and very careful because there were a lot of concerns, even with the whole concept of self-testing, but HIVST has since been demonstrated quite clearly to be safe and effective. Thus, many of the concerns that caused the original process to be so laborious have been mitigated through experience with the devices. FDA has been working with manufacturers to determine ways they can use existing data, for example, especially if it is an already approved point-of-care device, and adding a self-testing claim to that. This differs from a manufacturer who is submitting a brand-new device never approved before.

HIV self-collection kits also require FDA approval. All self-collection kits are medical devices that require FDA authorization before they can be distributed regardless of their intended use, but the review pathway can vary based on the intended use of the device. For example, a device might be intended for home use or use in a clinic for self-collection that is supervised or unsupervised based on disease indications. The reason that FDA needs to review these devices is that adequate and appropriate sample collection is essential for device to meet performance expectations. Self-collection means that an untrained individual is collecting their own sample, so there is no automatic assurance that collection has been performed properly when the sample arrives at a laboratory. FDA reviews instructions for sample collection and the device's performance with the intended sample type to ensure a reasonable assurance of safety and effectiveness of the device.

In terms of the current landscape, FDA recognizes there is a need for self-collection kits for HIV diagnosis for individuals who are unable or unwilling to attend a clinic. However, HIV self-collection kits require approval of a PMA or clearance of a 510(k) following reclassification of HIV diagnostic device to comply with the FD&C Act. Distribution of unapproved HIV self-collection kits is a violation of the Act. There are no FDA-approved HIV self-collection kits that use blood samples currently on the market. FDA's goal is to bring unapproved/uncleared

devices into compliance with the law and regulations. In the interest of public health, FDA is committed to working with device developers to meet the requirements.

Turning the Tide on Self-Testing and Sample Collection Background and Need

Michele Owen, PhD

Associate Director of Laboratory Science
NCHHSTP, CDC

To ensure that everyone was on the same page, Dr. Owen first shared the following terminology and definitions:

- **Point-of-Care Test (POC):** Conducted near an individual also referred to as point of contact or rapid tests administered by trained staff or health care providers
- **Self-Test:** A complete test conducted by an individual for their own knowledge—also referred to as an over-the-counter test (OTC) or direct-to-consumer test (DTC).
- **Self-collection (self-collected test):** A scenario where an individual collects their own sample, and hands it off or ships the sample to a laboratory for testing

There are many considerations for self-testing and self-collection testing. It is very important for populations where clinic or laboratory testing is difficult or not feasible. However, it is very important to provide clear information regarding assay limitations. For example, the oral fluid assays will detect some early infections.²⁷ These are never the final diagnosis. They are used in conjunction with clinical testing for a definitive diagnosis. Ideally, these tests should be available at a price point that will allow wide access for many people to have the ability to use them. As noted, OraQuick® is the only FDA approved HIV self-test. This is an oral fluid test that costs about \$35 to \$40 retail. It is important to note that this test does not detect acute HIV infections (e.g., up to 90 days for positive result post infection) and there are limitations for its use in the context of PrEP. Based on delayed reactivity shown in PrEP trials, this test is not optimal for prescribing PrEP. There are currently no cleared self-tests for STIs or viral hepatitis.

In terms of HIV self-testing data in the US, CDC in conjunction with Emory University conducted a longitudinal randomized control trial (RCT) known as eSTAMP²⁸ that demonstrated the feasibility, acceptability, and benefit of distribution of self-test kits. The study used the FDA-approved OraQuick®, a fingerstick test under IDE (Sure Check®), and a dried blood spot (DBS) test. Infection was identified in first time testers and social contacts and no harmful adverse events (AEs) were reported. A partnership with CDC's Let's Stop HIV Together Campaign-to launch TakeMeHome distributed approximately 100,000 HIV self-test kits through a portal on the CDC website.²⁹ This event demonstrated that self-testing serves people who might be reluctant or unable to seek clinic- or community-based testing. This tool was identified by 80% of jurisdictions that are part of the EHE as being very important for their community EHE plans.

The World Health Organization's (WHO's) stance of self-testing is informative. WHO has made recommendations twice that self-testing should be part of eliminating HIV or identifying people and getting them into treatment. The first recommendations were in 2016. After reviewing the data in 2019, the WHO updated their recommendations to make a strong recommendation for HIV self-testing. They also pointed out that testing in this manner reaches high-risk people who

²⁷ Stekler et al, JCV 2013 and 2016; Luo et al JCV 2013

²⁸ MacGowan et al. JAMA Intern Med, 2019

²⁹ <https://www.cdc.gov/mmwr/volumes/70/wr/mm7038a2.html>

might not test otherwise, so it should be an ongoing approach for testing services.³⁰ There are a number of HIVST products available outside of the US with WHO pre-qualification.³¹

As mentioned earlier, there are no FDA-cleared self-collection test for HIV and Home Access is no longer on the market. Commercial laboratories have set-up laboratory-developed test (LDT) services, primarily because of testing during COVID for HIV, STIs, and PrEP initiation because it was known that people were not getting tested. This also was done for hepatitis B and C antibody tests. Multiple studies have been conducted on STI self-collection inside and outside the US. WHO also funded a meta-analysis of STI self-collection tests³² after which they published recommendations for self-collection testing for STIs. Similar to HIV self-collection, WHO pointed out that self-collection of samples for *Neisseria*, gonorrhea, and chlamydia are very important and reach people who might not normally be tested.

In the US, various institutions have set up programs for self-collection for STIs.³³ One of the most well-known program is I Want the Kit³⁴ that came out of Johns Hopkins where they are doing chlamydia and gonorrhea testing. Originating in Baltimore, this testing has now been expanded to Maryland, Alaska, and Arizona residents. The District of Columbia (DC) conducted a similar type of project called GetCheckedDC.³⁵ This is a mail-in STI testing program. Both programs have reached priority populations and data indicate that the methodology is feasible.

CHAC Member Discussion on Special Presentation

To focus the discussion, Dr. Gayles reminded CHAC members of the advice related to this topic that was requested from CDC/HRSA and asked them to be thinking about action items CHAC might address and vote on later in the business section related to these questions:

1. How important is self-testing and self-sample collection to overall public health efforts?
2. Are there specific analytes (e.g., antibody or antigen tests for HIV, HCV or treponemal/non-treponemal test for syphilis) that CHAC would consider a priority?

The following questions, observations, and suggestions were raised:

- Dr. So emphasized that there is a lot of value in having rapid tests for home use and use at outreach events for HIV, STIs, and hepatitis. He asked whether one reason for not having more approved rapid tests and self-tests was because industry is not submitting applications and if FDA should be sending out notices to welcome industry to submit applications.
- Dr. Lathrop indicated that FDA has engaged in increasing outreach to manufacturers to encourage them to submit all of these devices. There tends to be a lot of mythology around what FDA will and will not consider in terms of data. Some of that is because that is the way it used to be and some of it is because people talk amongst themselves and have decided this, or they may have gotten an unhappy answer and then decided that FDA would never consider using data from outside the US. In some cases in the past, that might have been true. However, FDA has been working hard to open up alternative validation strategies that might not have been considered in the past, and is trying to engage outreach to get people

³⁰ WHO recommends HIV self-testing. (2016) World Health Organization. <https://apps.who.int/iris/handle/10665/251549>; Consolidated guidelines on HIV testing services. <https://www.who.int/publications/i/item/978-92-4-155058-1>

³⁵ <https://www.getcheckeddc.org/>

to come in. Fundamentally, FDA can only review what people submit. People also can simply start conversations with FDA regarding what is/is not required. There is a pre-submission process that is simple and can be informational. They want people to talk to them about what they have and what the expectations are. There is no penalty or user fee to clarify what is needed. In a pre-submission, FDA's feedback is binding. If they say that a study design is acceptable, they cannot change their mind later unless the science changes. It also is confidential on the part of FDA.

- Dr. Anderson observed that there seemed to be no question about the need for self-testing and self-collection devices for various infections. Perhaps the barrier at this time is that more data are needed for validation. She wondered whether manufacturers and laboratories do not have the protocols, are not interested, et cetera. Obviously, the need for more data has cost implications. While FDA is reaching out to individual manufacturers for technologies that are already developed and being used abroad, she wondered what realistically could be done to move this along in the US such as some sort of incentive structure. It sounded to her like a lot of data already have been generated, at least in a global setting, some of which may be useable for US approval. She clarified that when she said "incentivize," she was not suggesting that they pay manufacturers. She just wondered what outreach mechanisms might be available.
- Dr. Lathrop said she could not speak to whether FDA has the ability to incentivize manufacturers and they do not sponsor trials. Manufacturers may assume that the barriers are so high that they could not possibly get approved, but validation is validation. FDA recognizes Clinical and Laboratory Standards Institute (CLSI) standards for measuring assay precision. These are voluntary standards, but they are best practices developed by the device manufacturers. CDC and FDA are on the panels for some of the standards and follow those principles. Good device validation follows the CLSI standards to be properly validated in many cases. FDA has a number of roundtables that are designed specifically to engage in open discussion with manufacturers. She agreed that finding ways to reach out to various manufacturers who are developing these tests is crucial.
- Dr. Owen added that CDC also has tried very hard to engage in outreach with manufacturers by interacting with the Advanced Medical Technology Association (AdvaMed) to discuss the needs for HIV, STI, and HCV tests. In addition, CDC recently convened a diagnostics conference that they have had for many years. Most manufacturers either attend and/or have booths. Manufacturers have said that they will not bring a test to the market if they do not see a market share for that. They are private companies and they want to make money. It is important to continue to emphasize the need for these devices and that there will be a market for them.
- Dr. Dionne-Odom inquired about the role of clinical investigators who design RCTs. In order to reach this vulnerable population who is at-risk and not accessing care, self-testing for HIV and STIs is critical. If researchers receive funding for trials from NIH to conduct this type of research with donated kits from companies that have told them the bar is high for validation through the FDA, she wondered whether that would be the type of data that would be compelling or if the real work needs to be done at the level of the company to put their specifications and QI in place.
- Dr. Lathrop indicated that the clinical data is part of the package, but someone has to actually sponsor and submit the application. There is nothing that says a clinical laboratory or a university cannot do that, but they have to have all of the information that supports the analytical validation for the device as well. That can be challenging. A kit can be made that

works on an already approved instrument, and that a laboratory or university could submit that as their test and take responsibility for it. It does not have to be the manufacturer. While there are some risks associated with that, it can be done. It is difficult when someone is just doing the trial component, because they may not have access to all of the information needed. That would have to be acquired from the manufacturer or the researcher working with the manufacturer to provide that for an FDA application. The data generated in those kinds of studies, if well-designed and potentially can be submitted to FDA in the end, speaking very generically, should be usable.

- Dr. Mermin observed that while the efforts to reach out to manufacturers are appreciated, it is extremely expensive to put forward an application for PMA for a Class III device. For a university to want to conduct the clinical trials is not an easy process, for HIV in particular.
- Dr. Lathrop indicated that the user fee for a PMA is substantial. One benefit for reclassification is that when diagnostics are 510(k), it is a much lower user fee. At the moment, a self-collection kit is a PMA because the assay is a PMA. Once the assays are reclassified as Class II, the self-collection kits can come in as a 510(k). FDA is awaiting the finalizing of the reclassification, but when that occurs, it should lower the financial cost. The clinical studies still need to be done with performance criteria that are in the special controls, but certainly the submission and maintenance of that application are much lower.
- Dr. Markham reported that the IWantTheKit program from Johns Hopkins has made an incredible impact in reaching Native American and Alaska Native communities working with colleagues at the Alaska Native Tribal Health Consortium (ANTHC) and the Inter Tribal Council of Arizona, Inc. (ITCA). They are expanding their work to the Southern Plains Tribal Health Board (SPTHB) in Oklahoma. This has been a phenomenal program and working with the Johns Hopkins team has been outstanding. Testing is only one part of it. There also is a need for funding the culturally sensitive outreach and marketing, because those testing kits are only as good as the folks that they reach. It also is important to have support to linkage to care in local communities. For remote tribal communities where youth do not want to go see their Auntie at the local clinic because that is not going to be confidential, the importance of having that self-testing and anonymous/confidential access and linkage to care is critical.
- In terms of the mention earlier that different centers within FDA have adopted different approaches, Dr. Mermin asked whether thought has been given to aligning the requirements of both centers so that there is more consistency.
- Dr. Lathrop clarified that they do not have different interpretations. They have different intended uses. The requirements for an HIV diagnostic will differ from the requirements for an HCV diagnostic because the risks associated with the intended uses are different. Both centers are assessing them in the same way in terms of the potential impacts of the incorrect results to the individual. For instance, the risk from an incorrect result for a viral load monitoring test versus a screening test are very different. The centers talk all of the time and try to align as much as possible.
- Dr. Mermin indicated that CHAC, CDC, and HRSA have discussed that they do not believe the distinction between hepatitis C and HIV diagnostics at the point of use are different. They talked with FDA about that as well. They are left with a situation in which they are an organization trying to get testing out to the people who need it, but see different routes being required by different centers in the FDA even when it is not clear why one is being treated differently than the other.

- Dr. Lathrop said she understood why it appears that way sometimes. FDA's feeling is that the risks from a wrong result for HIV are not the same as the risk of a wrong result from HCV, especially in terms of a false negative and a person believes they are not infected and go about their life. HIV is treatable when people know they are infected.
- Dr. Dowler expressed an interest in understanding from the payer perspective how they can pay for these tests so that companies will invest the resources to go through the process. No Medicaid program is going to pay for a self-collected test with no incentive to do that. There is an opportunity for CHAC to assess the rigor of going through the approval process, incentives for industry to want to do that, and making sure that tests are equitably distributed and accessible to various communities in terms of being offered and the payment structure.
- Dr. Daskalakis shared a resource for HIV self-testing:
Issue Brief: <https://www.cdc.gov/hiv/policies/data/self-testing-issue-brief.html>

Panel 3: Applied Syndromic Approach to HIV, VH, and STIs: Focusing on People

Moderator: Demetre Daskalakis, MD; Director, Division of HIV Prevention, NCHHSTP, CDC

Comprehensive Harm Reduction Supports Navigation to Curative Hepatitis C Virus (HCV) Treatment and Syphilis Services

Andrew Gans, MPH

HIV, STD and Hepatitis Section Manager
New Mexico Department of Health

Josh Swatek

Hepatitis and Harm Reduction Program Manager
New Mexico Department of Health

Mr. Gans and Mr. Swatek presented on comprehensive harm reduction supports navigation to curative HCV treatment and syphilis services provided by New Mexico Department of Health. Typically, when speaking about harm reduction and high-volume, high-quality, low-barrier harm reduction programs as a great access to services, it is normal to assume that there will be hepatitis C, maybe HIV testing, and syphilis services to build trust in the community. Unfortunately, with the release 10 days ago of the STD surveillance data for 2020, New Mexico is number one in congenital syphilis. Small number, high rate, and very alarming.

New Mexico is able to do navigation because they have such a high-volume harm reduction program. While previously they were performing rapid HIV and hepatitis C testing, they have moved away from rapid hepatitis C testing because they have clients who have been antibody tested repeatedly over a decade or more, but it does not actually get them into care. It is expected that all harm reduction includes navigation to substance use services. New Mexico's enhanced model is about navigation to services rather than just referrals. As part of the hepatitis C elimination plan, it is necessary to get people into curative treatment. This involves getting them insurance, getting them into primary care, getting them medication opioid use disorder (MOUD) treatment, syphilis services, and ensuring that the DIS who are involved in a lot of these services can be doing partner services, testing, and linkage to STD or hepatitis treatment as well.

New Mexico wants to be among the first, if not the first, to eliminate hepatitis C as a public health threat by 2030 meeting national and international goals. New Mexico has 5 wins and innovations in the state that really place them ready to do this:

1. Project ECHO, which was founded in New Mexico at the University of New Mexico specifically to increase access to HCV treatment.
2. New Mexico Corrections Department (NMCD) is actually providing STD treatment actively and was doing antibody testing upon entry for almost a decade, switched to do confirmatory testing as well, and now has funding in the legislature to do curative treatment for about 2,800 inmates.
3. New Mexico has one of the most progressive Medicaid policies, which opened up for hepatitis C treatment without pre-authorization, fibrosis restrictions, or sobriety restrictions in 2015. The consultant who pulled off this amazing feat is now their Cabinet Secretary for Health.
4. New Mexico has an innovation with a high-risk pool, which they have been using to ensure that everybody living with HIV has insurance coverage, even if they are categorically ineligible due to immigration. The New Mexico Medical Insurance Pool (NMMIP) was approved at the end of 2019.
5. Comprehensive harm reduction services are available statewide.

Project ECHO has a peer education program working with state corrections, which does a lot to promote referral to hepatitis C treatment. They have the funds now and the 340B discount, which has allowed them to increase from about 150 inmates being treated for hepatitis C prior to this innovation to an average of about 600 a year. They have to motivate people to ask for it. It is not just for people with advanced disease, fibrosis, et cetera. It is for everybody, but not everybody knows they need it. NMCD has a plan for HCV elimination and received a very large allocation of funds. Project ECHO is a key part of that in terms of consultation and includes the NM Peer Education Program that educates the population on HCV screening and treatment. Partnerships are highly essentially in New Mexico. New Mexico's innovative policies for hepatitis C treatment that began in 2015 increased access to treatment for Medicaid recipients. They have good coordination that is constantly improving with Medicaid MCOs, which helps somebody who leaves corrections who did not start or complete treatment get community treatment as well. A lot of people are cycling through jails where there is less excellent coverage, state prisons, and then back into the community for Medicaid.

New Mexico's innovative high-risk pool has done very well with wrap around insurance. Before ACA, New Mexico was a state that never had an HCV drug assistance program waiting list, because with this high-risk pool, they were ensuring everybody with HCV who could not get insurance 10 years ago. When ACA rolled out and there was Medicaid expansion, a lot of folks with HCV moved to Medicaid or to an ACA plan. Others still have employer insurance. The NMMIP is still the last option. There are only about 200 people with HCV in the state, but the hope is to be able to serve 50 to 100 people with hepatitis C who cannot get any other insurance. The exciting part is that they thought this would be a treatment model where the state health department and public health offices would be the wrap-around safety net. In some communities, one of the few providers in the county is the Department of Health Public Health office. Even in some of the larger communities, there may not be a lot of providers who are willing to provide hepatitis C treatment, so they hope to ramp this up. While they got set back about 2 years by the pandemic, they have a protocol for hepatitis C simplified treatment and can serve a lot of people who do not have advanced disease right in their health offices to be that safety that helps people get access to MOUD, which is essential for a lot of the population. New Mexico has comprehensive harm reduction program services available statewide. More than 18,000 unique people were provided with syringe services in 2021. An important piece of

that is that 87% of people have been tested for hepatitis C, but only 24% have had access to treatment. Harm reduction programs are a key place to provide services for viral hepatitis. Component 3 through the 2103 CDC DVH grant has allowed New Mexico to expand its services, which is essential for preventing reinfections.

Some of the strengths of the New Mexico model are negotiated exchange, which allows tailoring to client needs while still striving to maximize collection of used syringes. Services are comprehensive. Locations at NMDOH Public Health Offices offer HIV, HCV, and STD testing and services, WIC (Women, Infants, and Children), family planning, et cetera. Many sites are within FQHCs or other health care providers. Services are low threshold, meaning that new clients can enroll with just a brief interview. The program is confidential, but unique client identification codes can be used to ensure immunity from prosecution for possessing syringes. Program sites were an ideal venue to provide hepatitis A vaccines during an outbreak among persons experiencing homelessness.

This is a comprehensive model that provides new, sterile syringes. Safe disposal of syringes can be done through both program interactions and community drop boxes. Small sharps containers are provided to participants to return to the program. There also is provision of other “works” needed to prevent the spread of infectious disease, as well as overdose prevention services. Referrals and navigation are provided to substance use services, public health interventions, and social services. Some people might not be ready for treatment because of the circumstances of their lives (e.g., lack of childcare, food insecurity, lack of housing, et cetera). Active navigation helps to address those gaps first, with the eventual goal of getting people into treatment.

In terms of messaging, New Mexico’s older campaign had 6 messages for people in their services who may not have thought of PrEP, PEP, curative treatment, or rapid testing. The new campaign is being rolled out as harm reduction across the state around maternal testing for syphilis, which is very important for responding to congenital syphilis. The issue with New Mexico’s congenital cases is that a lot of people are not in prenatal care, very often due to substance abuse.

The New Mexico Harm Reduction Act passed in 1997. It authorized the Department of Health to compile data to assist in planning and evaluation, provided immunity for exchange or possession of hypodermic syringes from the Controlled Substances Act for both participants and providers, and approved community providers across the state. Program operations started in 1998. There were a lot of problems with the original policy. Original state rules were detailed in terms of data collection and reporting. This necessitated long intake interviews and some irrelevant questions (i.e., sexual behaviors). Eligibility is only for state residents aged 18 and over. Some educational messages that became outdated (i.e., use of bleach) were written into initial regulations. Exchange was one-for-one only with a limit of 200 syringes per interaction (hindering secondary exchange). However, policy changes have increased the scope of harm reduction services. House Bill 52 passed in the 2022 legislative session, with a lot of bipartisan support. It allows NMDOH to promulgate rules that reduce negative health outcomes associated with drug use such as overdoses and infectious disease and reduce harm by improving participant engagement in harm reduction.

Harm reduction is now being used to respond to maternal and congenital syphilis. New Mexico has a lot of moms who are not accessing prenatal care due to immigration status, using substances, experiencing homelessness, engaging in transactional sex work, et cetera. They fear that if they get connected to a system of care, they will lose custody of their baby. A lot of training is being done for providers to make sure those who do come in are tested. Harm reduction efforts include strategies to engage at-risk persons in harm reduction, including meth users and those who do not inject; rapid and conventional syphilis testing; incentives for testing, including for male partners of persons of child-bearing age; social network strategies (SNS) to recruit; and integration with DIS to ensure treatment, disease investigation, and better quality services.

Corrections Health is Public Health for the Justice-Involved Community!

John J. Hagan, MD

State Correctional Health Authority

North Dakota Department of Corrections and Rehabilitation

Dr. Hagan noted that he has the privilege of leading a small but mighty team of medical and psychiatric professionals who provide care to a unique and vulnerable population. Together, they change the lives of residents in the North Dakota Department of Corrections and Rehabilitation (DOCR). There is an epidemic of incarceration, with 1.43 million adults held in federal or state prison facilities currently. There are about 735,000 persons in jails. Across the country, about 0.7% of the adult population are held in jail or prison. The North Dakota State Prison system houses 0.3% of the adult state population. That does not include folks on parole or probation. North Dakota is a very rural state of 774,000 total humans. The adult count in the prison system is very small at 1,685. They are happy to be small and are trying to go out of business if they can. Their average turnover is 1,500 admits per year, the median length of stay about 16 months, and the recidivism rate has been about 40% over 5 years.

North Dakota residents are a vulnerable and underserved population. People of color are over-represented in prison in probation and on parole. Someone who is Black in North Dakota is 4.2 times as likely to be under DOCR control compared to their White counterparts. Latino North Dakotans are 1.8 times as likely and Native Americans are 5 times as likely to be incarcerated. Residents arrive uninsured with very fragmented medical care. They suffer significantly higher rates of hepatitis C, SUDs, serious mental illness, diabetes, and hypertension. The goal is simple. The mission of the North Dakota DORC is to transform lives, influence change, and strengthen the community. They work hard because they believe the work is worth doing. They practice dynamic security, the goal of which is to create a humane, normalized environment to the extent possible. They have security available if having issues, but they found that when their patients are treated normally, they respond normally. They are trying to get folks ready to head home by creating an environment in which residents attain and practice prosocial skills in a setting where they are safe.

DOCR's plan for success in treating STIs, hepatitis C, and HIV is straightforward. DOCR is tremendously well-supported by the North Dakota Department of Health (NDDOH). DOCR partners with NDDOH to bring screening and treatment service to the DOCR system, and they form a large platform for DOCR's more comprehensive treatment programs. DOCR would have no opportunity to do this without the superb NDDOH, which underpins everything DOCR does.

One of the things that drives DOCR's programming at every level of operations and security is that their residents are going to become their neighbors. Of the individuals in DOCR's care, 98% will be discharged to North Dakota, South Dakota, or Minnesota. They ask themselves with their programming what kind of neighbors they want. They are very much person-centered rather than diagnosis-centric. DOCR considers what these folks need to be successful in the community, and challenge their clients to work to remodel and revitalize themselves. The testing and treatment programs that they offer are concrete actions that convey to the residents that DOCR is heavily committed to investing in their future. This is a great place to find and treat folks. Upon arrival, 31% of DOCR residents identify themselves as PWID. It is suspected that the numbers are higher. About 15% of the residents suffer from chronic hepatitis C with elevated viral load. In the last 10 years, DOCR has had 2,388 unique patients arrive with hepatitis C antibodies and 80% of them are typically HIV-positive. Only 0.6% of DOCR residents test positive for HIV. The chlamydia rate is 20.7/1000.

The goal is to build trust from day one. In the first 30 days, there is an orientation program during which the DOCR Nurse teaches health-related issues and answers questions. The result of offering a stable and humane environment is that residents asked for treatment on arrival. There is an opt-out program for testing. Virtually nobody opts out. For the first time in 6 months, only one individual in the state of North Dakota asked not to test, so the environment definitely is right for this. The only reason DOCR succeeds with this program is because of the unwavering support of the NDDOH. This translates to 20% of adult men on arrival are antibody positive and 15% overall have active virus, while 37% of women are antibody positive and 25% have active virus. This is known due to the ability to perform universal testing on arrival. The reason they can do this is because their cost for HCV antibody is \$26 underwritten by the NDDOH. The HCV RNA/Genotype is \$55. The average screening cost for hepatitis C is \$37 dollars per arrival. DOCR cannot come close to that anywhere in the private world, so that helps them a great deal. That turns out to be important because NDDOH reports that 15% of individuals in North Dakota who have an HCV positive laboratory result reported to NDDOH each year have at least one HCV associated laboratory report in a correctional setting.

DOCR cures hepatitis C. They have the support of leadership and their legislature. DOCR treats and cures 43% of the people who come through the door who are infected and they test everybody. Because we partner with the NDDOH and have access to 340B pricing, their average cost is \$12,560. Their 2021-2023 budget is \$1.9 million. For an additional \$2.4 million for a joint program, they can get to micro-elimination and treat everybody they see. This is a great opportunity to impact the state. Since NDDOH steeply discounts their laboratory costs through Section 318 of the Public Health Service Act (PHSA), DOCR's GC and chlamydia tests are \$10 and HIV tests are \$10. They treat by protocol for GC and chlamydia. As soon as they are notified, their staff completes Level I contact tracing on behalf of NDDOH. They also are the first to notify patients on HIV results on a regular basis. People have wanted testing, they have feared testing, but they feel safe at DOCR. Fortunately, they have immediate counseling, psychiatry, psychology, primary care, and infectious disease services available.

Prisons face challenges in treating justice-involved individuals. Most states do not have a unified system. Jails and prisons look the same on television, but they are not at all the same in real life. They are separate organizations. They speak to each other and about each other, but they are not in the same organizations. Jails are funded by county budgets and prisons are funded out of state budgets. The scope and breadth of services differ by county and by state. Some counties have comprehensive services, while some counties have no services. DOCR does not have direct control over prisons. They have a relationship, but programs written for jails and prisons may not work in one setting or the other.

It is important to note that justice-involved individuals are ineligible for Medicaid, Medicare, VA, or private insurance as soon as they are incarcerated—even if they are still paying premiums. States pay cash for all DOCR services. They negotiate and pay out of the general fund. Public funding opportunities for these services is fragmented and separate programs exist for hepatitis C, GC and chlamydia, HIV, SUD, serious mental illness, and wraparound services. For all of the issues that this vulnerable group is expected to have, support disappears when the door is slammed shut by law. Another challenge is attracting and retaining providers. Medical staff are state employees who are underpaid compared to the community. State medical and mental health case management for transition is badly underfunded in most states, so they do not have the services that are known to have a high impact. Jail resources for education, screening, and treatment are very sparse and jails are unable to shoulder the burden as a result.

The next step is to expand the import model. The ultimate goal is to engage the community and patients. That is working well. DOCR partner with federal, state, and local agencies to bring services that already exists into the prison system. The advantages include a steady and predictable volume for agency partners, a solid source of reliable care for this vulnerable population, and continuity of care on release. A great example is DOCR's cooperation with the UND Family Medicine Residency Program, which runs the Center for Family Medicine and also takes care of Custer Family Planning, which is the public health STD treatment programs. For its residents, DOCR also uses the HerCare clinic to bring in onsite prenatal/obstetric care and reproductive health services (e.g., LARC, reversible contraceptives, education). There also is continuity of care, in that those leaving DOCR's care are plugged into that service and they continue to work. Another example like this would be the use of methadone and opioid treatment providers in the community to perform services. DOCR's goal is to expand this important model.

The takeaway messages are that prisons and jails are ideal settings intervening in the syndemic of HIV, STIs, and VH. Justice-involved individuals are a vulnerable population at high-risk for these conditions and are eager to accept treatment. Corrections health is community public health in its purest form. It is important to remember that these individuals are not always in prison or jail. There are actions that can improve the health of justice-involved community members dramatically. While DOCR has 1,685 folks in prison and 800 in jail currently, the total count is 7,500 to 8,000 who are in prison or jail and on parole or probation. It is important to envision justice-involved individuals as a community, and jails and prisons as an ideal location to deliver impactful programming. Further developing programming to discount the cost of syndemic testing in jails and prisons has been highly effective. It is entirely the low cost that allows them to be universal. It is no longer risk-based, there is no stigma, and people are very accepting of it. Allowing flexibility to unify and align existing programs to meet the unique needs of this vulnerable population is very beneficial. Restoration of the HRSA/HPSA special designation for determining workforce shortages for jails and prisons that is independent of the surrounding community represents a major need. This is an incredibly effective way to add staff.

Providing Comprehensive Sexual Health Services to SFUSD Youth

Rosalia Lopez, M.Ed

Student Family Services Division
San Francisco Unified School District

Dr. Lopez shared information on how comprehensive sexuality education and how sexual health services or appointments outside of the school system work in the San Francisco Unified School District (SFUSD) in the context of policies and mandates that support programs, community partnerships, and the tier systems of support. It is extremely important to have intentional policies and mandates that support programs at the state, local, city, and school district levels. Several policies and mandates are highlighted below:

- **Health Education Content Standards for the State of California**³⁶ for which 2 examples of interest are: 1) 1.9.G, which explains laws related to sexual behavior and the involvement of minors; and 2) 3.2.G, which identifies local resources concerning reproductive and sexual health, including all FDA-approved contraceptives, HIV/STD testing, and medical care.
- **The California Healthy Youth Act (AB 329)**,³⁷ which went into effect in January 2016, requires that schools provide comprehensive sexuality education for students in grades 7-12 at least once in middle schools and at least once in high school.
- SFUSD Board Policy **6142.1 Sexual Health and HIV/AIDS Prevention Instruction**³⁸ requires comprehensive sexual health education and HIV prevention education shall be offered to all students in grades 7-12, including at least once in junior high or middle school and at least once in high school.
- **Sensitive Services/Minor Rights: California Family Law Code Section 6920-6929**³⁹ Parental/guardian consent is not required for minors under the age of 18 to access sensitive services. These services may include treatment having to do with drugs/alcohol, reproductive health, sexually transmitted diseases, and mental health.
- **Condom Availability Program - SFUSD Board Policy 5141.25, California Education Code 19-24- Sp1** requires a Condom Availability Program at all SFUSD Middle and High Schools; delineates guidelines, parent/guardian notification, exclusions, education component, and abstinence message; and creates alliance with schools and community health care providers.
- **Meeting the Needs of LGBTQ Students - SFUSD Board Policy 610-8A6, California Bill AB537** prescribes a variety of activities, interventions, accountability, and support to ensure that schools are a safe place for LGBTQ youth; and ensures that sexual orientation and gender identity be included as protected categories in all non-discrimination policies and procedures applying to all SFUSD students, teachers, staff, administrators and other employees.

³⁶ <https://www.cde.ca.gov/be/st/ss/documents/healthstandmar08.pdf>

³⁷ https://leginfo.legislature.ca.gov/faces/billNavClient.xhtml?bill_id=201520160AB329

³⁸ <https://go.boarddocs.com/ca/sfusd/Board.nsf/goto?open&id=BDVSWC74A618>

³⁹ <https://law.justia.com/codes/california/2005/fam/6920-6929.html>

In terms of partnerships, SFUSD has a cooperative agreement with CDC-DASH, San Francisco Department of Public Health (SFDPH), and other CBOs to implement programs that support sexual health, education, sexual health services, and safe and supportive environments. SFUSD uses a multi-tier system of support, including health education, wellness programs, and LGBTQ student services programs. Because of the partnerships with the SFDPH and other CBOs, SFUSD has been able to support comprehensive sexuality curriculum to ensure that there is a common language (Be Ready, Be Real for High School; Healthy Me, Healthy Us for Middle School; Healthy Me Resource Guide). Staff training is provided on policies and procedures to providing youth-friendly services; providing sensitive services and referring students to local clinics if needed; and logging services and follow-up one-on-one services to youth when needed.

The SFUSD team work closely with the Wellness Program and the LGBTQ Student Services Program for consistent assessment of the health education curriculum to determine where it needs to be updated to meet the needs of LGBTQ and all other students. One example would be if the topic of human trafficking is being discussed, a social worker is in the classroom in case students need services beyond just awareness. Because of policy, schools are not allowed to pass out condoms and the role of the teacher is just awareness. The nurse in the Wellness Center would provide students with condoms. Because a student would need to go to the Wellness Center to complete a quick needs assessment and receive condoms, there is relationship-building between the teacher, the nurse, and the students in terms of where students receive services. Those who need further services beyond what the Wellness Center can offer are referred to a local teen clinic.

SFUSD's Sexual Health Services & Multi-Tier Systems of Education has 3 tiers: Intensive, Targeted, and Universal. Health education is considered Tier 1, given that it is for everyone. Tier 2 is for those who need smaller social groups. Tier 3 is for those who need more support (e.g., testing, mental health services, medical issues, et cetera) for which students are referred out to partner organizations. This year more than ever, there is a lot going on in schools and the help of CBOs and health clinics has been key. Though it has been somewhat difficult to reconnect during the pandemic, this is a work in progress.

These innovative collaborations have yielded some excellent expected and unexpected results, including fantastic lessons, connecting classrooms to services, and increased collaboration of SFUSD partners with over 50 CBOs. The top 5 types of services based on number of students served include general counseling, case management, medical services, behavioral health counseling, and sensitive services.

Advancing Syndemic Approaches Through Cluster Detection and Response

Alexa Oster, MD, CAPT USPHS

Acting Chief, Detection and Response Branch
Division of HIV Prevention, NCHHSTP, CDC

Dr. Oster pointed out that cluster detection and response offers a framework to guide tailored implementation of proven HIV prevention strategies where transmission is occurring most rapidly. After an outbreak, detection helps to identify when HIV is spreading quickly and to work to stop that spread. The presence of a cluster or outbreak indicates a failure of care and prevention services that needs to be addressed to improve access to services, such as antiretroviral therapy, PrEP, and sub-transmission. This is an opportunity to identify the needs of affected communities and generate ideas for improving services, because cluster and outbreak response involves curating care and prevention services to be more accessible to the

people who need them most. Cluster response is an opportunity to identify gaps in services and curate tailored treatment and prevention interventions where standard population interventions have failed. Importantly, cluster detection and response involves adapting resources for those who use them rather than expecting people to adapt to access services in a system that has failed them.

Concurrent with the opioid crisis, there have been a number of HIV outbreaks among PWID in the US over the past several years, beginning with a large outbreak in Scott County, Indiana that was detected in 2015. PWID experience numerous syndemic conditions, including HIV, STDs, VH, SUD, and mental health challenges. In addition to these medical issues, they often face unstable housing, food insecurity, and other needs for social services.⁴⁰ Clusters and outbreaks affect a variety of populations, and these principles apply to sexual transmission as well as injection-related transmission.

In an example from Kanawha County, West Virginia, HIV diagnoses among PWID drugs increased rapidly beginning in 2019.⁴¹ As a result, the West Virginia Bureau for Public Health requested CDC assistance with an HIV outbreak investigation. CDC built its team with syndemics in mind. The CDC team, led by DHP, also collaborated with HRSA's HAB and the Department of Housing and Urban Development (HUD), both of whom have become very important partners for response support. This team collaborated to support the state and local health departments in conducting an investigation that included a medical record review and a rapid assessment with qualitative interviews. At the local level, a diverse set of partners from the state and local health departments and multiple other healthcare CBOs were involved.

To highlight some findings from qualitative interviews with 26 PWID and 45 key community members, many people described using substances to cope with feelings of hopelessness and despair associated with a confluence of health and social challenges, such as unstable housing, depression and anxiety, and unemployment. Among the numerous health and social conditions PWID faced at the time, HIV and SUD were just a couple of the many issues. This constellation of challenges underpins the complex needs of the populations served, as well as the challenges that can slow progress in implementing holistic approaches.

The medical record review, which included 496 healthcare encounters among 65 people with HIV, showed missed opportunities for prevention and care for a wide range of conditions, including low provision of naloxone and medication for OUD. Medical encounters for overdose and STIs were infrequent. Hepatitis C diagnosis was common and preceded HIV diagnosis by about 4 years. Most people were covered by Medicaid and housing instability and incarcerations were prevalent.⁴² Surge DIS staff from the Division of STD Prevention brought a syndemic approach to partner services, going above and beyond to ensure appropriate testing, treatment, and linkage to care for various syndemic conditions and working to meet a variety of other food and social service needs. The findings mentioned informed one of the team's recommendations, which was to improve access to HIV, hepatitis C, substance use, and mental health services through service integration by co-locating services and cross-training service providers to improve access to effective infectious disease prevention efforts. Co-location of services, along with multidisciplinary teams and intensive case management, can help to address important barriers to care for multiple conditions. Low barrier, one-stop-shop models can help. It also is important to involve people with lived experience in the development, implementation, and monitoring of programs.

⁴⁰ Lyss SB et al., JID 2020

⁴¹ Hershow R et al. MMWR 2022

⁴² Bonacci R et al. CROI 2022; Hudson A et al. CROI 2022; https://oeeps.wv.gov/hiv-aids/documents/data/EpiAid_Report.pdf

In terms of challenges to syndemic success, integrating data sources from multiple conditions can be difficult, but is essential to understand the various needs of the people served. Silos in data systems can reflect silos in programs, and bridging those programs silos can be critical to facilitating integration of data. Policy barriers also can be a major challenge. For example, expanding harm reduction services and SSPs was a primary recommendation of the investigation. Although SSP policies were changed where possible, state laws and city ordinances related to SSP limited the ability to expand these services to meet the need. Likewise, limitations to eligibility for hepatitis C treatment for people covered by Medicaid meant that testing and linkage ended up being deprioritized. Limited eligibility led to misconceptions that affected the care-seeking behaviors of even those who were eligible for treatment. Program and funding silos are an important consideration. This is relevant at a macro-level, including how federal funds are distributed, but also applies to how health departments are structured with separations between infectious diseases and behavioral health and also at a micro-level where providers and systems have incentives to only address immediate needs, including in EDs and correctional settings. Finally, health department capacity limitations also were a challenge. Even when funds are available, health departments sometimes have difficulty hiring and retaining staff, and this limits their ability to perform recommended activities, including partner services for every new diagnosis of HIV and syphilis. CDC can provide surge support to help address a backlog of cases or additional cases during an outbreak, and federal support provides an opportunity to build program and systems capacity, but this can be limited by other capacity issues at that health department.

It is important to note that although outbreaks among PWID have been highly visible due to concerns about rapid transmission in these populations, most clusters of rapid transmission are related to sexual transmission. Among 144 clusters first identified through molecular analysis in 2018-2019, 82% were primarily among gay and bisexual men. Among the largest clusters that had grown to more than 25 people as of September 2021, 72% were among gay and bisexual men. These clusters were typically small when they were first detected, but grew to be just as large as the concerning outbreaks seen among PWID. Many of the same syndemic issues and others apply to gay and bisexual men, who also face homophobia and other systemic injustice.

To share an example of a cluster related to sexual transmission that resulted in response to syndemic issues, Michigan identified a molecular cluster of rapid transmission in 2021 in Wayne County affecting a network that included Black or African American transgender women. About half of the network members indicated participating in sex work or having partners that engaged in sex work. The health department immediately began engaging with community partners that serve trans communities to talk through potential gaps in services and how to improve them. Over a few months, 13 meetings were held with these community partners. The health department also spoke with members of the network, who were supportive of the response efforts and willing to share information about the community's needs and also helped to indicate additional people in need of services. They indicated that there were not enough providers who provide gender-affirming care. As a result, Michigan has created a mobile services initiative to offer gender-affirming care that includes general health and wellness checks, immunizations, a food pantry, and HIV and STI testing. Michigan is also developing community-oriented social media and messaging campaigns developed with input from the trans community.

Although value and opportunity have been demonstrated in advancing syndemic approaches through cluster detection and response, there are a number of needs and considerations, most of which are not unique to cluster and outbreak response. Those at the federal level can support syndemic approaches by communicating the priority of a syndemic approach from federal funders to state and local recipients consistently across all federal funding programs

and partners. This work cannot be successful if driven by a single program. This includes working to minimize silos between federal funding that serves as a disincentive to collaboration. Teams need to be designed with syndemics in mind, modeling at the federal level what is thought to be needed at state and local health levels. This collaboration cannot occur only when there is an escalated response, but must involve long-term work to integrate and align programmatic guidance and technical assistance.

Additionally, policy issues are often at the heart of the most stubborn barriers and where possible, state and local partners must be supported to address these policy issues. It also is important to build systems to meet the needs of the people served rather than expecting people to adapt to systems. To do so, it is necessary to listen to people with lived experience. Qualitative interviews have been a powerful tool to identify what is broken in systems and get ideas for how to fix them. Often the barriers to delivering seamlessly integrated services are issues like funding, training, separate service organizations, time, or physical space. Funding and program requirements can help to dismantle these barriers. That core set of integrated services should be a primary goal and not a bonus or afterthought. Solutions need to address syndemic health conditions that people are facing, but that is not enough. Intervening only on health concerns may not be effective if social conditions are not considered and addressed.

Identifying partners well-equipped for syndemics is key to success. Local health departments, health centers, or community organizations that receive broader funding that is not siloed or who receive funds from various sources already are well-positioned to support this work. Likewise, providers that recognize their clients' holistic needs and meet clients where they are have the most success in linking and engaging them in services. Community outreach workers and partner services staff can embody this approach and this trust is so critical for populations stigmatized on many levels. Moving from the current systems to a gold standard syndemic approach, while an important goal, will take time, so it is important to be prepared to accept incremental progress. Setting expectations too high can sometimes have the unintended effect of disincentivizing staff from initiating response efforts and other work that can unmask the many changes that are needed. Syndemic approaches rely on building cross-cutting teams that can best support this work and the people served.

CHAC Member Discussion on Panel 3

To focus the discussion, Dr. Anderson reminded CHAC members of the advice related to this topic that was requested from CDC/HRSA and asked them to be thinking about action items CHAC might address and vote on later in the business section related to these questions:

1. What priority policies and actions should be considered in operationalizing a syndemic approach to service provision?
2. What settings should be considered for the highest public health impact?
3. How can CDC and HRSA make syndemic strategies and programs more common and effective?
4. What are the best practices for integrating non-HIV-specific services into HIV systems?
5. What strategies would better link youth to clinical services through school health programs with collaboration with public health departments?

The following questions, observations, and suggestions were raised:

- Dr. Anderson noted that one of the fun aspects of these meetings is hearing about all of these impressive programs that a lot of them would not hear about otherwise.
- Mr. Driffin said one of his finals for ethical consideration for one of his DrPH classes is on HIV sequencing and non-positive response. He wondered whether the presenters could share additional insight on racial and ethnic demographics that have been observed in response to the cluster response teams.
- Dr. Oster indicated that they looked at people who were in clusters of rapid transmission nationwide and found that about a third were White, about a third were Black or African American, and about a third were Hispanic or Latino. Rapid transmission is occurring in a variety of populations, and it is important to ensure that they are assessing the gaps that are driving this and supporting changes in programs and services along with those populations. In the analyses that assessed large clusters among gay and bisexual men, they found that most were in the South and West.
- Mr. Lindsey noted that a key barrier to syndemic approaches has been segregated funding streams in the past, which also was a barrier to personnel or workforces who are unable to work together because of segregated funding streams. He wondered whether it is all state funds or if there is anything else that can be done to address ideological or financial barriers to allow more of these population focuses and syndemic approaches to flourish.
- Mr. Gans responded that New Mexico integrated HIV, STD, hepatitis, and harm reduction into one section in 2015. Because they are a centralized health department, having all programs under one roof and operating on the statewide and local levels gives them a lot more flexibility. New Mexico is unique in a couple of ways. First, they have a lot of state support for a variety of programs and second, they have a lot of flexibility as long as they meet performance measures globally. For instance, they have had a long-term shortfall in their harm reduction budget, but they have about \$1 million in state funds in harm reduction. When he started it was \$4 million or \$5 million a year and now it is closer to \$12 million. It has dipped somewhat as people moved to fentanyl and smoking rather than injecting. While they could not afford that out of that budget, they could use state general funds in HIV prevention, HIV care, STD, et cetera. The other thing is that they have other revenue sources. They generate pharmacy revenue, which sustains a lot of HIV PrEP programs around the country, including community health centers. They do something similar with their direct services. Generally, they do not have a huge amount of flexibility in federal grants but when there is flexibility, they use it. They always have had fully integrated DIS who are largely funded in HIV and STD, and they are all cross-trained in HIV, hepatitis, harm reduction, and other navigation along with STD as the focus. New Mexico is always looking for ways to be creative. It is easier to have a syndemic approach at the local level, when they are all located in the same building and talk about their budgets all of the time across the agency.
- Dr. Hagan responded that they have syndemic issues with treating different illnesses. More importantly, most of their program availability begins and ends at their doorstep. There is a sharp cutoff when folks are detained or when they are incarcerated. When incarceration ends, the transition of services is a particularly weak section for them. That is where the natural silos have occurred as people try to create programs for incarcerated folks and folks in the community. That crossover is missing for them because there is not longitudinal thinking. They have the same problems in prisons and jails. When the door slams or opens,

programs begin or end and they are not well-connected. A lot of efficiency is lost that could be capitalized on. We track data out into the community and have tremendous longitudinal data for parole, probation, and recidivism, and recognize the continuum of care. We are taking actions based on the data. Prisons have the infrastructure, and it is shocking how much data they have, but do not crunch it. He can say which of his residents bought FUNYUNS® last week and other incredible data. They have to be careful with it, but they do have incredible data. They just do not use it as well as they might.

- Dr. Lopez stressed the importance of working together in order to provide universal services for everyone and to avoid duplication of efforts.
- Dr. Greene said she was hearing themes throughout about meeting people where they are, low barrier and low thresholds to care, flexibility, and how self-testing could help facilitate people where they are. As someone who works in geriatrics, she pointed out that this is very relevant to older adults, people with mobility limitations, and people with other issues that affect their access to care across all of these systems.
- Dr. Hagan replied that their approach in jails has been largely to try to get services. For instance, for some of the large local jails, they have worked hard to bring the university residents on site. These folks need customers, need to meet people, and need to understand their population. They do have folks with serious mental illness (e.g., schizophrenia, bipolar psychosis, major depression) who come off of their medication and cannot operate well within the social system. Once someone has had a single felony, they become felonized. He thinks there should a DSM-5 diagnosis called “felonized” because they never again will go to public health or mental health care. They will go to prison or jail. The first thing is linking work and bringing folks on site, irrespective of the ability to pay. In jails the focus is largely on getting patients what they need most and establishing trust. Some folks will be up to a year in jail depending on the jail, but most are not. The focus in jails is to get them basic services.
- Dr. So congratulated Dr. Hagen for running such a great program in the prison system. It is a model program. He asked whether they test their prisoners for hepatitis B and whether they are offered hepatitis B vaccination. Some prior CDC studies showed that about 2% of the incarcerated population have chronic hepatitis B and as many as 6% will develop acute hepatitis B infection in this country who have a history of prior incarceration.
- Dr. Hagan said that while they do not do universal testing, they do offer universal immunization. On arrival, they check everybody in the immunization registry, which is very complete in North Dakota. They are proud to be the state’s number one provider of adult hepatitis B immunizations. They have lost their funding for hepatitis A immunizations. The American Correctional Association’s goal is to fully immunize everybody for hepatitis A and B and fully test everyone for C. They do not do the testing unless there is a question clinically, but immunization is offered to everybody on arrival as a public health function.
- Dr. So suggested considering testing before vaccination, because the Medicare cost of a 3-panel hepatitis B test is only \$30. If they had prior infection or already have a chronic infection, it would save on vaccine cost since the vaccines are still very expensive. They also would pick up those who have chronic hepatitis B and may need antiviral therapy.
- Dr. Mermin said he was struck by the fact that in some ways, they were doing too good a job. Each of the presenters showed so much of what could be done with screening, comprehensive SSPs, comprehensive student health services, et cetera. He wondered

whether there were policies that would need to be put into place that would prevent people from getting hepatitis C, HIV, STDs, TB, et cetera—something that would have an effect even more upstream to make the work easier.

- Mr. Gans indicated that New Mexico wanted to get ahead on hepatitis C curative treatment to move towards elimination because they had some of the highest prevalence in the country. They are working to improve their surveillance system because the quality of active risk factor and race/ethnicity surveillance in hepatitis C is not the quality of HIV because it has not been funded as well. It is probably too late for the upstream changes, but they are probably a good model for all of the best policies He wished Medicaid expansion was universal, but it is not.
- Dr. Lopez said that while California has some of the strongest policies, the problem is that they are unfunded policies. That is well-intentioned, but it becomes challenging to address the policies.
- Dr. Hagan said he would like to see much better availability for needle exchange, which is still a taboo subject in his state. The state is really good at taking care of incarcerated folks. The rationale is simple. Everybody is someone's brother, cousin, uncle, daughter. Everyone knows somebody. He also would like to see better access to SUD treatment in the community. One place to focus is on jails since many people enter and cycle out of jails a number of times. Before they ever get to prison, they have been to jail 10 or 15 times.
- In terms of specific policies, Dr. Guilamo-Ramos said that from his point of view, the "low-hanging fruit" is to look at the workforce. The example shared about limitations on pharmacists and PrEP could be applied to other disciplines. The largest segment of the healthcare workforce is nurses, yet they have many regulatory limitations around the country that do not make any sense and limit the ability to improve access to prevention and treatment. Another thing that was striking to him in terms of settings was that he had not heard a lot about the important role of families, biological or non-biological. Families are an important setting, particularly for young people. Thinking about SDOH is impressive in terms of trying to integrate services, co-locating, and cross-training. Consideration must be given to how particular groups or communities thrive and overcome adversity despite significant challenges. He is a little concerned about the narrative, given that it has been focused on vulnerability but does not provide a path forward in terms of how to use the science of how people overcome and what has worked as being important to understand.
- Mr. Driffin suggested that more consideration be given to additional community engagement strategies that can continue to be lifted between CDC, HRSA, and other federal partners to ensure that communities move along with them to beef up strategies.
- Dr. Oster indicated that they are collaborating on some sessions with HRSA HAB for the Ryan White conference that relate to cluster detection and response. Some of the topics include community engagement, partnering with community organizations and providers, how everyone can come together to ensure that they are responding to clusters in a way that helps to make services better for these populations, et cetera. Community engagement around this topic is a major focus. She and Dr. Daskalakis have been spending a lot of time together working to have discussions with lots of different partners, community organizations, policy partners, healthcare organizations, and public health partners over the past few months.

- Ms. Hayes indicated that PACHA is hosting an HIV molecular surveillance small group think-tank that will include their community and federal partners.
- Dr. Anderson indicated that there is a current ECHO program related to the intersection of HIV, substance abuse, mental health, and intimate partner violence (IPV) for which she could share information.

Telehealth/Telemedicine WG Report

Dr. Shannon Dowler, Lead CHAC Telehealth WG

Dr. Dowler reported that the Telehealth WG had engaged in several meetings since its launch during the last CHAC meeting. The first thing the WG did was dig into the benefits and risks of telehealth and summarized their findings into potential areas of interest for CHAC. In terms of benefits, telehealth broadly has the potential to improve various types of access (e.g., geography, transportation, provider limitations, et cetera). Particularly in the sexual health space, telemedicine offers a unique opportunity to reduce stigma. It results in decreased costs, such as non-emergency transportation, lost work time, and practice infrastructure. It has the potential to close care gaps and improve health equity. Telemedicine also has the potential to improve retention in care, empower folks who are receiving services to take control of their healthcare, be more patient-centered, and increase provider productivity. There are many reports showing that patient no-show rates using telehealth are improved and that the barriers that keep people from getting to a scheduled office visit are mitigated with virtual care. As an example, North Carolina Medicaid wanted to know what was happening with its beneficiaries, so they added an adult experience and child experience with telehealth into their Consumer Assessment of Healthcare Providers and Systems (CAHPS) survey. They found that people were generally as happy with their care whether they had telehealth or in-person care. There was not a statistically significant difference for adults or children. Beneficiaries/patients seem to be happy with this modality of care.

There also are risks and challenges to telehealth. The WG found that there is disparity in terms of access to technology and broadband access depending upon where someone lives and the ability to pay for technology and services. Maintaining confidentiality and privacy in the home setting can be a risk and challenge. Not everyone has a large home in which they have the benefit of spreading out or going somewhere private for telehealth visits. There is a loss of ability to identify IPV. There is a risk of influence or manipulation by people who are not seen in the visit, which has significant implications. It takes time and energy to train people to use telehealth technology. There is a potential to break up services and have multiple visits, which may not be ideal. From the standpoint of fragmentation of care, there is always the risk of breaking up the medical home experience, not having good communication, and creating challenges in continuity of care—particularly when there is not shared documentation. There is a risk of losing some of the components of in-person care. This raises questions about the percentage of visits using technology versus in-person visits so that critical pieces of care are not lost. The issue of language barriers comes up repeatedly. In terms of the payment and integrity standpoint, there is a risk of fraud and abuse, particularly in the telephonic arena where it is not possible to confirm someone's identity.

Another challenge in the field pertains to the fact that everyone is using different terms and has different rules. Until everyone can come together nationally and agree on certain terms and on what is/is not covered, there will continue to be of mixed-metaphor of what people are saying. When the terms telehealth, telemedicine, or virtual health are used, everyone is saying and

allowing for different services or benefits. North Carolina Medicaid has 2.8 million beneficiaries. They began an evaluation to determine what was happening. There was a huge plummet in visits when the stay-at-home order was issued by the Governor. Simultaneously, there was an exponential and steep rise in telehealth. There were essentially no services prior to the pandemic, so the baseline was zero. The dramatic improvement in access would have been lost if people had relied on in-person visits, because it completely dropped off the radar.

After studying these data for over 2 years and looking at the relative probability of adults using telehealth services as a function of race, ethnicity, and geography, Black and Hispanic persons and those living in rural areas were less likely to engage and there was not a tremendous amount of improvement over time. While there is a lot of discussion about all of the great opportunities Telehealth offers to improve health equity and access, the lived experience in North Carolina is that the odds are still against closing those gaps. On the other hand, people with chronic conditions leaned in hard and fast to use telehealth early in the pandemic. Over time, that number decreased. In the rural/urban space, there has been an increase in the last 6 months with people beginning to use the technology more consistently in rural areas.

Looking at some specific codes, North Carolina assessed child developmental services to decide what would be kept as permanent policy versus what would not. Consideration was given to a service as a function of whether it changed geographic, racial, or ethnic equity. Consistently, the findings did not identify changes. They found that urban individuals were more likely to engage in telehealth even though they have more child development centers than in rural areas. The same patterns were observed by ethnicity in that someone who was not Hispanic was more likely to engage in child development virtually. The same difference was seen in terms of whether someone was Black or White. Gaps were not being narrowed in this area, and this pattern was reproduced across multiple codes. The data show that the same people who are using telehealth are the same people who are using in-person care, and that new patients are not being entered into care.

The WG talked specifically about opportunities to improve sexual healthcare in the context of modernization of technology and proposed a few areas they think are the most important. One opportunity is with home or alternate testing for STIs. The conversations over the last 2 days of the CHAC meeting aligned nicely with these recommendations. Consideration should be given to ways to normalize home testing and increase home delivery of medications, which could reduce the stigma of going into a pharmacy to ask for something. PrEP access could be enhanced to have a more patient-centered approach. Inequities around access to PrEP are significant and broad across the country, and PrEP is just not getting to people in an equitable way.

With this background information in mind, the WG developed the following recommendations and invited input regarding any priority areas for which CHAC thought proposals might be made to CDC, HRSA, or both.

- **Build on the PrEP letter that went out early in the COVID-19 Pandemic (CDC):**
 - Recommend that CDC launch a formal campaign to teach providers how and where virtual services can assist in the EHE goals specific to PrEP
 - Recommend the potential for the same initiative related to retention in care for HIV

- **Explore how virtual services can enhance routine STI screening for all populations (CDC):**
 - Recommend that CDC fund pilot home testing service delivery models broadly to seek to understand the impact of this model
 - Award sites based on factors such as poverty indicators, payer mix, population and geographic disparities
- **Study health equity as it relates to telehealth service provision (CDC/HRSA):**
 - Early data suggest that telehealth has not overcome barriers to access to care
 - A formal study could spawn interventions that might impact equitable service delivery more effectively
- **Deploy a Tele-PrEP initiative for FQHCs (HRSA):**
 - Recommend that HRSA fund a Tele-PrEP initiative for FQHCs to pilot focused on areas with high need to PrEP ratio

CHAC Member Discussion and Vote on Telehealth/Telemedicine WG

Dr. Gayles noted that while he and Dr. Anderson would moderate this discussion, they both recused themselves from participating in the discussion and any related votes due to COIs related to telehealth.

The following questions, observations, and suggestions were raised:

- Dr. Driffin said the only thing he would add, especially for others as they begin, was that the processes address the nuts-and-bolts questions around what success looks like for communities. This means ensuring that Black and Brown people have access to the internet, tablets, and/or whatever other vehicles are necessary to get them to the option of telehealth/telemedicine.
- Dr. Mermin noted that the data presented were very impressive and showed that a smaller proportion of certain populations participated in telehealth during the pandemic. He wondered whether they still participated in health visits and if those using telehealth were the same as those presenting in-person. He thought it would be beneficial to understand whether people who did not participate in telemedicine dropped out of care entirely or continued care through in-person visits.
- Dr. Dowler indicated North Carolina found that the same people who are using telemedicine are the same people who are presenting in person. The Duke-Margolis Center for Health Policy also performed a data analysis and came to the same conclusion that the same people who are using telehealth are the same people that are presenting in-person and new patients are not getting into care. People who are engaged in health care are engaging in health care maybe in more convenient ways or in different ways, but access to care is not actually being broadened. The exception to that seen in North Carolina was in primary care homes. Rapid adopters picked up telehealth really quickly and made it a large part of their practice, increased the number of patients they saw overall and improved access to care. Generally, the beneficiaries who are accessing care are just accessing care differently. In terms of whether people who did not participate in telemedicine dropped out of care entirely would have to be analyzed specifically. While they saw overall engagement, the beneficiaries did not change. North Carolina Medicaid

maintained a lot of telehealth services, but their commercial partners have not been as clear. The things that they are keeping would allow people to use their smartphone. In the sexual health arena, there are many positive opportunities because of stigma in that people will feel more comfortable in using self-collected tests and it would feel more patient-centered.

- Dr. Mermin emphasized that technologies are increasingly being seen as tools for helping people stay healthy. Perhaps providing someone with a smartphone and software might make a difference in people participating. Consideration would have to be given to whether there could be reimbursement by Medicaid or private insurance. The upfront investment could be prohibitive for both providers and individuals unless it was covered by insurance, but this could eliminate some of the obstacles for people—particularly those with limited resources.
- In terms of the idea of a more formal campaign to teach providers how/where virtual services can assist in the EHE goals specific to PrEP, Dr. Daskalakis indicated that NCHHSTP's Capacity Building and Technical Assistance Branch has materials⁴³ for providers that focus on telemedicine around PrEP, which probably could be nuanced more to specifically identify places where telemedicine may be more or less appropriate.
- Dr. Greene suggested that perhaps the proposed recommendation to study health equity as it relates to telehealth service provision should be elevated to the first bullet.

CHAC Action

Mr. Riester made a motion to approve the proposed Telehealth/Telemedicine letter, with the suggestion of moving health equity to the top bullet in terms of prioritization. Dr. Markham seconded the motion. CHAC approved the letter with 8 affirmative votes and 2 abstentions.

Public Comment Period

Mark Misrok

Executive Director

National Working Positive Coalition

I am Mark Misrok. I'm Executive Director of the National Working Positive Coalition (NWPC), which works to strengthen responses to the long-ignored employment needs of people living with or at greater vulnerability to HIV. I'm a person living and aging with HIV and a member of the Steering Committee for the US People Living with HIV Caucus (US PLHIV Caucus). Last Summer, the CDC released their most recent data report from their ongoing collection of surveillance data of people living with HIV in the US from their MMP, or Medical Monitoring Project, surveillance data. This latest data report is for 2019, the last full year before the impacts of the COVID-19 pandemic in this country. This most recent data report presented 41% of people living with HIV as unemployed prior to the impact on employment and the job market of the pandemic. This extraordinary high unemployment rate among people living with HIV in this era of care and treatment reflects the profound lack of access to employment-related

⁴³ <https://www.cdc.gov/hiv/effective-interventions/library/telehealth/implementation-materials/cdc-hiv-ei-telehealth-practitioners-guide.pdf>

information, services, and resources within HIV supportive services that has continued unchanged across all areas of the epidemic. We know that communities most vulnerable to HIV and most impacted by COVID and a host of health crises are always also communities with long histories of unequal access to quality education and to employment and economic opportunities. Meanwhile, the HIV/AIDS Bureau has kept directives in place since the 90s that ban use of supportive services dollars by Ryan White HIV/AIDS program grantees to provide employment or job readiness services, suppressing growth of responses to the employment needs of people living with HIV, that could grow organically and community-based programs most trusted and often most committed to communities not prioritized in mainstream workforce development or vocational rehabilitation initiatives. It is time that our leaders, and advisory bodies, and government agencies shaping the US HIV response end the cruel abdication from understanding and addressing the employment-related needs of people living with or at greater vulnerability to HIV that has been our long-sustained pattern. Thank you.

Amy Killelea

Killelea Consulting (PrEP for all)

Hi everyone. My name is Amy Killelea. I am a consultant and for the purposes of what I'm going to talk about today, I've been working with Johns Hopkins University over the past about 12 months working on a proposal for a national PrEP program. Thank you for the opportunity to speak to you all today. I want to highlight that we have got an opportunity presented to us in the President's Budget for FY23, which was released a few weeks ago. It includes an incredible opportunity to expand access to PrEP in this country and includes a call for Congress to enact a new \$9.8 billion 10-year national PrEP program for the uninsured and underinsured, coupled with significant reforms to ensure that people on Medicaid who need PrEP can easily access it. I want to focus my remarks on both the opportunity before us with the new momentum from the Administration as well as what I think is a growing and should be a growing sense of urgency around PrEP. PrEP uptake, as I am sure this body has discussed in meetings prior, continues to be very low in the US, with only about a quarter of folks who could benefit from PrEP actually taking it and growing disparities among Black, Hispanic, and Latino communities in particular. I think it is becoming more and more apparent that we will not end the HIV epidemic without a drastically different approach to PrEP. A few things to really highlight in terms of the systems failures when it comes to PrEP. One is that we have a system for PrEP access, particularly for those who are uninsured and even those on Medicaid that is fragmented, that is confusing, and that is incomplete. For those who are uninsured, the medication is often available through a different program and mechanism than the lab services, which may also be separate from the ancillary services for PrEP. We also have put our thumb on the scale of a largely clinical approach to PrEP heavily dependent on primary care, on community health centers, and 340b entities who are big and savvy enough to navigate the complexities of PrEP financing. And let me be clear, because we heard from the previous presentation about community health centers and telehealth clinical entities are necessary for PrEP access, but they are nowhere near sufficient. And so the opportunity before us, I think, is to re-envision what a national PrEP program and functioning system for PrEP access could look like. What was submitted in the public comment was a sign-on letter from over 20 national, state, and regional organizations that really outlined a set of principles that provide a foundation for a national PrEP program, so I want to highlight just a few of those. First is that the program has to prioritize equity, has to invest in mechanisms that increase access to Black and Brown communities, trans folks, cisgender women, folks in the South, and others who are currently failed by our current PrEP delivery systems. The program has got to be simple and it has got to be accessible and include medication, labs, and the ancillary services needed to support PrEP access. I think the accessibility part means that it has to be available through a greater range of community-based access points outside of just clinical delivery sites and community health centers. By expanding

those touch points, the goal is also to increase PrEP demand in communities who are not well-served by, and not touching frankly, traditional healthcare delivery sites. Finally, a PrEP program has to be sustainable and it has to be based on evidence. We have got a generic form of Truvada, TDF/FTC, that is safe. It is highly effective. It is incredibly cheap. It is clinically appropriate for the vast majority of folks. But we aren't maximizing that potential to open the floodgates for PrEP, largely because we have a current system that incentivizes brand name drugs at every turn. We are also going to fail to maximize some of the newer forms of PrEP like long-acting cabotegravir if we don't insure that that drug and the drugs that are coming down the pipeline are available at fair public health prices and through a much broader network of public health providers. I will close with just saying that this is an opportunity and it's a challenge. We have a tough political environment to get this ambitious proposal through Congress, but I hope that through the CHAC and the folks on this call today that we can harness the momentum that we have with the President's Budget and build a better system for PrEP access. Thank you.

Chris Jowett

Chief Commercial Officer
Visby Medical

Good afternoon. Thank you for the opportunity to summarize our recommendations committee. I'm Christopher Jowett and I represent Visby Medical. I am the Chief Commercial Officer with Visby Medical based out of San Jose, California. Accurate STI point-of-care tests can revolutionize patient care. The "CDC's 2021 STD Treatment Guidelines" recommend nucleic acid amplification testing (NAAT) for the detection of chlamydia and gonorrhea and specifically call out chlamydia and gonorrhea in symptomatic women. In the "STI National Strategic Plan," there is a recurring theme requesting innovative solutions and approaches to address the ongoing and emerging challenges in STI prevention and control. Specifically, it calls out the need to develop point-of-care diagnostic tools. Visby Medical has developed such a tool which delivers PCR results in less than 30 minutes in the palm of your hand and received FDA clearance and CLIA waiver in August 2021. Visby Medical developed this rapid point-of-care platform with substantial support from the NIH and yet there remains significant hurdles to deliver these tests equitably nationwide. The CDC and other government agencies can help in the following ways. Support implementation science studies to assess clinical adoption in various settings. Implement policies and funding to provide equitable access to technologies that can improve patient health. Understand the true prevalence of trichomonas, a silent epidemic and not yet reportable. Support reimbursement incentives to promote breakthrough innovations. Breakthrough technologies come at a cost. Extraordinary pressure to reduce testing costs comes at the expense of patient care. Rather than reimbursement based on reagent and operational costs, CMS should consider the value that rapid and accurate point-of-care diagnostics provide to the patient and to public health. Visby has engineered out the need for highly trained lab personnel to interpret and operate the results. This and enabling specific targeted treatment based on PCR diagnostic results at the point-of-care is better for the patient, reduces the risk of antibiotic resistance, lowers operational costs, and reduces spending over the long-term by preventing more expensive sequelae, like pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. As the CDC is focused on advancing health equity and insuring access to diagnostic innovations, the Visby medical sexual health test is designed to support that goal and can fundamentally transform patient care and the public health. This point-of-care test platform is patient-centered and convenient, which in-turn can address access and equity concerns across the country. We asked the committee to focus on the value of point-of-care diagnostic testing and consider how to incentivize its use to address the STI epidemic. We are eager to serve as a resource for you at the CDC, HRSA, and HHS to reduce and prevent STIs moving forward. We look forward to continued opportunities for collaboration

with the Visby medical sexual health preventive care product and our future direct-to-consumer STI product offering. Thank you.

Jules Levin

Executive Director/Founder
National AIDS Treatment Advocacy Project

Hi, everybody. This is Jules Levin. I'm the Executive Director and Founder of the National AIDS Treatment Advocacy Project (NATO). I come to you as a person today living with HIV for 40 years. I'm now 72. I've been an advocate for 25 years. I am HIV aging and am now what I call "elderly." I think the CDC, Jonathan, calls people over 65—that's the category "elderly." Over 50 is "aging." I also come to you as a person cured of hepatitis C 21 years ago with pegylated interferon and ribavirin. I'm going to discuss 2 things today, hepatitis C and aging and HIV in 3.5 minutes. Number one, hepatitis C. I think it's disgraceful that here in the United States where we have had a cure for a number of years for hepatitis C, where you can cure hepatitis C in an inexpensive, safe manner with 8 or 12 weeks of therapy that we don't have a national hepatitis C elimination program. It's beyond talk. It's beyond speech. The discussion over the past 2 days around hepatitis C at this CHAC meeting has not been fully comprehensive. The needs for people living with hepatitis C have not been adequately discussed or addressed. Curing hepatitis C requires, in my opinion, a program, a Ryan White Care Act type program, that can be done in 5 or 6 years of limited time or \$5 or \$6 billion dollars, which is in the full scheme of things nothing. A drop in the bucket for the federal government. We need full funding for screening. We need to use electronic health records. We already have new models of care that provide support services for IDUs that could be utilized. The CDC is not working. They are not doing their duty. They are not providing and meeting the needs of this community and what is needed. The CDC is not working with local departments of health, many of whom already have elimination plans. We need funding and the CDC does not seem to be working with the local and state DOHs to develop and push these programs forward and help support them further. They're not providing resources and collaborations. Yesterday, somebody said DAAs are expensive. Are you kidding? They're \$15,000 for a course of treatment. To treat someone like me with HIV for 20 years is \$400,000. Syringe exchange programs and needle exchange programs is only one issue in the full framework that needs to be addressed to eliminate hepatitis C. Aging and HIV. The response has been completely inadequate. It's also a disgrace that this CHAC meeting at CHAC meetings have not had a panel on aging and HIV. We are experiencing more comorbidities than people without HIV. We have reduced life expectancy. We're getting bad care. The 20-minute visit does not work. African Americans get the worst care. Suffice it to say and in summary, it's just really unfortunate and a disgrace that aging and HIV is not adequately addressed and is not part of the discussion in almost every circle that participates in that is a discussion amongst the leaders at the NIH, CDC, many circles around leadership and HIV, our federal government, and state governments as well. Thank you.

Lorren Sandt

Executive Director
Caring Ambassadors Program, Inc.

My name is Lorren Sandt. I am the Executive Director of the Caring Ambassadors Program in Portland, Oregon. We do education and advocacy for people living with hepatitis C and lung cancer since 1997. Dr. Mermin opened the meeting discussing the Center's equity initiative strategy to achieve equity and eliminate health disparities, and the need to address some syndemics. You said you wanted to become as holistic as possible and asked what you could do better. Well, with all due respect, funding holistically, break it down, break down the silos, include reimbursement silos across all agencies. If these funding silos are not broken down,

hepatitis and STIs, health disparities, and health equity will never come to fruition in our country. The \$40 million in funding is frankly something everyone at CDC should be ashamed of. One program highlighted yesterday gave 36 community-based organizations \$400,000 dollars in funding to address one part of HIV. The average funding each state receives in hepatitis funding is \$315,000 dollars. The last professional judgment from the CDC and 2016 called for closer to \$400 million in funding each year for 10 years. This is a finite number so we can reach our elimination goals. We have an elimination plan like HIV, but we have no implementation plan and we have no funding. In Oregon, we have 7600 people living with HIV. We have dozens of case managers and a room full of epidemiologists. We have 90,000 people living with hepatitis C, 1 case manager at 1 HIV organization, and 1 state epidemiologist that we just got after 15 years of no epi. Funding must be commensurate with the impact of the disease. Almost every presentation we've seen, and they've been great, has been a call to break down silos so programs can meet people where they are. We are missing too many opportunities to help people when they reach out for care to help them. There is a cost-savings when people are tested and treated for the disease they present with rather than sending them down the road to test for something else or go somewhere else for care. Every time someone is denied, we are telling them they are not worthy. Hepatitis care and treatment is cost-saving to our health system. I respectfully ask every member of CHAC to be bold. Consider asking the Administration and Congress for an expansion of Ryan White programs to fully integrate hepatitis care and treatment and STI care and treatment, and the CDC to fully integrate the Center with your programs and your funding. We're done PCSIs. We're done with demonstration projects. We know what works. We need the political will to change the policies that keep these funding and silos and place. Thank you very much. And one final comment. I never heard what the outcome was on the discussion of whether the CHAC should weigh in on the mental health of our children. I firmly believe that it is your duty to weigh in on that. I hope that you guys voted to do that and will be weighing in and helping our children to live fully as they grow. Thank you very much.

Daniel Raymond

Director of Policy

National Viral Hepatitis Roundtable

I'm Daniel Raymond. I'm the Director of Policy for the National Viral Hepatitis Roundtable (NVHR). You heard from my colleague yesterday, Adrienne Simmons, with our colleague from Harvard Law School, Julia Harvey, on the current state of Medicaid access to hepatitis C direct-acting antiviral. I just want to go back to their remarks and note that, John, when you asked for guidance that there was a recommendation that more guidance to state Medicaid programs would be enormously helpful. My colleague Adrienne specifically called out the value in recent years of the HHS Medicaid Affinity Working Group, which the Office of Infectious Disease Policies led, but wrapped up its work last year. That Affinity Working Group was really instrumental in aiding states, not only in removing barriers to coverage, but also serving as a catalyst and incubator for discussing innovative payment and financing models for comprehensive care, including elements like case management and peer patient navigation that can be especially vital for achieving health equity goals, but also for analyzing administrative data to construct care cascades for states' Medicaid beneficiaries. This kind of work has become even more important. As some of you may be familiar, the manufacturers of hepatitis C therapeutics have recently imposed greater restrictions on 340B-covered entities. The need for strategizing about ensuring access and scale-up of care is vital. I would encourage CHAC to consider opportunities for making recommendations to further that work through concerted efforts. And then secondarily, I wanted to note the release last week of the White House Office of National Drug Control Policy's "Drug Control Strategy," which included very strong discussion of harm reduction, including support for syringe services programs and

specifically in their performance measures, committed to increasing the number of counties with elevated overdose rates that had an operational SSP by 85% between a 2020 baseline and 2025. I would suggest that there's an opportunity here for CHAC to make recommendations that CDC and HRSA, as part of broader efforts, provide guidance, technical assistance, and policy development on accelerating SSP implementation. I would call attention particularly to opportunities through federally-funded facilities, including Ryan White-funded providers and clinics, STD clinics, and Federally Qualified Health Centers. As we heard earlier today in terms of, for example, the West Virginia experience with clusters and outbreaks, this work has taken on an increased urgency. With the leadership of the Biden/Harris Administration and the new drug control strategy, there is ample opportunity to dive in and make meaningful progress. Thank you.

Recap Day 2

Travis Gayles, MD, PhD

CHAC Co-Chair, CDC Appointee

Jean Anderson, MD

CHAC Co-Chair, HRSA Appointee

Dr. Anderson emphasized that CHAC heard some incredible presentations and some very important topics covered. Reflecting on those and high-level messages, they started the morning with a special presentation from FDA and CDC about self-testing and self-collection of specimens in the diagnosis of HIV, HCV, and STIs. There was broad agreement on the needs and advantages of these tools now more than ever. The technology is available. Many of these are available globally. However, there are some barriers that they learned more about during the day in terms of meeting regulatory requirements. Some of the barriers identified include a possible need for additional validation for some tests, the high cost to seek regulatory approval, perhaps the lack of incentives for manufacturers regarding return-on-investment (ROI) in putting in the time, effort, and funding. The take-home message is that there needs to be concerted outreach, which to some degree already is being done, to key players and key stakeholders. It seems like the first step is to discuss with FDA avenues to reduce cost and consideration of where and when manufacturers can be incentivized to provide these critical tools. In the afternoon, CHAC heard about exemplary programs from New Mexico, North Dakota, and San Francisco. All of them exemplify a syndemic approach. They also heard a presentation on CDC cluster response and interventions. The take-home messages include the fact that in New Mexico, North Dakota, and San Francisco, the local or state policies enabled some of these programs and were able to breakdown silos and address things in a cross-cutting way. The issue of silos has been a recurring theme of this meeting and every CHAC meeting in which Dr. Anderson has been involved. The issue of the importance of meeting people where they are intersects with the discussion on self-testing and self-collection. There is a need to link to care and to pay attention to certain high-risk key populations, including incarcerated individuals and pregnant and post-partum women in terms of congenital syphilis, mental health disorders, and SDOH. There also was mention of some of the workflow issues that brought to mind some of the work that has been done in low- and middle-income countries on task-sharing and task-shifting and how the US could do a much better job of that.

Dr. Gayles indicated that in addition to Dr. Anderson's very thorough and comprehensive summary of the day, he had only a couple of points to add. Everything that Dr. Anderson mentioned was a reminder of the importance that all of this work takes into consideration the whole person and not just one aspect as they continue to think through access to testing, access to healthcare, and the full picture of what people face in terms of being able to access

and fully utilize all of the available resources needed to be successful. Regarding a comment raised during the public commentary about looking into the issue of children's mental health, particularly in the face of different legislative efforts occurring across the country specifically tied to sexual and gender identities, he assured everyone that CHAC is looking into that and would be addressing that as a group during the next day's Business Session. CHAC does believe this is an important issue, does take their role as a committee seriously, and hopefully will be able to utilize this role to raise further awareness to the relevant parties who may have an opportunity to fill some of the gaps or address some of the issues that are secondary to the various efforts underway.

Adjourn

Dr. Mermin thanked everyone for another day of outstanding presentations and discussions. He then officially adjourned the meeting for April 27, 2022 and CHAC stood in recess until 10:00 AM ET on April 28, 2022.

Day 3: Welcome and Roll Call

Jonathan Mermin, MD, MPH (RADM, USPHS)

Director, National Center for HIV, Viral Hepatitis, STD and TB Prevention
Centers for Disease Control and Prevention
CHAC Designated Federal Officer
Centers for Disease Control and Prevention

Dr. Mermin called the proceedings to order at 10:05 AM ET and welcomed participants to the third day of the CHAC meeting. He conducted roll call and asked members to disclose any new COIs. COIs did not differ from the previous day and are reflected in the table on page 8 of this document. He confirmed that 21 members were in attendance, which established quorum for the CHAC to conduct its business on April 28, 2022.

Recap of Days 1 and 2

Travis Gayles, MD, PhD

CHAC Co-Chair, CDC Appointee

Dr. Gayles provided some high-level highlights from the previous 2 days. The first day began with updates from colleagues at CDC at HRSA describing the fantastic work that they continue to do, including efforts to better understand the increased presence of mental health concerns among children, the increased work at CDC regarding health equity and infusing equity into all aspects of their work, and the great work underway at HRSA and introductions to new key staff members there. There is a lot of great innovation and it is important that CDC and HRSA continue to lead the way at the federal, state, and local levels. One of the key issues that arose during the morning session regarded the role CHAC might play in terms of commenting on or putting forward recommendations to offset some of the political efforts that are putting the great work at CDC and HRSA have invested in at risk, as well as creating obstacles and challenges for communities in being able to take advantage of the programs and opportunities that result from the work of these agencies. Programs from Mississippi, New York, and Minnesota highlighted innovative strategies they are implementing to increase utilization and access to testing, such as using the school space to increase access to young people and leveraging some of the technologies and strategies that were put in place during the COVID-19 response to modernize the public health infrastructure. These programs underscored the importance of using COVID-19 pandemic innovations as models for securing and sustaining funding to continue to support these efforts and codify that work moving forward in a post-COVID world.

During the second day, CHAC heard presentations highlighting how impactful self-collection kits could be in communities that have historically not utilized traditional brick-and-mortar structures. As a result, the availability of self-collection kits increased testing practices in a number of communities. It is known that when people are tested more frequently, the incidence of new cases is reduced. Self-testing also can be used as an opportunity to connect people to clinical care, social-emotional support, and other services such as those that address SDOH. There were discussions with colleagues from FDA regarding the pipeline and approval process for self-collection kits, given concerns that arose with regard to how FDA views HIV versus HCV self-collection kits. CHAC wondered if/how manufacturers producing self-testing kits could be incentivized to increase production in the variety and availability of self-test kits. There are authentication methods domestically and internationally that could serve as models to increase the self-test kit approval process. CHAC also engaged in discussion related to key topics in syndemic analysis, which continues to underscore the need for all work to take a whole person

approach with respect to the various issues that influence an individual's ability to access resources that are being put forward, utilize them effectively, and have successful health outcomes. Exciting and impressive syndemic approaches were presented, along with limitations many jurisdictions will have in moving those creative ideas forward due to financing challenges, particularly in under-resourced districts that do not have significant financing outside of the federal government. While this may not lend itself to a letter at this point, this topic deserves further discussion and consideration in future CHAC deliberations. The Telehealth WG put forth an excellent letter, which was approved and will be sent out following the meeting. Suggestions were made for potential development of 2 letters, one to the Secretary of Health regarding LGBTQ youth and one to FDA regarding the pipeline and approval process for self-collection kits.

Business Meeting

Adoption of November 2021 CHAC Minutes

Jean Anderson, MD

CHAC Co-Chair, HRSA Appointee

Dr. Anderson indicated that members had been provided with a copy of the November 2021 CHAC minutes for review. No errors or omissions were identified, no questions or concerns were raised, and no edits were suggested.

CHAC Action

Dr. Mehta made a motion to approve the November 2021 CHAC minutes, which Dr. Greene seconded. CHAC members unanimously approved the minutes with no changes or further discussion.

Update from the Presidential Advisory Council on HIV/AIDS (PACHA)

Ada Stewart, RPH, MD, FAAFP, AAHIVS, HMDC

PACHA Liaison Representative for CHAC

Dr. Stewart reported that PACHA last met virtually on March 14-15, 2022 for its 73rd full council meeting where they had an opportunity to bring back "PACHA-to-the-People." When PACHA was re-established in 2019, the goals of the Co-Chairs recognized the importance of reaching out to the people on the ground—the individuals working in, living with, or at risk for HIV and AIDS—to help guide the work of the PACHA. She expressed gratitude to PACHA's current Co-Chairs for allowing "PACHA-to-the-People" and thanked them for a very successful virtual meeting. The first day consisted of a welcome from Dr. Rachel Levine, Assistant Secretary for Health at HHS, and Harold Phillips, Director of the White House Office of National AIDS Policy regarding NHAS and their commitment to EHE. Reports were presented from PACHA's Stigma and Disparities, EHE, and Global Subcommittees and the Stigma and Disparity Subcommittee's WG that prioritizes molecular surveillance and cluster detection issues. PACHA took this on as a priority due to the growing number of responses they have heard from individuals living with HIV and others regarding the application of this response tool, especially in terms of criminalization of HIV and other social justices.

During the PACHA-to-the-People interactive community engagement session, community members provided feedback in breakout sessions focusing on 2 main topics. The first breakout session focused on HIV prevention in the context of EHE. This group focused on prevention of HIV in women and adolescent girls, those 55 years of age and over, persons living with substance use and mental health disorders, the LGBTQ+ community, and PrEP assistance programs. In the NHAS and EHE Initiative breakout, community folks provided input about how the strategy is working in their states, cities, and territories and how PACHA can help. During these community engagement sessions, there were passionate and robust discussions from communities highlighting the need for whole person care; addressing QOL issues; the need to address aging with HIV; the need to address persons with physical and/or mental health issues, and/or SUDs; the importance of elevating U=U and recognizing the needs of all women, cisgender and transgender; ensuring that there is a national comprehensive program to address barriers to prevention and making sure that rural communities are engaged; and the importance of advocacy in terms of funding.

There was an update on the President's Emergency Plan for AIDS Relief (PEPFAR). PACHA's Global Subcommittee has worked diligently to ensure that HIV/AIDS is elevated from a global perspective, making sure that future guidance is sought from global and domestic lessons learned. There was an important panel discussion related to HIV amongst women and adolescent girls and why representation matters in response to HIV in this population. There was an emphasis on the importance of women, especially women of color, being part of clinical trials and addressing the bias that exists in prescribing of PrEP to women. There was a call to action to shift the narrative to ensure that all women living with HIV need to have a seat at the table and that IPV and QOL must be addressed for both cisgender and transgender women.

There was a panel discussion regarding PrEP for the nation and how to get PrEP to everyone who wants and needs it. There was discussion and approval of a draft letter to the HHS Secretary with PACHA's recommendation on scaling up PrEP to the nation. There also was a panel discussion on strengthening the HIV workforce. Dr. Wendy Armstrong and Vincent Guillermo-Ramos presented as part of the panel about how this important goal can be accomplished. They discussed the importance of removing regulatory barriers that place restrictions on practice at the highest level of training and licensure to ensure that the talents of Advanced Practice Nurses (APN), Nurse Practitioners (NPs), and Social Workers can be leveraged to the fullest of their ability to increase the HIV workforce; ensuring that CMS offers reimbursement for decentralized, team-based, whole person, HIV prevention and care services; supporting a shift toward education and training for the future health workforce that emphasizes key competency of team-based, whole person, HIV care; providing training for those not only pursuing full-time HIV work, but also those who are intimately involved in that; having the knowledge to be able to address co-morbidities using training tracks, residency programs, access to experts, et cetera; investing in infrastructure; developing decentralized and differentiated HIV prevention and care such as telehealth and community-based services; and allocating funding toward HIV using specific demonstration projects.

CHAC Member Observations/Suggestions: PACHA Update

The following questions, observations, and suggestions were raised:

- Dr. Guilamo-Ramos noted that this speaks to the issue of meaningful engagement of people living with HIV in the workforce and expanding definitions of the workforce beyond the clinical to think about a range of important actors who could help to end the epidemic in the country.
- Mr. Lindsey pointed out that there is a community health worker apprenticeship program that came out of the broader HRSA environment.
- Dr. Armstrong indicated that HRSA established and put many resources behind a Community Health Worker Training Program (CHWTP). More programs such as this are needed, but do require additional resources for childcare, transportation, and other supports peers will need to take advantage of such opportunities.
- Dr. Driffin emphasized that it is important to be mindful of diversity, equity, and inclusion in the workforce so that there is racial and gender diversity in key health departments along HIV jurisdictions and such that the community sees more people who look like them in key leadership and executive decision-making roles.
- Dr. Gayles said that he was hearing that perhaps it would be beneficial to stand up a CHAC Workforce Development WG. There previously was a CHAC HIV and Aging WG. Perhaps it would be beneficial to hear an update on this WG and the status of its efforts.

Action Item #1: Potential Letter Regarding LGBTQ Children/Youth**Jean Anderson, MD**

CHAC Co-Chair, HRSA Appointee

Dr. Anderson reminded everyone that the work that CHAC does and the advice they can give to CDC and HRSA is somewhat limited between meetings. The reason they chose the 2 action items for this business meeting was because they felt that there was some sense of urgency for these topics and that some bullet points could be created that CHAC could vote on during this meeting, which could then be developed into a letter over the next few weeks. She then reviewed the proposed components for the letter:

- Background:
 - In December 2021, the Surgeon General warned of a “devastating mental health crisis among adolescents.”
 - There was a 60% increase in major depressive disorders from 2007 to 2019 (National Survey of Children’s Health. HRSA October 2020).
 - Suicide rates increased nearly 60% in youth 10-14 years of age from 2007-2018 (National Vital Statistics Reports September 2020).
 - These problems are magnified among LGBTQ youth (CDC Adolescent Behaviors and Experiences Survey (ABES) 2021).
 - More than 60% of LGBTQ students experiencing poor mental health during the pandemic, which is over twice that seen in heterosexual students.

- LGBQ students were more than 3 times as likely to have attempted suicide in the past year.
 - Three-quarters of LGBTQ students experienced emotional abuse at home during the pandemic.
- For youth to thrive in schools and communities, they need to feel socially, emotionally, and physically safe and supported.
- There are ample data showing that LGBTQ students experience more bullying, harassment, and physical assault as compared to heterosexual students (2015 National Youth Risk Behavior Survey).
 - Young gay/bisexual men are at increased risk for HIV infection (**need update**). In 2014, they accounted for 8 of 10 new HIV diagnoses among youth (HIV Surveillance Report 2014).
- LGBTQ-supportive school policies and practices support all youth with decreases in depressive symptoms, decreases in suicidal thoughts and behaviors, and decreases in suicide attempts—especially among LGBTQ students (National YRBS 2015 & 2017; CDC School Health Profiles 2014 & 2016).
- From 2015-2019, over 200 pieces of anti-LGBTQ legislation were proposed in 35 states. In 2022 alone, over 300 bills have been introduced in state legislatures, often focusing on restricting school curricula, access to books or other educational materials relating to gender identification/gender-affirming care, or sexual orientation (<https://childtrends.org/publications/anti-lgbtq-policy-proposals-can-harm-youth-mental-health>; NYT 4/27/22)
- Implications/Concerns:
 - These legislative efforts send a clear message to LGBTQ youth that they are not okay.
 - Legislative efforts at the state level likely will create significant gaps in access to health care and social support services critical to these youth, including mental health services.
 - These legislative actions also can cause significant anxiety and depression that can further impact adherence to and engagement in medical care.
 - These legislative efforts will put HRSA and CDC efforts (demonstration projects, funding mechanisms) at risk and will impair successful delivery of services.
 - These gaps in care introduce spaces for the federal government to step in and provide a connection to support services that fill that void.
 - Recommendations:
 - Develop and disseminate resources at the federal level for youth and their families, as well as teachers and school counselors, to try to mitigate the potential harmful effects of any LGBTQ legislation.
 - Develop and disseminate resources at the federal level targeted to healthcare providers to better educate them about LGBTQ health and mental health and risk reducing strategies, and to provide information about assistance when problems are identified.
 - Develop public service messages (PSAs) and social and other media to educate the public about these harms and the need to reduce/prevent stigma and discrimination for these vulnerable youth.
 - PSAs also should be developed to target social media and other electronic platforms most utilized by youth, including LGBTQ youth, to provide information and resources.

CHAC Member Observations/Suggestions: LGBTQ Letter

The following questions, observations, and suggestions were raised:

- Consider forming a CHAC WG around these issues.
- Be explicit about promoting ways to encourage healthy sexual behaviors.
- Be specific about risk reduction strategies for at-risk adolescents, such as availability and provision of PrEP.
- Recognize the importance of school counselors at the state and county levels, and support school connectedness in general.
- Thinking particularly about youth who are in the foster care system, target information to social service providers outside of the schools.
- Discuss the potential need for housing assistance, which often goes unnoticed as part of their lived experience.
- Discuss the lack of gender-affirming care and the lack of provision of services/information that involves gender identity, and be more explicit about the mental health challenges that entails. There are efforts to prohibit conversations about sexual or gender identity, some of which is legislative and is actively seeking to bring child abuse charges against anyone who provides gender-affirming services and/or information.
- Perhaps there should be something about starting earlier than the education system. For instance, Oklahoma wants to ban any markers of non-binary gender identities on birth certificates. This seems to be going even further in an effort to erase identities that have been long and hard fought for.
- Highlight the importance of safe spaces, including safe spaces in which families can receive high quality and accurate information. For youth who already feel isolated or for whom the online space or social media is exacerbating their mental health issues, perhaps there could be some opportunities for in-person convening or collective healing through safe spaces or similar avenues. Parental consent was raised during the presentations. Sometimes, parents may be the bullies. Youth need to have safe places where they can speak freely about bullying from one or both parents, as well as school and/or social bullying that is occurring.
- Willful disinformation campaigns should be mentioned in the background section.
- Discuss funding.
- Perhaps there could be a leading bullet point before getting specifically into LGBTQ youth to recommend enhanced effort across the board to increase access to mental health services for all children, particularly around connectedness, coping mechanisms, access to therapy in a timely manner that addresses their mental health needs. That could be the big take home since all youth are currently behind the metaphorical 8 ball. Then it could go on to say, because of everything Dr. Anderson laid out, there needs to be special attention to

LGBTQ youth given particular legislative efforts and include the data showing the implications and connections within all of that.

- Dr. Cheever noted that the topic pertains to LGBTQ issues. If the letter and recommendations are made more general, this topic could be swept into a more general set of discussions around mental health for children. While this is critical as well, it would not focus specifically on the needs of trans and LGBTQ youth who are in places where there have been specific political movements to make it more complicated for them.
- Dr. Mermin added that there are data that support the idea that not only is there a disproportionate effect on mental health among LGBTQ youth, but also there is a fairly large proportion of youth who identify as LGBTQ and, therefore, this has public health importance in this political and social environment that CHAC has been discussing. It is possible to make a difference and it seems like a very important issue, particularly because for STDs (though maybe less) and HIV, there is a highly disproportionate rate among gay and bisexual youth, males particularly. This is a strong rationale for the focus. Based on the discussions, it is very hard for parents, youth, and teachers to obtain information about how to deal with this. The idea for the first bullet to focus on dissemination and access to credible resources is the next generation. CDC/HRSA and other partner organizations have a responsibility to get information out that can be useful and there is also the legal/policy level.

CHAC Action

Dr. Anderson made a motion to approve the letter for LGBTQ youth, which will be developed and circulated for review by CHAC before sending it out, including the 4 original recommendations presented and the addition of the following 4 recommendations:

- Increase efforts across the board to develop and disseminate information and resources for youth and their families, as well as teachers/school counselors addressing the mental health crisis in adolescents.
- Develop and disseminate messages about healthy sexual behaviors and resources to improve access to PrEP and other preventive services to at-risk youth.
- Encourage development of safe spaces for youth in general and LGBTQ youth specifically to access accurate information and support.
- Ensure that resources for LGBTQ youth are available to address disparities in care related to social determinants of care (including homelessness, domestic violence, and racial/ethnic discrimination).

Dr. Dowler seconded the motion. CHAC unanimously approved the LGBTQ letter.

Action Item #2: Letter on Self-Collection and Self-Testing

Travis Gayles, MD, PhD

CHAC Co-Chair, CDC Appointee

Dr. Gayles noted that while this proposed letter to the FDA was not fully fleshed out, the CHAC discussions prompted them to put this forward, recognizing that data will need to be identified in order to further shape the letter before it is ready to move forward. Some of the highlighted

points discussed as key areas of concern pertaining to self-collection testing included the following:

- There is a differentiation in how HCV and HIV are viewed, particularly around the impact of results.
- Criteria required for the authentication process domestically versus internationally. One of the major issues was that there are similar tests that are utilized internationally that are not accessible in the US.
- There is a need for incentives and an increased sense of urgency to foster and facilitate a production pipeline. This may involve proactive outreach to manufacturers to encourage them to seek approval for tests, beginning with a discussion with FDA to explore how to decrease the costs associated with premarket approval (PMA). As raised the day before, the cost is just shy of \$400,000 for that process. Consideration needs to be given to how to remove barriers, as well as the existing data related to the impact of self-collection in terms of increased testing in certain groups. It is important to figure out ways to increase the pipeline and help foster a smoother process to move things forward in order to increase access to these testing modalities for certain groups.

CHAC Member Observations/Suggestions: FDA Letter on Self-Collection Testing

The following questions, observations, and suggestions were raised:

- This seems like a critical place for CHAC to focus its efforts to intervene.
- It is important to remember that payers cannot pay for self-collection tests without CPT HCPCS codes for home tests. This was done for COVID-19, which opened the door for other tests. Perhaps someone could reach out to the AMA to discuss this.
- There are some incentives already. Companies would like to market their products and have them widely used, which is why they develop them. Some companies have said the barrier is too high at the FDA level to get approval. FDA spoke about the risk-benefit comparison, but that does not align with the true risks and the true benefits of home testing. A high-level conversation is needed with FDA to come to an agreement that everyone needs to work together to make self-collection kits available to the people who need them. Regulatory barriers were put in place 10 or 20 years ago and need to be revisited.
- There are larger issues to consider when tests are brought to market pertaining to affordability, awareness of availability among communities who need the tests, linking people to services, payer issues, et cetera. With that in mind, perhaps CHAC should consider standing up a Self-Collecting Testing WG to further explore the issues.
- Dr. Mermin asked CHAC to consider whether a very specific, short-targeted, single-pointed letter could be more effective than one that tries to redress all of the comprehensive issues related to testing, which may be better suited for ongoing discussions. The first and part of the third bullets contain the major points. Based on the CHAC discussions throughout the meeting, FDA is aware that the marketing in Europe is different than in the US. While articles have been written about Europe's more efficient process, it is not going to change the US approach to approval processes. While it has been explicitly stated that HIV is exceptional in that it is much more dangerous for someone to have a false negative HIV test than it is to have a false negative hepatitis C test, there are theoretical arguments

against that view. Many years of HIV self-testing are already in place, so the rationale is unclear about the danger. High-quality thoughtful letters are more effective than ones that have not been thought out as well.

- Dr. Akolkar, FDA, clarified that the user fee is not determined by FDA. It is legislatively determined by the Congress. There are also regulations FDA has to abide by, even though they may want to do something for both HIV and HCV. HCV approval was basically done on the basis of persons with signs and symptoms, which is different than for HIV. It is not just a simple equation that HIV and HCV are the same—there are historical nuances. FDA has learned a lot from the self-test experience for HIV and is working with the sponsor, but it is important to remember that the sponsor must approach FDA before a process can begin. They are open to have preliminary discussions with sponsors who believe they have something of value and some data to support that.
- There was CHAC support for the idea of crafting a pointed letter that addresses and engages on the first bullet point specifically, plus/minus some language around asking for the deeper conversation to revisit the processes and how they can be updated to match current thinking versus the thinking of 20 some years ago when self-collection reviews were beginning.
- Some CHAC members wondered if perhaps they were rushing this and that it might be better to establish a WG rather than trying to litigate everything during this meeting. It was noted that an alternative to a WG would be to convene an interim business meeting, which would allow time to assemble the facts and develop a draft letter. Establishing a WG could prolong the process.
- Dr. Gayles recapped that they were hearing that there is still much to be clarified in terms of what would best fit into such a letter, which would take more time to flesh out into more detail. There are 2 mechanisms for moving forward that could work, which are to: 1) convene an interim business meeting that probably could not be scheduled until September; or 2) create a WG to study the key points, with specific tasks of differentiating the bullet points, determining whether the letter to FDA should focus on one point or be more general, and then reporting back to the full CHAC during its November meeting. Given the timeframe, the reality seemed that creating a WG would offer more time to further explore the issues and develop action items.

CHAC Action

Dr. Gayles made a motion to create a Self-Testing and Self-Collection WG to study this issue with the specific task of obtaining more information on: 1) differences in risk classification of HCV and HIV; 2) criteria required and data available for the FDA approval process; and 3) downregulation to Class II diagnostics. The WG will then propose messaging that should go into the letter related to self-collection, including the development of a set of recommendations to be presented during the November 2022 CHAC meeting. Dr. Dowler seconded the motion. CHAC unanimously approved the motion to create a Self-Testing and Self-Collection WG.

Action Item #3: Stand Up a Workforce Development WG

Dr. Anderson reminded everyone that a suggestion was made during the meeting to consider standing up a Workforce Development WG with several specific tasks.

CHAC Action

Dr. Gayles made a motion to create a Workforce Development WG to study this issue with the specific tasks of: 1) formulating a potential panel for the November CHAC meeting in order to have a larger discussion on this topic; 2) liaising with PACHA to ensure that CHAC is not duplicating and is supportive of their efforts that are already ongoing in this space; and 3) exploring the role of other health-related professionals and CHWs to enlarge the workforce and to task-share when appropriate. Dr. Guilamo-Ramos seconded the motion. CHAC unanimously approved the motion to create a Workforce Development WG.

Next Meeting / Proposed Agenda Items

The next CHAC meeting is scheduled for November 1-3, 2022. The following future agenda items were proposed:

- Gender-affirming care, coverage, and outcomes
- Barriers to providing PrEP for uninsured and under-insured individuals
- Lessons that can be learned from the global setting (e.g., task-sharing to enhance the workforce, availability of self-testing and self-collection of specimens, et cetera)
- Issues specific to pregnancy (e.g., perinatal transmission of HIV, HCV, HBV, and congenital syphilis; underuse of PrEP in at-risk pregnant women; mental health; intimate partner violence; breast and chest feeding; et cetera)
- The effects of COVID-19 in a variety of areas (e.g., healthcare overall, HIV, persons ≥50 years of age, disparities, and comorbidities post-COVID, et cetera)

Recap and Closing

Dr. Gayles expressed his personal gratitude to everyone for their thoughtful input, continued and consistent engagement across 3 days of Zoom meetings, and great input and work. He recognized that the work they all do on regular basis contributes to their expertise and membership on CHAC. He thanked Dr. Anderson for keeping the meeting moving along and for being the epitome of comprehensiveness and thoroughness.

Dr. Anderson echoed that this had been a tremendous meeting in terms of the topics covered, the work done, and the exciting future topics identified. She complimented Dr. Gayles on his amazing abilities not only to summarize, but also to draw out all of the implications. She also expressed gratitude to their CDC and HRSA support.

Adjournment

Dr. Cheever thanked everyone, recognizing that very good panels had been assembled with excellent presenters who brought forward important information. Secondly, she recognized the CHAC members for their ability to listen carefully and reflect on the information presented and engage amazing discussions. She expressed her gratitude for Drs. Gayle and Anderson for their leadership as Co-Chairs and their wonderful abilities to synthesize the information and discussions.

Dr. Mermin expressed his gratitude, emphasizing that he had learned a great deal. At its best, an advisory committee provides useful advice that can help influence the thought process on various topics. CHAC's did exactly that over the past 2.5 days with their thoughtful input, which raised important issues for CDC and HRSA to think about as they consider many issues of importance. He recognized that it is time-consuming and that everyone is very busy. Especially in the time of COVID-19 when site visits have been reduced, it is very difficult to understand what is occurring. It is great to have input from people who are thinking about the issues and want to make a positive difference in these areas of diseases that are of great public health importance and that experience a lot of inequity. He thanked everyone for their time and effort and emphasized that he was looking forward to the November 2022 CHAC meeting.

Certification

I hereby certify that, to the best of my knowledge, the foregoing minutes of the proceedings are accurate and complete.

Travis Gayles, MD, PhD

CDC/HRSA Advisory Committee on HIV, Viral
Hepatitis and STD Prevention and Treatment
Centers for Disease Control and Prevention
1600 Clifton Road NE, Mailstop US8-6
Atlanta, GA 30329-4027

Submitted by email to nchhstppolicy@cdc.gov

Subject: Spring CHAC Public Comment Registration

Dear Advisory Committee Members:

Thank you for the opportunity to submit written comments to the upcoming meeting of the CDC/HRSA Advisory Committee on HIV, Viral Hepatitis and STD Prevention and Treatment (CHACHSPT). Founded in 2015, Everly Health is an Austin, TX based company offering modern, diagnostics-driven care. Our goal is to meet the consumer where they are by leveraging our national clinical network composed of hundreds of physicians, nurses, genetic counselors, pharmacists, and member care specialists along with our digital platform and fully-owned CLIA certified, CAP accredited laboratories. We provide services both directly to the consumer through Everlywell as well as complete solutions for diagnostics-driven virtual care at scale to health plans and enterprises through Everly Health Solutions.

Everly Health is an industry leader in facilitating telehealth and at-home services for laboratory testing. In total, we offer over 2500 tests with our partner laboratories in addition to the thirty tests across six key categories within our own diagnostic laboratories. Our demonstrated success in at-home collection and testing enabled us to mobilize quickly and early in the pandemic to provide nationwide access to testing for COVID-19. We were the second company to receive emergency use authorization (EUA) from the Food and Drug Administration for our at-home collection kit and since March 2020, we have provided clinical oversight, care coordination, and physician services for tens of millions of tests for COVID-19. Everly Health Solutions' 50 state provider network can facilitate test ordering, follow up with patients who test positive, and offer assistance with accessing treatment.

Just released this month, the Centers for Disease Control (CDC) preliminary report on 2021 surveillance of sexually transmitted diseases (STDs) shows that rates of syphilis continue to increase, with a 34% increase among women.¹ The agency also reported that the pandemic led to underreporting of infections and increased transmission in 2020 due to reduced screening as healthcare clinics either closed or restricted in-person visits to limit spread of COVID-19.² Additionally, public health departments are already facing limited resources needed to move

¹ <https://www.cdc.gov/std/statistics/2020/preliminary2021.htm>

² <https://www.cdc.gov/std/statistics/2020/impact.htm>

everly health

personnel from STD prevention and control efforts to the pandemic.³ Recognizing this shift in access to STD prevention, in its 2021 update to its Sexually Transmitted Infections Treatment Guidelines, the CDC identified an opportunity to build upon the lessons learned from the response to COVID-19 including the use of at-home collection for STDs.⁴ The pandemic clearly illustrated the critical role at-home testing plays in responding to and controlling infectious disease outbreaks and for these reasons, we were very pleased to see that the agenda for the upcoming CHACHSPT meeting included a focus on self-testing and self-sample collection for STDs.

We currently offer a direct-to-consumer testing channel for men and women to self-sample within the comfort of their own home to test for chlamydia, gonorrhea, hepatitis C, HIV, syphilis, trichomoniasis and herpes simplex virus type 2. For those who test positive, we provide access to providers who can initiate access to appropriate treatment. We have found that patients prefer privacy when testing for sensitive conditions and the seamless access to treatment to quickly resolve their infection and symptoms. In 2021, we had 77,800 sexual health kits ordered and registered to 47,400 unique users. Of those, 6202 tested positive for one or more STD, and 8,604 consults were scheduled. We have surveyed our customers about their at-home testing experience and they consistently report high levels of satisfaction.

We hope that our experience in providing access to laboratory testing directly to consumers will help inform future policy recommendations that support self-testing and self-sample collection for testing for STDs. Our own experience has proven that the sampling technology and digital platforms exist to successfully enable at-home collection and testing for STDs. Not only will it remove major barriers to access, including during public health emergencies, but our data show that people prefer and desire this testing option. Now we just need proactive policy to support the delivery of these critical and innovative prevention and treatment tools directly to those at greatest risk.

Thank you for your consideration of our comments and we hope that you will look to Everly Health as a resource and partner as you consider the role of self-testing and self-sample collection in preventing STDs. Please do not hesitate to contact me at marisa@everlyhealth.com if I may be of further assistance.

Sincerely,

Marisa L. Cruz, MD

April 4, 2022

The Honorable Xavier Becerra
Secretary, U.S. Department of Health & Human Services
200 Independence Avenue, S.W. Washington, DC 20201

Dear Secretary Becerra:

We, the undersigned national, local, and state-based health, education, and civil rights organizations, outline our support for a national program to finance and distribute medications that prevent HIV infection, known as pre-exposure prophylaxis, or PrEP. A key goal of a national program is to scale up access to PrEP substantially in order to help end the HIV epidemic. A national PrEP program should be guided by these principles: accessibility, equity, simplicity, affordability, sustainability, and adaptability. We were pleased to see the historic investment in a national PrEP program included in the President's 2023 budget. We believe systems-wide reforms and innovative policies are needed to end the HIV epidemic in the U.S., and we look forward to working with the Administration to help make this ambitious proposal a reality.

HIV in the United States (U.S.)

In 2019, nearly 37,000 people in the U.S. were diagnosed with HIV. Black and Latinx/Hispanic individuals comprised 42 percent and 29 percent of new diagnoses, respectively. Every person living with HIV requires a lifetime of treatment at an estimated individual cost of about \$501,000, with potential adverse effects that include liver toxicity and insulin resistance. HIV was the underlying cause of death for more than 5,000 people in 2019 in the U.S.

A major gap in U.S. efforts to address HIV is the under-utilization of medications that can virtually eliminate the acquisition of HIV. Fewer than 25 percent of people who could benefit from PrEP actually receive it, with large and growing disparities by race, ethnicity, gender, and geography. In 2019, the CDC found that 63 percent of White Americans recommended for PrEP received a prescription, compared to 14 percent of Latinx/Hispanic Americans and just 8 percent of Black Americans.

The current role of the federal government in HIV prevention

In 2019, the federal government launched a major new initiative called *Ending the HIV Epidemic*, investing more than \$500 million in HIV prevention, treatment, and research programs. The goal is to reduce new HIV infections in the United States by 90 percent by the year 2030. Though achievable, success will require substantial improvement over the modest 9 percent decline in new infections from 2015 to 2019.

The recently updated National HIV/AIDS Strategy for 2022-2025 recognizes the need for much greater use of PrEP. The major reasons for poor access include high prices, expensive and inaccessible laboratory tests, complex and confusing eligibility requirements to access PrEP services, limited provider availability in many parts of the country, and stigma. The Department of Health and Human Services (HHS)'s *Ready, Set, PrEP* Program, launched in 2019, aimed to reduce this gap by providing free PrEP medication for those without prescription drug coverage; however, the program does not cover the required associated clinic and lab costs for PrEP. The program also relies on high-cost, brand-name oral medications from a single manufacturer, despite the fact there are currently 12 manufacturers marketing generic PrEP in the U.S as well as a new long-acting injectable form of PrEP approved in December 2021.

Benefits of a national PrEP program

To scale up PrEP as part of an effective, sustainable strategy to end the HIV epidemic, a national PrEP infrastructure must move away from the current reliance on high-cost, brand-name drugs that have resulted in overly complex, difficult-to-navigate programs for the un- and under-insured and a relatively small number of access points in the Medicaid program. The [proposal from Killelea and colleagues](#) provides one potential path for a national PrEP program focused on these populations. A call for a national PrEP program builds off of recent efforts to secure congressional and Administration support for expanded access to PrEP. Any new funding must be strategically invested to ensure that scarce dollars are stretched to help the most amount of people and focused on reversing growing inequities in PrEP access. A multi-pronged approach will be needed to create a system in which individuals and providers can equitably and sustainably access PrEP.

To reduce the growing inequities enabled by our fragmented PrEP financing system, we seek your support for a national PrEP program which:

- Expands access to PrEP medications and lab services for people who are uninsured and on Medicaid
- Allows the federal government to negotiate with manufacturers and labs for fair public health prices
- Scales-up access to generic PrEP medication as a safe, effective, and cost-effective option for the majority of those indicated for PrEP and provides access to other PrEP options when indicated
- Creates an expansive provider network of non-clinical community-based PrEP providers and local health departments serving the uninsured and Medicaid that are paired with clinical providers via telehealth partnerships
- Works in tandem with existing PrEP funding and programs to supplement, not supplant programs and activities that are working
- Creates a platform for the effective and rapid deployment of novel PrEP medications

- Provides new opportunities to effectively raise awareness and combat stigma by enrolling and educating a new, broad network of providers and building community-led campaigns that connect key populations to this new PrEP infrastructure

A national PrEP program would help put the U.S. on track to end the HIV epidemic.

Re: Written Comments for the CDC/HRSA Advisory Committee on HIV, Viral Hepatitis and STD Prevention and Treatment (CHACHSPT)

Dear Members of the CHACHSPT:

On behalf of Visby Medical, Inc. (Visby), a medical diagnostics technology company headquartered in San Jose California, and the patients and providers we seek to support with our point-of-care (POC) testing, we appreciate this opportunity to submit comments for consideration during the spring meeting. Our mission is to "empower anyone to test for any infection anywhere with near-100% accuracy." As such, we very much support the CHACHSPT's focus on activities related to the prevention and control of sexually transmitted infections (STI) and stand ready to be a resource and partner with you in your important work.

About Visby

Visby Medical is transforming the order of diagnosis and treatment for infectious diseases so clinicians can test, talk with, and treat the patient in a single visit. The Company's proprietary technology development program culminated in the world's first instrument-free, single-use PCR platform that fits in the palm of your hand and rapidly tests for serious infections. Originally developed for sexually transmitted infections, the Company's FDA-cleared, CLIA-waived Sexual Health Click Test for women returns accurate results within 28 minutes. The Visby Medical technology is also helping to fight the global pandemic via the Visby Medical COVID-19 Test, and its robust pipeline includes tests for other infectious diseases. Visby Medical is accelerating the delivery of fast and accurate, palm-sized PCR diagnostics to the point of care, and eventually for use at home. Visby Medical has received Federal funding from NIH and BARDA to support the development and validation of the PCR platform. For more information, visit www.visbymedical.com.

Accurate POC Tests Can Promote and Protect Public Health

The nation is in the sixth year-over-year increase in chlamydia and gonorrhea cases and this silent – and neglected – epidemic will not wane unless we become more intentional as a nation in how we deploy accurate, rapid test modalities. The Centers for Disease Control and Prevention's (CDC) 2021 Sexually Transmitted Disease (STD) Treatment Guidelines recommends Nucleic Acid Amplification Tests (NAATs) for detecting chlamydia and gonorrhea. The 2021 STI National Strategic plan includes a recurring theme of the need for "innovative solutions and approaches to address the ongoing and emerging challenges to STI prevention and control" and specifically calls out the need to develop "point of care diagnostic tools."

Visby has developed and introduced such a test to the market. We have the first FDA-cleared and CLIA-waived instrument-free PCR platform that can detect and distinguish

April 19, 2022

between three of the most common and curable STIs – chlamydia, gonorrhea, and trichomonas. This test provides lab-accurate results in less than 30 minutes without the need for trained laboratory technicians to operate or interpret test results. These tests can be used in any POC setting that has a CLIA-waiver, including STI clinics, OBGYN offices, emergency departments (EDs), urgent care settings (UC), and mobile vans. Because this platform does not require an extra instrument, it lends itself well for use in resource-constrained and remote settings. Many tests can be run in parallel to meet surge capacity.

The standard of care (SOC) practice is to send-out STI test samples for PCR testing, which typically does not return results for at least 24 hours, oftentimes longer. In the absence of real-time test results, patients are presumptively treated based on symptoms and sexual history. While this generally no longer happens in any other disease-state, it is common practice for STIs. Often the initial diagnosis is incorrect, meaning that the patient will need to be contacted with the right diagnosis and a new prescription for treatment or the patient may have to return for a second appointment to get the appropriate treatment. Women bear the greatest burden of this delay in accurate treatment, where untreated STIs can result in pelvic inflammatory disease (PID), ectopic pregnancies, and infertility. Moreover, STI infection increases the risk of HIV transmission. In sum, the current SOC practice delays accurate treatment, inconveniences the patient, can burden providers, and increases costs – and decreases efficiency – within the health care system.

The reality is that we are treating patients before test results are available. The rates of overtreatment (e.g., patient is treated for chlamydia, but laboratory results show she is not infected with chlamydia) can be as high as 80%, especially in settings such as EDs and UCs where staff fear patients will be lost to care. The Visby STI test can prevent overtreatment thus reducing the unnecessary use of antibiotics and promoting antibiotic stewardship. Conversely, undertreatment (e.g., patients are not given treatment, but laboratory results show they are infected with chlamydia) are also high. The consequences of undertreatment are detrimental to both individual and public health as untreated STIs can lead to PID and other severe sequelae, and patients can continue to spread disease. Importantly, clinic staff spend time calling the patient back with their test results and, in many settings, can never get in contact with the patient. The patients lost to care can be as high as 40%, posing a risk to public health by continuing to spread untreated disease.

Because Visby test results are available during the span of a patient's clinic visit, this enables:

- Accurate treatment informed by real-time PCR results
- Patient education (treatment and how to avoid future infections)
- Expedited Partner Therapy (EPT) (this is permitted in most states)

POC STI testing is better for the patient because:

- Patients are accurately treated based on what they have. This in turn improves their outcomes directly and helps reduce the spread of STIs.
- Treatment in a timely fashion means chlamydia infection does not progress to pelvic inflammatory disease (PID), which if left untreated can result in infertility and

visby medical

2

April 19, 2022

ectopic pregnancies, which can be devastating for patients and expensive for the health care system.

- Accurate treatment means the patient does not receive an unnecessary antibiotic (and not subject to unnecessary side effects from the antibiotic).
- Unnecessary additional clinic visits are avoided and clinician effort spent trying to reach patients for follow-up is eliminated.

Taken together, these advantages reduce costs and decrease the burden on the health care system.

Visby's STI Test Helps Advance the 2021 STI National Strategic Plan

Deploying a test like the Visby sexual health test supports all of the goals in the STI National Strategic Plan that was released in 2021.

Goal 1: Prevent new STIs

- By treating patients with the right drug in the initial clinic visit patients are not at risk of transmitting disease to other sexual partners; this provides timely, appropriate care to the patient directly and results in a better outcome for public health
- The provider has an opportunity to educate the patient face-to-face in real time. This will help increase awareness of STI prevention and sexual health.

Goal 2: Improve health of people by reducing adverse outcomes of STIs

- By providing test results within a patient's clinic visit, morbidity is reduced:
 - Patients are accurately treated based on what they have, not the best guess of the physician.
 - Timely treatment will reduce morbidity and in turn, improve outcomes and reduce costs. As noted above, timely treatment means chlamydia, gonorrhea, or trichomonas infections do not progress to PID, which, if left untreated, can result in infertility and ectopic pregnancies. Because infection with these STIs can increase the risk of HIV transmission, it is important to test, educate, and treat patients quickly.
 - Accurate treatment means the patient does not receive an unnecessary antibiotic and is not subject to unnecessary side effects from the antibiotic: Antibiotic Stewardship.

Goal 3: Accelerate progress in STI research, technology, and innovation

- By using an innovative diagnostic like the Visby Sexual Health STI test, the government can support shifting the paradigm from syndromic treatment to 'test, talk, treat'. Evidence-based treatment and decision-making is strengthened by POC accurate testing.

Goal 4: Reduce STI-related health disparities and health inequities

- Making a POC test like this available as standard of care can help advance equity, reduce health disparities, and decrease implicit bias that may be a component in syndromic treatment and diagnosis.

visby medical™

3

April 19, 2022

- Innovations in diagnostic testing, like that of the Visby STI test, can fundamentally transform the patient experience, making it more patient-centered and convenient, which in turn can address access and equity concerns.
- STIs disproportionately affect women, and particularly minorities. For example, even though the population/clinic-based prevalence for trichomonas is 0.2%, black women bear the highest burden of disease (9%).
- The newly released 2020 STD Surveillance Report showed that while STDs are increasing across many groups, some racial and ethnic minority groups, gay and bisexual men, and our nation's youth continue to experience higher rates of STDs.

Goal 5: Achieve integrated, coordinated efforts that address the STI epidemic

- A key attribute of the Visby test is that it does not rely on a separate instrument, meaning that it is deployable almost anywhere, and lends itself well for surge capacity; as many people as possible can be treated contemporaneously.
- These tests can easily be deployed in the community and utilized in mobile clinic vans. For example, Visby is supporting a study to assess how this test can be used when deployed into a harm reduction mobile van that reaches rural individuals with substance use disorders.
- As a POC test the Visby test facilitates the delivery of integrated, coordinated care; all within one visit, the patient will be tested, diagnosed, educated about their infection, and prescribed a treatment pathway.

Call to Action

The potential for innovative, game changing POC STI tests to have a significant, positive impact on the STI epidemic is enormous. However, a number of barriers preclude the test becoming available to all who need it. As such, we respectfully call upon the CHACHSPT to support and recommend to Department of Health and Human Services (HHS), CDC, and the Health Resource and Services Administration (HRSA) the following:

1. *Implementation science studies* to assess clinical adoption in various settings, especially those settings where health inequities can be improved, such as with underrepresented groups, rural populations, novel health care delivery settings (e.g, mobile vans), and others.
2. *Policies, programs, and funding for equitable access to innovative technologies.* Access to innovative technologies should not be limited to those with means; innovation, especially that funded with taxpayer dollars, should be available to everyone. HHS should advance policies, programs, and funding that facilitate equitable access to technologies that can improve individual and public health.
3. *Efforts to uncover the true prevalence of Trichomonas* in all geographies and demographics. Trichomonas, as with other STIs, is a silent epidemic. Currently, Trichomonas is not required to be reported, so the true prevalence is unknown. Some clinics in the South report 30% prevalence in women and 10% in men, but in other geographies it appears to be less prevalent; however, this could be

visby medical

4

April 19, 2022

because people are not being routinely tested for *Trichomonas*. Knowing the true prevalence will help guide CDC treatment and reporting guidelines.

4. *Adequate coverage and payment policies for breakthrough innovative technologies that can make a difference to patient outcomes.* Patients and providers want, need, and deserve access to accurate, POC testing. However, reimbursement for such tests can be so low that it thwarts utilization of the technology when and where it is needed most. Moreover, the current federal coverage and payment system – as operationalized by the Centers for Medicare and Medicaid Services (CMS) – is built around laboratory-based testing and not POC. As many commercial payors and Medicaid often follow CMS, the adverse impact on the adoption rate for new diagnostic technology can be significant. The Visby test was built intentionally to engineer out the need for highly trained laboratory personnel to operate and interpret the test results so that it could be used nimbly in a variety of care settings to have the maximum positive impact on public health. Unfortunately, without improved coverage and payment policies, the test will not be adopted, and its promise will not come to fruition.

Conclusion

Again, on behalf of Visby and the patients and providers we seek to support with our POC testing, we thank you for your consideration of our views and recommendations. With sufficient reimbursement and intentional deployment, we feel strongly that our POC STI test has the potential to make a significant difference in addressing the STI epidemic. We are eager to serve as a resource to you, CDC, HRSA, and HHS to reduce and prevent STIs.

Sincerely,

Christopher J. Jowett
Chief Commercial Officer

1 Executive Summary and Statewide Coordinated Statement of Need (SCSN)

The United States (U.S.) has taken on a bold plan to end the HIV epidemic by the year 2030. In order to reach national goals of reducing new HIV infections by 75% by 2025 and by 90% by 2030, the country must take aggressive actions by scaling up key HIV prevention and treatment strategies. The presentation of **Florida’s HIV Integrated Prevention and Care (IPC) Plan, 2022–2026** is the culmination of several local (rapid HIV antiretroviral start programs), state (Data to Care programs), and federal initiatives including:

- *National HIV/AIDS Strategy, 2022–2025 (NHAS)*
- *Ending the HIV Epidemic (EHE) in the United States (2019)*
- *National Strategic Plan: A Roadmap to End the Epidemic for the United States, 2021–2025*

These plans work in unison to achieve national goals. This plan builds upon the previous work in Florida’s Statewide Integrated HIV Prevention and Care Plan, 2017–2021 and Florida’s Unified Ending the HIV Epidemic (EHE) Plan, 2020.

The impact of Human Immunodeficiency Virus/Acquired Immune Deficiency Syndrome (HIV/AIDS) in Florida is far reaching with 120,502 persons with HIV (PWH) living in the state as of 2021, which represents only 86% of PWH—the remainder of whom are unaware of their status (approximately 14%). We believe people in Florida have the right to:

- Know their HIV status.
- Access Pre-Exposure Prophylaxis (PrEP) if they are negative but at risk for developing the disease.
- Receive services needed to achieve or maintain a high quality of life if they have tested positive.
- Obtain health care, free of stigma.
- Be a voice in their local communities to effect positive change.

According to the Centers for Disease Control and Prevention (CDC), in 2020 (the most recent data available), Florida was ranked third highest (15.7 per 100,000 population) for new HIV diagnosis rates in the United States (including the District of Columbia). In 2021, 4,708 persons received an HIV diagnosis in Florida, a 37% increase from the 3,441 HIV diagnoses in 2020. In 2021, 83% of those newly diagnosed were linked to HIV-related care within 30 days of diagnosis. The number of AIDS cases diagnosed in 2012 in Florida was 2,846, and in 2021 case numbers dropped to 1,860. The current estimate of 14% of PWH in Florida not knowing their status, along with the substantial decrease in AIDS cases over a 10-year period, together underscore the importance of HIV prevention and care service delivery in Florida.

The seven Florida EHE counties make up approximately 11% of the total national HIV burden as outlined in the EHE plan and represent 72% of the total persons with an HIV diagnosis in Florida. Five of the EHE

counties, Pinellas (77%), Hillsborough (71%), Orange (72%), Broward (70%), and Duval (69%) had a viral suppression rate equivalent to or greater than the state rate of 69%, while Palm Beach (65%) and Miami-Dade (63%) had lower viral suppression rates than the state at the end of 2021.

Florida is a large and diverse state. It has both rural and metropolitan areas, an extensive mix of cultures, and an oscillating population due to seasonal residents, tourists, and itinerant workers. These factors can challenge the planning processes of disease control. The IPC Plan is designed to demonstrate coordinated HIV prevention and care activities by assessing resources and service delivery needs across HIV prevention and care systems to ensure the allocation of resources based on data.

Florida receives funding for and implements a wide range of programs and services for persons with and those at increased risk for HIV, including: the AIDS Drug Assistance Program (ADAP), Ryan White HIV/AIDS Program (RWHAP) patient care programs, prevention (HIV testing, PrEP, linkage), housing, substance use disorder and mental health, and other programs.

Core medical and support services are provided by the federal RWHAP to low-income Floridians living with HIV or AIDS who have inadequate or no health insurance and are ineligible for Medicaid, Medicare, or any other public insurance programs through different entities. Services such as medical care, pharmaceuticals, dental services, payment of health insurance premiums, laboratory services, counseling and treatment for substance use disorder, and medical case management are provided through the various parts of the RWHAP. Each part has separate eligibility criteria that clients must meet.

Ending HIV requires partnership and collaboration. This IPC Plan was developed through collaborative efforts that span the continuum of HIV prevention and care, and with representatives from the Florida Comprehensive Planning Network (FCPN) and associated advisory groups, local HIV planning bodies, Department of Health staff, and communities living with and affected by HIV/AIDS. The IPC Plan also aligns with the previously submitted Florida EHE Plan (2020), Florida's 4 Key Component Plan (2016), and the NHAS goals and strategies.

Florida's IPC Plan encompasses the state's entire system of HIV prevention and care. The IPC Plan was reviewed with members of Florida's integrated HIV prevention and care planning body, FCPN, during the Fall 2022 meeting held in Lutz, Florida, October 18–19, 2022. During the two-day meeting, FCPN members and other stakeholders in attendance had an opportunity to provide feedback and suggestions on the draft plan. Concurrence for the plan was gained on October 19, 2022, through a vote of FCPN members. The Department of Health (Department) is pleased to present Florida's IPC Plan, which is intended to re-energize and strengthen a whole-of-society response to the epidemic while supporting PWH in Florida and reducing HIV-associated morbidity and mortality.

1.1 Approach and Partnerships

Critical information about the IPC Plan has been organized in the following sections:

- Community Engagement and Jurisdictional Planning Process (Section 2)
- Contributing Data Sets and Assessments (Section 3)
- Situational Analysis (Section 4)
- Calendar Year (CY) 2022–2026 Goals and Objectives (Section 5), organized by the goals of the National HIV/AIDS Strategy and inclusive of the four pillars of the EHE initiative: Diagnose, Treat, Prevent, and Respond.
- 2022–2026 Integrated Planning Implementation, Monitoring and Jurisdictional Follow Up (Section 6)

Plan development was facilitated by The AIDS Institute through multiple meetings with the FCPN. The FCPN became an integrated HIV prevention and care planning body in 2017 and is made up of representatives from HIV prevention, care, all parts of the RWHAP, federally qualified health centers (FQHC), state and local government, academia, service providers, consumers, and advocates as seen in the figure below. The FCPN is made up of three representatives per each of Florida's 14 HIV partnership areas—a prevention representative, patient care representative, and a Department representative (42 seats). In addition, there are five at-large representative seats—proposed and voted upon by FCPN—which represent specific populations and/or areas of practice (e.g., behavioral science). Each of Florida's six RWHAP Part A jurisdictions also have a representative at the FCPN table (six seats).

FIGURE 1: FCPN MEMBERSHIP DIAGRAM

The FCPN typically meets twice per year, in-person (with virtual meeting options for those unable to attend in person) and the FCPN committees (i.e., Membership, Nominations, and Bylaws Committee;

Medication Access Committee; Coordination of Efforts Committee; Needs Assessment Committee; and Executive Co-Chairs Committee) and associated advisory groups (Florida Gay Men’s HIV Workgroup, Community HIV Advisory Group) meet monthly via videoconference.

In 2021, in preparation for developing the IPC Plan, the Department, in collaboration with the FCPN and RWHAP Part A partners, hosted a series of virtual webinars delivered statewide to share information from the Integrated HIV Prevention and Care Plan Guidance, including the Statewide Coordinated Statement of Need, CY 2022–2026, released by CDC and Health Resources and Services Administration (HRSA) in June 2021. The figure below summarizes the key meetings held. Detailed descriptions of each meeting are bulleted after the figure.

FIGURE 2: PLAN DEVELOPMENT MEETINGS

- In January 2022, an integrated HIV planning kick-off meeting was held with Florida’s State Surgeon General, the FCPN Executive Co-Chairs’ Committee, representatives from Florida’s six RWHAP Part A areas (Fort Lauderdale, Miami, Tampa/St. Petersburg, Orlando, West Palm Beach, Jacksonville), The AIDS Institute, and the Department’s Division of Disease Control and Health Protection leadership, and HIV, sexually transmitted disease (STD), and viral hepatitis staff to discuss Florida’s approach to developing the statewide HIV IPC Plan for 2022–2026. There were 31 participants (29 in-person and 2 virtual).
- The first full-body FCPN meeting was held in April 2022 and was an in-person meeting with virtual attendance options. This meeting was used to develop goals, objectives, and strategies that were taken back to local planning bodies for discussion and feedback. There were 150 meeting participants (68 in-person and 82 virtual), representing all 14 HIV partnership areas.
- In August 2022, the FCPN met again as a full body to develop activities for the strategies that aligned with NHAS. This meeting included small-group exercises to ensure everyone around the table and attending virtually could provide input and actively participate in the activity development process. All proposed activities were collected, and a survey was distributed after the meeting to allow all attendees to vote on prioritized activities for inclusion in the IPC Plan.

Additionally, acquired consulting services from ISF, Inc. to assist in stakeholder coordination, research, reporting and writing for the 2022–2026 IPC Plan. ISF performed key stakeholder group interviews in each of Florida’s 14 HIV partnership areas and each group included lead representatives for the Department, RWHAP Part A, Part B, and local community planning group members. There were 165 meeting participants (52 in-person and 113 virtual), representing all 14 HIV partnership areas.

- The FCPN fall 2022 meeting was held in October and used to review the first draft of the IPC Plan, solicit public comment, and input, and conduct a concurrence vote with the full membership of FCPN. There were 149 meeting participants (53 in-person and 96 virtual), representing all 14 HIV partnership areas.

Letters of concurrence were drafted in November 2022 and subsequently signed by the community co-chairs of the FCPN for inclusion into the IPC Plan. The Department also worked to finalize and ultimately submit the IPC Plan in January 2023.

The Department prioritizes a collaborative approach and works directly with the six RWHAP Part A areas. Ongoing coordination efforts include monthly calls with RWHAP Part A and B programs which split responsibilities of running calls (each call hosted by one of Florida’s Ryan White Part A areas); the monthly calls are used to discuss major issues including the IPC Plan.

A data-informed approach was used to develop the IPC Plan, taking into account data and activities from Florida’s approach to HIV prevention and care, including routine HIV screening, rapid access to treatment and care (Test & Treat), epidemiologic data, HIV Care Continuum outcomes, and other data which help identify priority populations and HIV health disparities. The Department’s High-Impact Prevention (HIP) funding opportunity was developed with the HIV status-neutral approach at the forefront, and funds 44 community and faith-based organizations statewide to provide HIV testing and linkage to care, prevention, and essential support services. Florida also maintains more than 1,600 registered HIV test sites statewide. The HIV status-neutral approach to reducing new HIV diagnoses involves initial HIV testing services as the entry point to HIV prevention and/or care services irrespective of a positive or negative test result. The Department has also engaged in HIV stigma reduction efforts, participating in the University of Florida (UF) stigma workgroup, and contracting with UF for the provision of evaluation and planning activities that will be used to develop program interventions addressing the stigmas related to HIV. Information from Florida’s EHE plan was also used to develop content for the updated IPC Plan.

Florida’s RWHAP Part A areas have developed their own local integrated HIV prevention and care plans which, like the state’s plan, align with the NHAS goals and objectives, but contain locally developed activities tailored to each geographic region. Florida’s statewide IPC Plan and the RWHAP Part A IPC Plans will work in concert to advance the goals and objectives of the NHAS and build a pathway to end the HIV epidemic. Links to each of the RWHAP Part A IPC Plans are provided in Table 1.

HIV service regions are broken down into 14 partnership areas, each with an HIV/AIDS Program Coordinator (HAPC) to oversee prevention and care program operations in the area and assure that program activities are planned in an inclusive and collaborative manner to ensure the other local resources and specific client needs are considered and addressed. They work closely with RWHAP recipients, health district resources, other county programs, and academic and university resources as available.

The HIV/AIDS Section also works closely with many organizations to ensure coordination of effort because of the co-morbidities often associated with HIV/AIDS and their impacts on public health. These organizations include STD, TB, and Viral Hepatitis and Outbreak Response Sections; Children’s Medical Services; local community-based organizations (CBOs) and county health departments (CHD); universities; the Florida Department of Corrections; the Department’s state laboratories in Jacksonville and Miami; and the Department’s central pharmacy.

The six RWHAP Part A Eligible Metropolitan Areas (EMAs) and Transitional Grant Areas (TGAs), and the RWHAP Part C, D, and F programs collectively bring more than \$94.6 million annually to Florida and are key resources in meeting the service needs of PWH in their service area. The RWHAP Part C program directly funds local projects to support service capacity building as well as early intervention services; there are 20 RWHAP Part C programs in Florida. The RWHAP Part D program directly funds a local Tampa project that provides clinical services to women, infants, children and youth (WICY); there are six RWHAP Part D programs in Florida.

The Department HIV Surveillance Program works closely with each local area to provide customized data reports that reflect key information about the epidemic in each area. These data reports are provided to the local CHDs, planning bodies, and each of the RWHAP Part A areas to assist them in preparing grant applications and other reports. Local planning bodies use epidemiologic data, demographic, and service

data, focus groups, resource inventories, and client and provider satisfaction surveys to gauge areas of program strengths and weaknesses.

The Department's HIV Prevention Program collaborates with the Patient Care, ADAP, Medical, and Surveillance programs to deliver comprehensive HIP strategies and services with overarching goals of reducing the number of new HIV transmissions, increasing the proportion of persons living with HIV who know their status, linking PWH to care and support services, and reducing risk behaviors that may lead to HIV and STD diagnoses. Florida's HIP program is multi-faceted and includes HIV testing, linkage to care, peer navigation programs, comprehensive prevention interventions for PWH, partner services, PrEP and post-exposure prophylaxis (PEP), perinatal HIV prevention, corrections initiatives, condom distribution, community outreach (traditional and Internet-based) and engagement, and other services. The Prevention Program also collaborates with the RWHAP Part A programs, FQHCs, CBOs, academia, PWH, and other stakeholders to implement many HIP interventions and strategies. These essential partnerships help to ensure individuals are receiving comprehensive HIV prevention services along the HIV care continuum, leading to improved health outcomes for those living with HIV/AIDS.

Stakeholder engagement occurs on a regular basis through the FCPN and assists the Department in planning patient care and prevention activities. The FCPN is composed of representatives from the Department, all parts of the RWHAP, FQHCs, academia, service providers, CBOs, PWHs, and advocates. The FCPN reviews and gives feedback on projects the HIV/AIDS Section develops, such as the Needs Assessment, the SCSN and statewide IPC Plan, other programs funded with state general revenue, as well as various program standards, and guidelines.

The HIV/AIDS Section routinely communicates with the RWHAP Part A administrators to ensure that they are informed of program activities and have an opportunity to comment and contribute to various projects. Areas of collaboration have been on the transition of RWHAP clients to the Affordable Care Act (ACA) Marketplace® (Marketplace®), work on the Statewide IPC Plan, and development of the ADAP HCV treatment pilot project.

Over the past two years, there have been multiple meetings to plan for a uniform methodology to select insurance plans and move clients to the Marketplace®. Determining eligibility criteria for insurance coverage, planning for the provision of wrap around services, and the potential local coverage of additional clients were main topics of discussion. This project has been very successful; clients, regardless of whether they receive services from RWHAP Part A or Part B ADAP, or are mutual clients, have the same options for insurance selection criteria and process to enroll in the Marketplace® for insurance coverage.

Collaborations, partnerships, and stakeholder engagement exist in many forms throughout Florida; however, opportunities exist to expand partnerships further and engage new and non-traditional partners in more regular communication (for example, Department of Veterans' Affairs and Indian Health Service) to further the objectives and support the strategies of Florida's statewide IPC Plan.

1.2 Documents Submitted to Meet Requirements

In order to meet the submission requirements of the IPC Plan, as outlined in the CDC and HRSA Integrated HIV Prevention and Care Planning Guidance (2021), Table 2 provides descriptions for each document referenced in the IPC Plan. Documents have also been flagged where new material was created specifically for the IPC Plan or where existing material was used. These documents have also been linked in the Appendix, Section 9.5.

CDC and HRSA Integrated HIV Prevention and Care Planning Guidance, 2022–2026	Developed to support the submission of the IPC Plan for each state for the 2022–2026 cycle.	No (Existing)
Florida’s Unified EHE Plan, 2020	Unified plan representing the state and the seven counties identified as Phase 1 EHE jurisdictions: Broward, Duval, Hillsborough, Miami-Dade, Orange, Palm Beach, and Pinellas.	No (Existing)
State of Florida IPC Plan, 2017–2021	Developed collaboratively across Florida stakeholders to eliminate HIV transmission and reduce HIV related deaths for the 2017–2022 cycle.	No (Existing)
Meeting Notes from the August and October FCPN Meetings	The August FCPN meeting was used to identify Florida specific activities to address the Goals, Objectives and Strategies identified by the CDC. The October FCPN meeting was used to review the IPC Plan DRAFT with stakeholders, receive their feedback, and incorporate that feedback into the FINAL version of the IPC Plan.	Yes (New)
Local Area Resource Inventories	Includes recipients’ and community resources for prevention and patient care across 14 partnership areas in the state of Florida.	No (Existing)
Local Area Interview Questionnaires	Interviews were held with all 14 partnership areas and questions were raised to gather feedback in supporting multiple areas of the IPC Plan.	Yes (New)
Local Area Engagement Activities	Provided meeting summaries and feedback from a variety of engagement activities such as local area town halls.	No (Existing)
Documentation of Community Engagement	Describes Florida’s partners and the voices engaged along with engagement efforts at the statewide level and seven major metropolitan areas. Interviews were held with all HIV partnership areas to identify community groups active on local planning councils.	No (Existing)
Florida HIV Continuum of Care Dashboards	Consolidates “Resource Inventories” across the state.	No (Existing)

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Document	Description	Developed for this plan?
Florida’s Ryan White (RW) HIV Care Needs Assessment: Key Findings 2019	Survey to determine met and unmet service needs for PWH in Florida.	No (Existing)
RWHAP Part A Plans	Represents the latest collaborative effort for each Part A partnership area in developing their unique IPC Plan	No (Existing)
PS19-1906 EHE Plan Executive Summary Florida	Key points, including strategic partnerships and planning support, from Florida’s EHE Plan	No (Existing)

2 Community Engagement and Jurisdictional Planning Process

Community engagement is an overarching element of Florida’s 4 Key Component Plan which intersects with the four pillars of the EHE initiative and the NHAS. Community members were engaged in all phases of the planning process and will continue with the implementation of strategies and activities to build a pathway to eliminate HIV transmission in Florida.

During 2021 and 2022, varying degrees of community engagement took place at state and local levels in preparation for developing the IPC Plan. In addition to community engagement activities performed October 2019 through October 2020 for EHE planning and implementation, additional community engagement activities were conducted in each HIV partnership area to ensure stakeholders were included in the integrated HIV planning process.

The HIV Planning Process

Florida’s HIV planning process operates with the principle that determining the best way to support HIV prevention and care needs is through coordinated decision making with local entities, which collectively informs the overall statewide IPC Plan. As such, the Department engaged stakeholders and community members to create an IPC Plan for HIV efforts across the state. The remainder of this section outlines the planning process, inputs into the IPC Plan, analysis performed, priority goals and objectives, and a detailed plan to support successful implementation.

The Department arranges the state into 14 HIV partnership areas (shown in Figure 3), each with an HAPC to oversee prevention and care program operations in each HIV partnership area. HAPCs ensure that program activities are planned in an inclusive and collaborative manner to ensure other local resources and specific client needs are considered and addressed.

FIGURE 3: FLORIDA HIV PARTNERSHIP AREAS

Consortia are community-based regional planning entities established by RWHAP Part B recipients. The consortia plan and prioritize RWHAP Part B funds allocated to their area, promote coordination of services, and serve as a community forum. Representatives of local public and non-profit health and support service providers serve as consortium members. Lead agencies are member agencies in the consortium designated to perform contract administration as a fiscal agent.

Local jurisdictions around the state drive community engagement with the goal to educate and raise awareness about HIV and ensure programs and services are culturally and linguistically appropriate and developed with input from the populations intended to be reached. The local jurisdictions host focus groups, town halls, events for HIV/AIDS observance days, multiple outreach events, media interviews; teach public health classes at local universities; and use their social media presence.

Table 3 provides an example of different groups that participate in the community engagement and planning processes.

TABLE 3: HIV PREVENTION AND CARE PLANNING PARTICIPANTS

Local Jurisdiction Partnership Groups
• Existing community advisory boards • Community members resulting from new outreach efforts • Community members that represent the demographics of the local epidemic (e.g., race, ethnicity, gender, age, and others.) • Community members unaligned or unaffiliated with agencies currently funded through HRSA and CDC • STD clinics and programs • City, county, tribal, and other state public health department partners • Local, regional clinics, and school-based health care facilities; clinicians; and other medical providers • Behavioral health care agencies • Federally qualified health centers and community health centers • Medicaid/Medicare partners and private payors • Strategic planning and quality management collaboratives • Correctional facilities, juvenile services, local law enforcement and related service providers • Community- and faith-based organizations, including civic and social groups • Professional associations • Local businesses • Local opioid advisory groups • Local academic institutions • Commercial and retail pharmacies • Pharmaceutical and biomedical industry partners • Diagnostic industry partners • Digital media service providers • Adult entertainment industry partners

For a full list of specific community resources by partnership area, please refer to Appendix Section 9.3: Partnership Area Resource Inventories.

Florida's new IPC Plan for 2022–2026 was built upon the foundational goals, strategies and activities from the Florida Statewide Integrated HIV Prevention and Care Plan, 2017–2021; Florida's Unified Ending the HIV Epidemic Plan, 2020; the National HIV/AIDS Strategy; and input from local planning bodies and community members. Figure 4 shows the different inputs used to develop the 2022–2026 IPC Plan.

FIGURE 4: INPUTS TO THE 2022–2026 INTEGRATED HIV PREVENTION AND CARE PLAN

The Department's HIV/AIDS Section works in partnership with Florida's statewide integrated HIV planning body, FCPN. Members of FCPN include PWH and representatives across the state representing patient care and prevention groups, local planning bodies, state and local advisory groups, CBOs, academic institutions, local and regional clinics, city, and county governments, RWHAP programs and recipients, advocacy groups, substance use, mental health and social service providers and behavioral science groups. Figure 5 shows a representation of the community engagement and planning groups involved across the state.

FIGURE 5: COMMUNITY ENGAGEMENT AND PLANNING

In describing how the jurisdiction approached the planning process, the subsequent sections address steps used in the planning process, the groups involved, and representation from the priority populations:

- Entities Involved in the Process (Section 2.1)
- Role of Planning Bodies and Other Advisory Groups (Section 2.2)
- Engagement of People with HIV (Section 2.3)
- Social Determinants of Health (Section 2.4)
- Priorities (Section 2.5)
- Updates to Other Strategic Plans Used to Meet Requirements (Section 2.6)

2.1 Entities Involved in the Process

Florida has a long history of both engaging PWH and the broader community in developing plans for prevention and care services. This has been accomplished primarily through what is now known as the FCPN, which has been in existence since 1993. The available seats for FCPN are made up of three representatives from each of Florida's 14 HIV partnership areas—one representative each for prevention, patient care, and the Department of Health (total of 42 seats). Additionally, there are five at-large representative seats—proposed and voted upon by FCPN—which represent specific populations and/or areas of practice (e.g., behavioral science, substance use). Each of Florida's six RWHAP Part A jurisdictions also has a representative at the FCPN table (6 seats). There is a combined total of 53 representative, at-large, and RWHAP Part A seats available on the FCPN. Currently, 41 of the 53 FCPN representative seats are filled. Members of FCPN include PWH and other individuals across the state representing local partnerships. FCPN members are recruited statewide to represent local or at-large positions from patient care and prevention groups, local planning bodies, community and faith-based organizations, academic institutions, recipients of HIV prevention and care services, local and regional clinics, city, and county governments, RWHAP recipients, advocacy groups, substance use disorder and social service providers and behavioral science groups. The Department, in collaboration with the FCPN Membership, Nominations and Bylaws Committee will develop a plan of action to recruit for the remaining vacant seats.

Of the current FCPN member base—10 members disclosed living with HIV, 28 members disclosed they were not living with HIV, and 3 chose not to disclose their HIV status altogether. Nearly 60% of the current FCPN members are from the ages of 50 to 60+ years of age; followed by 30 to 39 years of age (20%); 40 to 49 years of age (15%); and 20 to 29 years of age (7%). Of the 41 current members, 49% are male, 46% female, and 5% are transgender. Approximately 54% of members reported their sexual orientation as heterosexual; 41% reported as gay, bisexual, and/or lesbian; and 5% chose not to disclose their sexual orientation. Race/ethnicity for members is as follows: White (52%), Black (18%), Hispanic/Latino (20%), Asian/Pacific Islander (6%), multi-racial/other (2%), and American Indian/Alaskan Native (2%).

Prior to 2017, the FCPN was made up of two planning bodies: the Patient Care Planning Group and the Prevention Planning Group. In 2017, the FCPN became fully integrated—merging prevention and care

planning bodies. Membership of the integrated planning body is made up of persons with and those affected by HIV; Department staff; representatives from mental health and substance use organizations; psychologists; social workers; case managers; AIDS service organizations; CBOs; RWHAP Part A, B, C, and D providers; RWHAP Part B lead agencies; advisory groups; and FQHCs. The FCPN maintains a biannual, integrated meeting structure and members are responsible for disseminating information from the meetings back to their respective areas of representation, as well as bringing concerns from those same areas to such meetings, ensuring that the voice of PWH in Florida are part of the integrated planning process. The HIV/AIDS Section oversees the composition of these groups, ensuring that they are representative of Florida's HIV epidemic in the various geographic regions, using the principle of Parity, Inclusion and Representation.

The Department routinely communicates and coordinates with other state partners such as The AIDS Institute; health planning councils; Medicaid/Medicare; Agency for Health Care Administration; Department of Corrections (FDC); Department of Children and Families (DCF); Department programs such as the STD, Viral Hepatitis, and TB programs and other state partners; and the Florida HIV/AIDS Advocacy Network (FHAAN). The AIDS Institute is a national nonprofit organization that promotes a full spectrum of HIV activities including prevention, care, and treatment, through public policy, research, advocacy, and education. Medicaid, FDC, DCF, and the STD, Viral Hepatitis, and TB programs are all state programs that impact and serve PWH. Medicaid is the single largest funder of HIV care in Florida. The HIV/AIDS Section contracts with FDC for pre-release planning services that link discharged inmates with HIV services upon release. DCF oversees mental health services and several housing and homeless programs. The STD Section is a key partner to the HIV Prevention Program, with Disease Intervention Specialists (DIS) providing partner services and following up with newly diagnosed individuals. FHAAN is a statewide effort comprising of PWHs, community advocates, HIV/AIDS and industry professionals, and anyone wanting to be involved to coordinate HIV advocacy efforts.

Collaborations, partnerships, and stakeholder engagement exist in many forms throughout Florida; however, opportunities exist to expand partnerships further and engage new and non-traditional partners in more regular communication (for example, federal Department of Veterans' Affairs and Indian Health Service) to further the objectives and support the strategies of Florida's statewide IPC Plan.

2.2 Role of Planning Bodies and Other Advisory Groups

The Department's HIV/AIDS Section receives advisement on HIV programs and services from various community partners and workgroups, some of which report out directly to the FCPN. These various groups consist of both members of the community, as well as PWH. These groups consist of the Florida Gay Men's HIV Workgroup, the HIV Section Medication Formulary Workgroup, and the Community HIV Advisory Group. Other groups operating in the state but not directly under the FCPN include the Florida Harm Reduction Collective, the Florida Black Leaders Group, and the Florida HIV Justice Coalition. The Department will develop a plan to ensure these groups have a representative at the FCPN table.

For the workgroups that report directly to the FCPN—the Florida Gay Men’s HIV Workgroup, the HIV Section Medication Formulary Workgroup, and the Community HIV Advisory Group—each group consists of PWH who use HIV services and community members selected through an application process and reflective of the profile of the HIV/AIDS epidemic in Florida. Members are appointed for a period of two years and may reapply for subsequent terms. These groups exist to provide a mechanism in which PWH and the community have meaningful input into the development of policies and programs to address their needs with and under the auspices of the Department and the HIV/AIDS Section.

Local Area Interview Results

To better understand the process of community engagement at the local level, interviews were held with each HIV partnership area, with a total of 72 participants. Participants included local Department staff, RWHAP Part A and B representatives, lead agencies, and other community planning body members. During each interview, participants were asked to report on membership, community engagement, outreach activities and keys to success.

Membership: Membership in area partnerships is consistent with all 14 partnership areas having county health departments and CBOs serving populations affected by HIV, as well as HIV service providers. Thirteen out of 14 areas include populations at risk for or with HIV representing priority populations, STD clinics and programs, and HIV clinical care providers and clinicians as part of their voting membership. Only 3 out of 14 partnership areas have epidemiologists and only 4 have representatives from state or local law enforcement or correctional facilities among voting members.

When asked about entities or organizations they would like to have in their planning body, but have not yet been able to secure, areas reported: pharmacists, a school system representative, local school-based clinics, elected officials, representatives from youth organizations, colleges and universities, health promotion groups, an epidemiologist, transportation agencies; faith-based organizations, the Association of Free and Charitable Clinics, and more staff to coordinate the planning body.

Community Engagement: All partnership areas report robust, comprehensive community engagement in each of their counties. All but one area reports challenges with maintaining representation from PWH receiving HIV care services (e.g., RWHAP Part A or B services). Most local areas report having PWH represent approximately 33% of their voting membership; however, these individuals may be staff at local community- and faith-based organizations or on local boards and not necessarily receiving HIV care services through the RWHAP. Several strategies have been used to try and encourage “everyday PWH” to become part of the local planning bodies. Many areas offer incentives and others send out mailers to PWH emphasizing the opportunity to have their voice heard and help the greater good. Other members that areas have difficulty recruiting and keeping are elected officials, faith-based leaders, hospital and health care planning agencies, and law enforcement.

One area restructured planning body meetings from formal events to more informal meetings using lay language and fewer acronyms. They reported that building planning activities around less structure

creates more freedom to speak. Additionally, the planning body keeps meetings to no longer than two hours, food is provided, and agenda items are suggested by members, so they drive future meetings.

To incorporate the perspective of PWH, almost every area sends surveys to clients about services they received and how satisfied they were with those services. This information is used to determine whether some services need to be enhanced, reworked, or streamlined. It is also used for gap analysis purposes and to determine future funding.

About half of the areas report a working relationship with local prisons and jails but felt more could be done to increase testing and treatment efforts. Areas overwhelmingly found value in monthly calls hosted by the Department's HIV/AIDS Section and saw them as a chance to exchange best practices.

Outreach Activities: Partnership areas report hosting focus groups and town hall meetings. Twelve areas held topic-focused community discussions and collaboration building meetings with new partners. Areas also rely on social media to reach PWH engaged in services; however, three areas report that different local restrictions present challenges. Some examples of outreach activities include harm-reduction events, annual surveys to RWHAP recipients, surveys to funded providers, local street fairs and block parties, and events planned around World AIDS Day and other key HIV observance days.

Keys to Success: Partnership areas identified several different ways they have built successful programs:

- Ability to work together to make service delivery appear seamless to clients, regardless of what organization was providing the service.
- Longevity in leadership positions and the sharing of funds between services.
- Consulting with adjacent partnership areas and assisting when possible.
- Having a continuous calendar of events and meetings.
- Participation in statewide calls.
- Collaboration and cohesiveness among partners.
- Cultivating a culture of trust and transparency.

Department Collaboration with RWHAP Parts

RWHAP Parts A, B, C, and D and ADAP programs are key local partners and are at the table as planning activities are performed since no single RWHAP part can meet the needs for all services. The RWHAP Part F program collectively funds Special Projects of National Significance (SPNS), as well as the AIDS Education and Training Centers (AETC) that provides support and training to the medical community in treating patients, and dental programs for PWH.

The planning process is guided by local resource inventories, demographics, satisfaction surveys and service needs expressed locally by PWH who use services. Given the multitude of RWHAP parts, as well as programs funded by other federal, state, and local sources, funding allocation necessitates collaboration and coordination at the local planning body level. Therefore, consortia and planning councils require coordination in RWHAP planning, which involves consideration of other programs in

such areas as assessment of needs, priority setting and resource allocation. Planning bodies must analyze existing resources, regardless of funding stream, to identify areas of unmet need. Likewise, in setting priorities, other resources must be considered in terms of how they help meet service demands so that RWHAP resources can be used to fill gaps.

The Department's HIV/AIDS Section routinely communicates with the RWHAP Part A administrators to ensure they are informed of program activities and have an opportunity to comment and contribute to various projects. Regular monthly calls are used to communicate program updates and policy changes, opportunities for collaboration, and solicitation of feedback. The hosting of the calls rotates, with one of the six RWHAP Part A areas leading the call each month. Examples of collaboration include the transition of RWHAP clients to the Marketplace®, work on the statewide IPC Plan, developing the ADAP HCV treatment project, developing reciprocal eligibility and Notice of Eligibility, data sharing, coordination with ADAP related to the changes in the pharmacy benefits manager, and ADAP formulary updates.

The Department's HIV/AIDS Section allocates RWHAP Part B funding for administration, planning and evaluation, clinical quality management and core medical and support services to 14 lead agencies annually to perform planning activities in their respective areas. Upon receiving RWHAP Part B funds from the Department, each lead agency is required to provide administrative assistance to the planning body (consortium) in the program area. The planning bodies serve as the entities that meet the RWHAP planning requirements for the program area and advise the lead agencies during the priority setting and resource allocation process. Lead agencies facilitate a provider selection process (internal services, external vendors, or competitive procurement process) through a network of local partners (CBOs, CHDs, consumers, planning bodies, and others).

There has also been collaboration with RWHAP Part A partners through EHE initiatives, as RWHAP Part A partners receive EHE funding directly from HRSA to address pillars 2 and 4 (Treat and Respond). The Department receives EHE funding directly from CDC and distributes the funds to the seven EHE counties (county health departments and community and faith-based organizations). Throughout the EHE planning and implementation process (2019 to present), it has been imperative that the Department and RWHAP partners coordinate to maximize efforts, promote information sharing, and ensure resources are used efficiently.

As the recipient of RWHAP Part B funds, the Department is required to develop and maintain a clinical quality management (CQM) program to ensure quality health care services are provided to persons living with HIV. The purpose of the HIV/AIDS Patient Care CQM Program is to provide a systematic approach for planning, measuring, implementing, evaluating, and improving the quality of RWHAP-funded care services delivered to PWH in Florida. Routine review of established performance measures leads to the identification of specific CQM goals for each quality improvement project. Stakeholders who are internal and external to the CQM committee review measures through formally established mechanisms using evidence-based quality improvement methods. This CQM requirement is also mandated by HRSA for each sub-recipient, at the local level. This includes having a formal quality committee and a local CQM plan. For 2019–2022, the following CQM goals were identified:

- **Percentage of Patients on ART (Antiretroviral Therapy)**—Ensure equitable access to RWHAP-funded HIV services in the state for PWH and ensure equitable results in HIV health outcomes; patients receiving ambulatory outpatient care are also on ART.
- **Improving Viral Suppression for PWH**—Drive maximum viral suppression for PWH in the state, with 90% of PWH achieving viral suppression by 2022.
- **Eligibility**—Ensure PWH in the state have complete eligibility documentation for all services received. Complete eligibility documentation prevents gaps in care and can help identify additional services for which the client has need. The goal is 90% of all clients having accurately completed eligibility documentation by 2022.

2.3 Engagement of People with HIV

Florida strives to actively involve key partners, stakeholders, and PWH and, in doing so, incorporates feedback received, for the IPC Plan, on an ongoing basis. The jurisdiction understands that to best serve those most marginalized, their voices must be involved in all aspects of the process. “Nothing about us, without us” is a call to action that informs the need for cultural shifts in programming, provisions of services, and community engagement. Changes have already been made to the planning process with a greater focus placed on creating an environment that is more welcoming to prospective members who represent communities most affected by HIV.

PWH were influential in the development of the statewide IPC Plan. PWH contributed by participating in the Statewide Needs Assessment and serving on local RWHAP Part B consortia, local prevention planning bodies, RWHAP Part A planning councils as well as RWHAP Parts C and D consumer advisory boards. There are also many robust peer-driven navigation and prevention programs that contribute greatly to PWH involvement on many different levels. They have helped identify what is working well (or not), barriers to care, and in accessing prevention and patient care services, and helping to develop the state’s unmet need matrix.

Further, PWH have participated widely in providing feedback to the Department by attending various town hall meetings that have helped develop goals and improve service delivery around eligibility, medical case management guidelines, HIP, PrEP, post-exposure prophylaxis (PEP), ADAP and many of the other programs overseen by the state. They have also played a key role in the success of the medical monitoring project (MMP) in Florida by willingly volunteering their time to be interviewed for this significant program. Florida has a very active Community HIV Advisory Group (CHAG) which also serves as the MMP’s Community Advisory Board. Proposed changes in policy are reviewed and feedback is provided by this group of dedicated individuals. Table 4 shows some of the community engagement and planning efforts across the state.

TABLE 4: COMMUNITY ENGAGEMENT EFFORTS

Location	Involvement
Statewide	Community engagement activities including: five ad-hoc consultations with representatives from priority populations (30+ participants per session) and launched Florida’s Undetectable=Untransmittable (U=U) campaign. The Department’s HIV/AIDS Section hosted virtual meetings (180+ reached) for FCPN and community guests to refine the elements of the unified EHE plan from a statewide perspective.
Area 1 Counties: Escambia, Santa Rosa, Okaloosa, Walton	Community engagement activities were conducted, including the implementation of a U=U campaign, launched with a press conference inviting local civic leaders and community partners. A meeting was also held with the superintendent of schools and a school board member to provide information on local HIV data.
Area 2A Counties: Bay, Calhoun, Gulf, Holmes, Jackson, Washington	Partnered with BASIC NWFL for HIV and HCV testing and condom distribution. PanCare of Florida (FQHC) conducted mobile HIV testing.
Area 2B Counties: Franklin, Gadsden, Jefferson, Leon, Liberty Madison, Taylor, Wakulla	Partnered with 4 community resources for the provision of ART, 3 community resources for HIV testing and diagnosis, 1 partner for HIV education/community outreach, town hall meeting (10 clients attended), and mailed 14 surveys
Area 3/13 Counties: Alachua, Citrus, Lake, Marion, Putnam, Hamilton, Suwannee, Columbia, Lafayette, Gilchrist, Dixie, Levy, Bradford, Sumter	Conducted a town hall meeting in Area 3/13 and results were shared at the April 2022 FCPN meeting. Draft goals and objectives were sent out to the local consortium via email for review and then discussed at the June 2022 consortia meeting.
Area 4 Counties: Nassau, Baker Duval, Clay, St Johns	Community engagement activities such as: 2 provider meetings and town halls, the creation of a local EHE committee, provider survey (68 reached), community-wide listening sessions (115+ reached), faith-based workshops to address stigma and the social justice aspect of the HIV epidemic, and exclusive focus groups (50+ reached) with priority populations.
Area 5/6/14 Counties: Hernando, Pasco, Pinellas, Hillsborough, Manatee, Polk, Hardee, Highlands	Community engagement activities such as: an online community survey (72 reached), focus groups (8 reached) with youth, community members, and private sector leaders; individual phone interviews (39 reached); virtual town hall meetings per pillar (34 across all meetings); and an HIV care needs survey (600+ reached). Additional activities included: focus groups facilitated by representatives of key priority populations (55 reached across all sessions); a virtual interview with local radio station to engage the community (1,000+ reached); virtual EHE Advisory Council meetings to engage new and existing stakeholders; Teen Talk Thursdays, monthly webinars facilitated by representatives revered by youth (50+ reached per meeting) and listening sessions with HIV service providers (45 reached).

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Area 7 Counties: Seminole, Orange, Osceola, Brevard	Community engagement activities such as: conducted 3 town hall meetings; key informant interviews (27 reached); EHE and HIV stigma conversations on Facebook Live with iHeart Media; 8 virtual town hall meetings with key priority populations (98 individuals participated across all town halls, viewed by 3,356 individuals on Facebook Live); quarterly provider meetings to discuss EHE plans and implementation; 8 pop-up HIV testing events; listening sessions with HIV service providers; and community-wide surveys (300+ reached)—one tailored to the community members and the other tailored to providers.
Area 8 Counties: Sarasota, Desoto, Charlotte, Glades, Lee, Hendry, Collier	Community engagement activities were conducted throughout the area, including health education and outreach, community forums and meetings, and testing events.
Area 9 County: Palm Beach	Community engagement activities such as: service provider interviews (19 reached); focus groups with PWH (10 reached); and Palm Beach resident phone interviews in English, Haitian-Creole, and Spanish (253 reached).
Area 10 County: Broward	Community engagement activities such as: 28 community presentations; community-wide listening session; listening session with youth (9 reached); outreach sessions with college students (40+ reached); 5 focus groups with providers, transgender individuals, men who have sex with men (MSM), Black heterosexual women, and Latino individuals; student survey (130 reached); 40 key informant interviews with community members and service providers; and needs-based surveys for providers (430 reached) and community members (1,780 reached) in multiple languages.
Area 11A County: Miami-Dade	Community engagement activities including: several listening sessions at different venues; met with workgroups; and focus groups outside the RWHAP or the Miami-Dade CHD. Additional activities included: key informant interviews with local CBOs and local government (23 reached); 2 needs-based surveys tailored to HIV service providers (37 reached) and community members (1,158 reached) in multiple languages; online community forums and focus groups representing priority populations (250+ reached); 11 community listening sessions with community mobilization groups that primarily serve Black and Latino populations. Mobilization also occurred among transgender individuals.
Area 11B County: Monroe	Engagement activities including quality management patient surveys in ADAP, customer satisfaction surveys in RWHAP Part B, focus group activities in the Client Advisory Board, multiple discussions in the Florida Keys Community Planning Partnership, and monthly Teams meetings, in which all prevention providers meet to discuss awareness day activities, nationally recognized testing day activities and ongoing local prevention activities (e.g.,

	testing sites, outreach activities and involvement and partnership with the Gay Men's Health Summit and Miami-Dade County).
Area 12 Counties: Volusia, Flagler	Various community engagement activities were conducted throughout the area and included numerous health fairs and HIV observance day events (e.g., health fairs at Bethune Cookman University, Stetson University and Daytona Beach College; HIV Testing Day; World AIDS Day; New Smyrna Beach Senior Summit; One Voice Volusia Health Summit; and HOPE Fest Community Outreach with Hope Church).
Area 15 Counties: Indian River, Okeechobee, St. Lucie, Martin	Conducted focus groups with PWH (25 reached); facilitated HIV needs assessment survey (175 reached); partnered with United Against Poverty St. Lucie County for HIV and sexually transmitted infection (STI) screenings and condom distribution (20+ reached); facilitated an HIV/AIDS symposium where attendees were community members, PWH, and service providers (100 reached); participated in Annual Showcase of Services community event and provided resource information to local social service agencies and community members (70 reached); conducted HIV and STI screening at local substance use disorder treatment centers (20 reached); participated in community health resource fair and provided HIV and STI screenings as well as condom distribution (100+ reached); hosted National Latino AIDS Awareness Day testing event (6 reached); and facilitated weekly HIV and STI testing and awareness events in 4 area counties (number reached varied), where all events were conducted in multiple languages.

2.4 Social Determinants of Health

To reduce new HIV diagnoses in Florida, it is critical to ensure that everyone with HIV is aware of their status, is linked to and retained in HIV medical care, and maintains viral suppression. Collaborative efforts from prevention and patient care programs at the state and local levels, including by CHDs, RWHAP partners, CBOs, and health care providers are an integral part of ending the HIV epidemic in Florida. There must also be a focus on the social determinants of health that preclude people from engaging in prevention activities, seeking treatment, and acquiring an adequate level of health literacy. Lower health literacy has been tied to poorer health outcomes in PWH; therefore, ensuring basic levels of health literacy is essential to ensure medication and treatment adherence and ultimately, viral suppression. Social determinants of health (as shown in Figure 6) include food and housing insecurity, geographic location, educational status, poverty, racism, violence, and stigma.

FIGURE 6: DEMOGRAPHIC HIV STATISTICS

In the past decade, Florida has seen a general decline in HIV diagnoses in Florida; however, Black and Hispanic/Latino populations are disproportionately impacted with higher rates of new diagnoses compared to the White population. Additionally, late-stage HIV or AIDS is also higher in the Black population. For males diagnosed with HIV in 2021, Black males were 6 times more likely to be diagnosed with HIV compared to the White males; additionally, Hispanic/Latino males were 4 times more likely to be diagnosed with HIV compared to White males. Similar trends are observed for females, where Black and Hispanic females were 12 and 3 times, respectively, more likely to be diagnosed with HIV compared to White females.

With respect to mode of transmission, in 2021, the majority (61%) of new HIV diagnoses were a result of male-to-male sexual contact (MMSC), followed by 31% who were persons who had heterosexual contact, and 4% who were persons who inject drugs (PWID). Through the identification of priority populations disproportionately impacted by HIV, Florida will continue to engage with and seek input from members of those communities to address health disparities and social determinants of health.

Florida's incorporation of the status-neutral approach and Undetectable=Untransmittable (U=U) into HIV prevention and care service delivery is a key component in addressing social determinants of health and stigma that may prevent individuals from engaging in HIV care services. In June 2020, the Department announced its endorsement of the Prevention Access Campaign's U=U. In becoming a U=U partner, the Department joined nearly 1,000 organizations around the world supporting the science-backed message that PWH who use antiretroviral therapy and have an undetectable viral load in their blood have effectively no risk of sexually transmitting HIV.

Florida will work to ensure programs and services for PWH and those at increased risk for acquiring HIV align with the National Culturally and Linguistically Appropriate Services (CLAS) Standards

(<https://thinkculturalhealth.hhs.gov/Assets/Pdfs/EnhancedNationalCLASStandards.Pdf>), which provide a structure to implement culturally and linguistically appropriate services, and increase the ability of the state to address health care disparities.

2.5 Priorities

The IPC Plan priorities are based on the four goals of the NHAS, 2022–2025:

1. Prevent new HIV infections.
2. Improve HIV-related health outcomes for people with HIV.
3. Reduce HIV-related disparities and promote diverse community wellness.
4. Achieve integrated, coordinated efforts that address the HIV epidemic among all partners and stakeholders.

For the complete list of unique activities to support each strategy, please refer to Appendix Section 9.1 Strategy and Activity Table.

Additionally, the RWHAP Part A's local priorities align with the NHAS, and the four pillars outlined in the EHE: diagnose, treat, prevent, and respond. All goals and objectives include various local initiatives with some overlap between several CDC and HRSA grants.

Based on the most recent HIV data trends for the state (2017–2021) and feedback from community engagement activities conducted in preparation for the IPC development, Florida's integrated HIV prevention and care planning body (FCPN), along with the RWHAP Part A partners, has determined to focus on PWH, Black and Latino populations, LGBTQ communities, PWID, and youth populations.

The planned outcomes of the IPC include reducing HIV-related disparities and promoting diverse community wellness by expanding targeted efforts to prevent HIV transmission using innovative and evidence-based approaches, decreasing the annual HIV diagnosis rate, ensuring early linkage to care, and increasing the number of PWH who are retained in care and virally suppressed. Progress on these outcomes will be ongoing throughout the project period and will benefit the overall community by improving population-level health and reducing the incidence of HIV/AIDS.

While setting goals and priorities, *Demanding Better: An HIV Federal Policy Agenda by People Living with HIV* (<https://www.pwn-usa.org/wp-content/uploads/2021/07/Networks-Policy-Agenda-FINAL.pdf>) was referenced to ensure the Meaningful Involvement of People with HIV/AIDS (MIPA) in decision-making, at every level of the response. In *Demanding Better*, the U.S. People Living with HIV Caucus outlines five recommendations which must be included in every aspect of the federal HIV response:

1. Concretely elevating the meaningful involvement of people living with HIV and disproportionately impacted communities in the HIV response.
2. Proactively creating an affirming human rights environment for people living with HIV.

3. Addressing inequities in the federal response by attending to racial and gender disparities.
4. Adding sex workers and immigrants living with HIV as priority populations.
5. Affirmatively committing to improving quality of life for people living with HIV.

MIPA requires dedication, planning and assessment, organizational buy-in, and a champion to help usher its development and continued assessment. Although the U.S. Department of Health and Human Services (HHS) *National Strategic Plan: A Roadmap to End the Epidemic for the United States, 2021–2025* (<https://files.hiv.gov/s3fs-public/HIV-National-Strategic-Plan-2021-2025.pdf>) largely did not address these recommendations in the final version, Florida’s statewide IPC Plan will do so to the greatest extent possible, as they were created by and for people living with HIV.

2.6 Updates to Other Strategic Plans Used to Meet Requirements

Local jurisdictions perform an annual needs assessment, based on core questions developed through the FCPN Needs Assessment Committee. The needs assessments are created using multiple sources of information from PWH and other stakeholders. Interviews are conducted with PWH and stakeholders to incorporate their feedback and needs. Additionally, surveys are sent out to clients and focus groups are held with the community to understand any changing of needs and priorities. Ongoing feedback of PWH and stakeholders is accomplished by broadly advertising public meetings, allowing public access to all draft, and completed reference documents through online postings, and encouraging participation by members and guests at all meetings. Following completion, the IPC Plan will be presented to the groups who contributed to ensure ongoing community engagement. With greater representation comes additional perspectives that are pivotal to evaluating and improving all planning processes, including the IPC Plan.

Florida’s new IPC Plan for 2022–2026 was built upon the foundational goals, strategies, and activities from the Florida Statewide Integrated HIV Prevention and Care Plan, 2017–2021, Florida’s Unified Ending the HIV Epidemic Plan, 2020, the National HIV/AIDS Strategy, and input from local planning bodies and community members.

3 Contributing Data Sets and Assessments

In analyzing contributing data sets and assessments used to describe how HIV impacts the jurisdiction, the subsequent sections will detail HIV prevention services, barriers to accessing those services, and gaps in the service delivery system:

- Epidemiological Snapshot (Section 3.1)
- Data Sharing and Use (Section 3.2)
- HIV Prevention, Care and Treatment Resource Inventory (Section 3.3)
- Gaps, Needs and Barriers (Section 3.4)
- Needs Assessment including Methodology, Approach, Priorities, and Actions Taken (Section 3.5)

3.1 Epidemiologic Snapshot

The full Epidemiological Profile of HIV in Florida, 2017-2021 will be provided separately. Below is a brief snapshot of the key points.

According to the CDC, in 2020,⁴² Florida had the third highest number of HIV diagnoses and was the third highest for new HIV diagnosis rates per 100,000 population in the U.S., including the District of Columbia. In 2021, 4,708 persons received an HIV diagnosis in Florida, a 37% increase from the 3,441 HIV diagnoses in 2020; however, these data should be interpreted with caution due to impacts from the COVID-19 pandemic which impacted testing, access to care and surveillance activities. In 2021, 83% of those newly diagnosed were linked to HIV-related care in 30 days of diagnosis. There were 120,502 PWH, regardless of AIDS status, living in Florida through 2021 which represents only 86% of all the PWH in Florida. The remainder of whom are living with the disease but are unaware of their HIV status. Among the PWH, 73% were retained in care and 69% had a suppressed viral load at the end of the year. Twenty percent (20%) of PWH had no care in 2021.

Geographical Region and Socio-Demographic Characteristics of Florida

Florida is a southern state that spans a geographic region of 53,624 square miles, comprises 67 counties and 283 cities, and has a mix of urban, suburban, and rural areas. The 2021 population in Florida was 22.0 million residents, with an average of 410 residents per square mile. Approximately 20% of the population is under the age of 18 and 21% is over the age of 65. According to the U.S. Census Bureau, in 2020, 12.4% of Floridians were living in poverty and 16% of Floridians under the age of 65 were without health insurance. The population of Florida is very diverse, with approximately 20.8% of persons residing in the state being foreign born (born outside the continental U.S.). Although most new HIV diagnoses in 2021 were among those born in the U.S. (58.1%), 41.9% of people newly diagnosed with HIV in Florida were born outside the U.S. mainland.

The racial distribution among the adult population (age 13 and above) in Florida in 2021, was 55% White, 15% Black, 26% Hispanic/Latino, and 5% other races including American Indian, Asian, or

multiracial. There were 4,708 HIV diagnoses among adults in 2021. The greatest burden was among the Black population, which received 38% of the new HIV diagnoses in 2021 despite only representing 15% of the adult population in Florida. Hispanic/Latino people were also disproportionately represented for new HIV diagnoses, with 40% of the new HIV diagnoses, compared to 21% among White people as shown in Figure 7.

FIGURE 7: ADULT (AGE 13+) HIV AND AIDS DIAGNOSES AND POPULATION BY RACE/ETHNICITY, 2021, FLORIDA

In 2021, Florida continued to see disparities in HIV diagnoses among adults, despite an annual decrease in the HIV diagnosis rate among Black persons in the past five years. The HIV diagnosis rate per 100,000 population among Black males (93.0) was nearly six times higher than for White males (16.3) and the rate for Hispanic/Latino males (69.3) was more than four times higher than for White males. The HIV diagnosis rate among Black females (36.0) was 12 times higher than for White females (3.0); the rate for Hispanic/Latina females (7.8) was more than two times higher than for White females (see Figure 8). Black persons had a lower statewide viral suppression (<200 copies/mL) rate of 64% compared to 77% for White persons and 71% for Hispanic/Latino persons.

FIGURE 8: ADULT (AGE 13+) HIV DIAGNOSIS RATES BY SEX AND RACE/ETHNICITY, 2021, FLORIDA

In 2021, there was at least one HIV diagnosis in all but 7 counties in Florida and the state HIV diagnosis rate was 21.4 per 100,000 population (see Figure 9). Miami-Dade (42.1), Broward (33.5), Orange (30.3), Duval (30.2), and Palm Beach (21.7) counties had rates higher than that for the state in 2021. The greatest numbers of HIV diagnoses were from the seven counties identified in the national EHE initiative: Miami-Dade (N=1,204), Broward (N=652), Orange (N=439), Hillsborough (N=323), Duval (N=300), Palm Beach (N=322) and Pinellas (N=130). These seven counties diagnosed a combined total of 3,370 cases in 2021, or 72% of the statewide total.

FIGURE 9: HIV DIAGNOSIS RATE BY COUNTY IN 2021, FLORIDA

Trends in HIV Diagnosis

Data for 2020 and 2021 should be interpreted with caution due to the impact of COVID-19 on HIV testing, care-related services, and case surveillance activities in state and local jurisdictions. Figure 10 shows that over the past 10 years (2012–2021), the rates of diagnosed HIV and AIDS in Florida have decreased 9% and 43%, respectively.

FIGURE 10: TEN-YEAR TREND (2012–2021) OF HIV AND AIDS RATES PER 100,000 POPULATION IN FLORIDA

The number of HIV diagnoses decreased by 4% from 2018 to 2019 and increased by 3% from 4,556 (2019) to 4,708 (2021). Additionally, the number of new HIV diagnoses increased by 6% among adult men and decreased by 6% among adult women from 2019 to 2021. The number of new HIV diagnoses over the past 5 years (2017–2021) decreased among all but two age groups: persons aged 30 to 39 (15% increase) and persons aged 40 to 49 (2% increase). The number of new HIV diagnoses over the past five years decreased among all race/ethnicity groups except Hispanic/Latino persons, where a 25% increase was observed.

With respect to mode of exposure, male-to-male sexual contact continues to be the primary mode of exposure for HIV among males (77% in 2021), followed by heterosexual contact (18%) and injection drug use (IDU) (3%). Over the past five years (2017–2021), transmissions among males that observed an increase in HIV diagnoses were MMSC (1%) and IDU (28%), whereas transmissions that decreased were MMSC/IDU (12%) and heterosexual contact (1%).

Among females, heterosexual contact is the primary mode of exposure for HIV (92% in 2021), followed by IDU (8%). Over the past five years (2017–2021), decreases in HIV diagnoses among females were observed among both transmissions: heterosexual contact (11%) and IDU (13%).

Thirty-eight out of the 67 counties (57%) saw a decrease in new diagnoses of HIV from 2018 to 2019. Twenty-eight out of the 67 counties (42%) saw a decrease in new diagnoses of HIV from 2019 to 2021. All but two of the seven EHE counties in Florida saw a decrease in HIV diagnoses from 2019 to 2021 (Pinellas [32%], and Orange [5%]). Palm Beach County saw a 31% increase from 2019 (N=245) to 2021 (N=322), and Hillsborough County saw a 12% increase from 2019 (N=288) to 2021 (N=323). The three remaining EHE counties (Duval, Miami-Dade, and Broward) all saw a 3% increase from 2019 to 2021. Challenges exist with many new HIV diagnoses being among people who may be new to the county, state, or country and who may not have benefited from the robust prevention activities available throughout Florida; yet the new (or re-diagnoses) count toward new HIV diagnoses for local jurisdictions and the state.

Perinatal HIV Transmission

A strategic long-term goal in Florida is to reduce or eliminate the annual number of babies born in Florida with perinatally acquired HIV. Since the introduction of azidothymidine (AZT) in 1994, perinatally acquired HIV diagnoses have drastically declined (see Figure 11). Over the past three years (2019 to 2021), there were eight perinatally acquired HIV diagnoses with an average transmission rate of 0.006. For the first time in the history of the HIV epidemic, there were no perinatally acquired HIV diagnoses born in Florida in 2019. There were four in 2020, and four in 2021.

FIGURE 11: PERINATALLY ACQUIRED HIV DIAGNOSES, 1979–2021, BABIES BORN IN FLORIDA

Prevalence of PWH in Florida

The rate of PWH in Florida in 2021 was 547.6 per 100,000 population, with the majority of PWH living in the large metropolitan areas and the seven counties outlined in the EHE plan. However, there is also a high rate of PWH living in smaller, more rural counties, such as those in northern Florida (see Figure 12). There were 120,502 PWH living in Florida in 2021. Among the adult PWH (N=120,379), 44% were Black, 28% were White, 26% were Hispanic/Latino, and 2% were American Indian, Asian, or multiracial. More than one-half (57%) were over the age of 50. MMSC was the mode of exposure for 71% of males. Heterosexual contact was the mode of exposure for 86% of females. Ten percent (10%) of PWH had a history of IDU. Among the PWH in 2021, 503 (0.4%) were transgender individuals and the primary mode of transmission was sexual contact (90%).

FIGURE 12: PWH, LIVING IN FLORIDA, BY COUNTY OF RESIDENCE, YEAR-END 2021

Late HIV Diagnosis and Resident Deaths Due to HIV/AIDS

HIV/AIDS-related deaths in Florida decreased markedly (30%) from 1995 (N=4,004) to 1996 (N=2,796) after the advent of highly active antiretroviral therapy (HAART) in 1996. Furthermore, HIV-related deaths in Florida from 2012 to 2021 decreased 34% over the past 10 years, 16% over the past five years, and 7% in the past year from 659 in 2020 to 612 in 2021. The Black community has been disproportionately affected by HIV in Florida since the epidemic began in 1981 and despite a large decrease in the rate of HIV-related deaths among Black persons (43% since 2012), HIV disparities still exist among Florida's Black population. In 2021, rates of HIV-related deaths were five times higher for Black males (11.9 per 100,000 population) compared to White males (2.6 per 100,000 population) and nearly 11 times higher for Black females (7.5 per 100,000 population) compared to White females (0.7 per 100,000 population) with HIV.

Of the 4,708 HIV diagnoses in 2021, 19% (N=895) were late diagnoses, which are defined as persons receiving an AIDS diagnosis within 90 days of their confirmed HIV diagnosis. By race/ethnicity, 20% of Black persons, 21% of White persons, and 16% of Hispanic/Latino persons were late diagnoses. Among adults (age 13+), the two groups with the highest proportion of late diagnoses by age and mode of exposure were persons aged 50 and over (29%) and males with a history of IDU (29%), respectively.

HIV Care Continuum

The HIV Care Continuum is a diagnosis-based model that reflects the series of stages from initial diagnosis to being retained in care and achieving viral suppression. The HIV Care Continuum has four main stages: HIV diagnosis, linkage to care, retention in care, and viral suppression. It demonstrates the proportion of individuals diagnosed and living with HIV who are engaged at each stage. This model is used by federal, state, and local agencies to identify issues and opportunities related to improving the delivery of services to PWH across the entire continuum.

In 2021, despite the COVID-19 pandemic, of the 120,502 PWH in Florida, 80% (N=95,959) were reported to be in care (received at least one documented VL (viral load) or CD4 lab, medical visit, or HIV-related prescription in 2021), 73% (N=88,274) were retained in care (had HIV-related care two or more times at least three months apart), and 69% (N=83,556) were virally suppressed. As Figure 13 shows, of the persons retained in care, 90% had a suppressed viral load (<200 copies/mL). Twenty percent (20%) (N=24,543) did not receive any HIV-related care in 2021.

FIGURE 13: PWH LIVING IN FLORIDA ALONG THE HIV CARE CONTINUUM, YEAR-END 2021

The seven EHE counties make up approximately 11% of the total national HIV burden as outlined in the EHE plan and represent 72% of the total persons living with an HIV diagnosis in Florida.

Five of the EHE counties, Pinellas (77%), Hillsborough (71%), Orange (72%), Broward (70%) and Duval (69%) had a viral suppression rate equivalent to or greater than the state rate of 69%, while Palm Beach (65%) and Miami-Dade (63%) had lower viral suppression rates than the state at the end of 2021. It's important to note that PWH who receive services from the RWHAP and ADAP tend to have better results of viral suppression. For example, although Miami's overall viral suppression rate was 63%, approximately 82% of the 8,418 clients served by Miami's RWHAP Part A and Minority AIDS Initiative (MAI) program in fiscal year 2021 were virally suppressed.

The five populations ranked lowest in the percentage of suppressed VL (<200 copies/ml) in 2021, in descending order, were as follows:

1. Male PWID (58%)
2. Black Males with Heterosexual Contact (59%)
3. Black Males with MMSC (65%)
4. Persons 25–39 years of age (66%)
5. Persons 13–24 years of age (67%)

When compared with the HIV Care Continuum for Florida, the above five populations demonstrated disparities, particularly in the last stage, suppressed VL (<200 copies/ml). In 2021, 69% of PWH in Florida had a suppressed viral load. The five populations of concern in this section show suppressed VL percentages below 69%. This is significant to note in observing the ultimate health outcome of treatment adherence and an individual living with HIV leading a healthier life.

HIV-Related Co-Morbidities

STIs and hepatitis B virus (HBV) and (HCV have been steadily increasing in Florida over the past five years, including a 4% increase in chlamydia, a 40% increase in gonorrhea, and an 88% increase in early syphilis. Co-infection of PWH with STIs also increased during this same time period, with an increase of 67% for HIV/gonorrhea, 72% for HIV/chlamydia, and 76% for HIV/early syphilis. In 2021, there were 302 adults who were also co-infected with HBV, 86% of whom were male; 59% of the males reported MMSC exposure, and 30% of females reported IDU exposure. There were 537 PWH who were coinfecting with HCV in 2021, the majority of whom were males (82%) with MMSC (66%), IDU (13%), or heterosexual (11%) exposure. Forty-eight percent (48%) of female PWH with a co-occurring HCV diagnosis had IDU exposure. An increase in routine screening of all STIs, HIV, and hepatitis is needed to capture and prevent disease burden.

HIV Transmission Clusters and Networks

One aspect of the Florida IPC and the Florida EHE plans is to detect and respond to rapidly growing HIV transmission clusters and networks and prevent future HIV diagnoses using data and laboratory results collected through routine public health surveillance. Transmission cluster network analyses are conducted using data from point-of-care HIV-1 genotypic resistance testing to identify genetic (molecular) links of similar virus strains by comparing those with similar HIV genetic sequences. Those data are then used to identify networks of recent and rapid transmission for prevention and linkage-to-care interventions. The observed HIV transmission rate in molecular clusters identified across the U.S. is, on average, 11 times higher than the transmission rate in the general HIV population, thus indicating the importance of quickly using proven interventions to stop further transmission of HIV. HIV molecular clusters are considered rapidly growing when there have been five or more new HIV diagnoses in the previous 12 months. The Department is actively conducting surveillance and investigation for HIV clusters. The Department routinely conducts monthly analysis to detect rapidly growing molecular clusters and time-space clusters of public health significance. Additionally, a state level HIV cluster review committee is convened monthly to review cluster data, discuss challenges, and brainstorm strategies to improve the statewide response. Since fall 2021, the Department's Bureau of Communicable Diseases has established routine communication with CHDs experiencing clusters to coordinate and guide local responses to investigate and respond to clusters. Florida's updated HIV Cluster Detection and Response plan was submitted to CDC in fall 2021 and will be updated in 2023.

Since the beginning of the Department's HIV transmission cluster detection program in November 2017, the HIV/AIDS Section has identified 64 clusters at a 0.5% genetic distance between strain of HIV demonstrating rapid growth. These molecularly linked transmissions comprise a total of 772 persons receiving an HIV diagnosis in Florida with a much larger, often underdefined transmission and risk network. Though members of molecular clusters live across the state, 554 (72%) have a current residence in one of the seven EHE counties. The state has also taken a collaborative approach to responding to other outbreaks that impact the care and treatment of PWH (e.g., COVID-19, Mpox, hepatitis A, and meningococcal disease), providing trainings, developing messaging, and promoting health resources and services.

3.2 Data Sharing and Use

De-identified HIV, viral hepatitis, STD, and TB data are routinely shared via ad-hoc requests to surveillance programs with outside entities including, but not limited to, academic institutions, community partners, RWHAP parts, internal agency partners and collaborators, and the public. Each of these programs provide annual data which are uploaded into FLHealth CHARTS (Florida Community Health Assessment and Resource Tool Set) (<https://www.flhealthcharts.gov/charts/CommunicableDiseases/default.aspx>). In addition, the Department is updating the FLHealth CHARTS website (a web-based platform that provides easy access to health indicator data at the community and statewide level for the state of Florida from a multitude of sources) with a new dashboard (at the county level) that will incorporate a multitude of HIV/AIDS indicators including but not limited to, demographic and socio-economic indicators, partner services data, testing and treatment facilities, PrEP, and other data not previously included on FL Health CHARTS.

By ensuring all these data and information are made readily accessible and user-friendly, the new dashboard will help local and state planning bodies develop more effective and efficient programs and corresponding activities and monitor progress of IPC strategies and activities. All data are protected securely and confidentially, adhering to the Department's internal policies and strictly adhering to CDC's, *National Centers for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention (NCHHSTP) Data Security and Confidentiality Guidelines*.

Summarized ad-hoc data requests are honored based on the ability of the program to generate the requested data within the time constraints of the request. Data requests for ZIP code data will receive suppressed data (data by ZIP code with three or more cases) based on internal Department ZIP code suppression rules.

Epidemiologic Data

Summarized annual data are uploaded to the Department's HIV/AIDS Section web page (<http://floridaaids.org>) and are also available on a SharePoint site for internal use at the state and CHD level. Annual data releases include a comprehensive epidemiological profile for the state and for each partnership area, a state slide set presented annually to FCPN, and other annual data products. The epidemiological profiles are an expanded Excel workbook with multiple tabs containing 5-year trend analyses of HIV (demographics, diagnosis, AIDS, deaths, and continuum of care), STIs, HBV, HCV, and TB.

Factsheet and Slide Sets to Support Stakeholder Engagement and Planning

Various factsheets are generated to portray epidemiology and disease highlights for a demographic population. These fact sheets address various HIV/AIDS awareness day topics as well as highlight summary data for high-risk population groups. These fact sheets are updated annually, shared with community stakeholders, and uploaded to the Department's external web and internal SharePoint sites. Integrated slide sets and epidemiological profile tables are generated to support stakeholder engagement and planning. The Department's HIV/AIDS Section has generated comprehensive slides sets

and epidemiologic profiles specifically for each of the 14 partnership areas each year since the 1990s. These slide sets and profiles are shared with the RWHAP Part A entities, community stakeholders, field surveillance staff, and others who may request these data. These data are frequently used as tools for program planning and evaluation.

Other Data Sources

Along with HIV data, the Department summarizes data from MMP and CDC's National HIV Behavioral Surveillance (NHBS) surveillance project, along with Department PrEP, Test and Treat, and HIV counseling and testing data. Data from the needs assessments are also shared in reports sent out to FCPN membership. Other data sources include the RWHAP Eligibility Portal, CAREWare, and Provide Enterprise (an online care management system).

Data Sharing Agreements

For persons requesting de-identified data in a database format that can be analyzed for public health research purposes, the researcher must first submit a concept proposal with research aims, benefit to public health, and required data variables and time frame for the requested data. An internal Department research committee reviews the feasibility of the project, including for potential human subjects impacts and ethical considerations. Once approved, the requestor must complete a Data Use Agreement (DUA) and obtain a study approval or study exemption letter from the Department's Institutional Review Board. Once received, the DUA is routed for legal review and signatures. Data are provided via secure FTP format and can only be housed on secure servers as part of the DUA.

Any program outside of the Department that is approved to receive HIV data through a Data Sharing Agreement (DSA) for the purpose of linking or re-engaging HIV clients into care must be in full compliance with the NCHSTP Data Security and Confidentiality Guidelines for HIV, Viral Hepatitis, STD, and TB Programs, Department security and confidentiality policies, Health Insurance Portability and Accountability Act (HIPAA) guidelines and have documented active-client consent to share. Data sharing with programs outside the Department requires approval of the overall responsible party, HIV/AIDS Section administrator and legal counsel. A memorandum of understanding or DSA must be completed between the Department and the program requesting data. The HIV Surveillance Program will provide only the minimum data required to conduct linkage and reengage to HIV care and services.

In partnership with the six RWHAP Part A programs located in the seven EHE counties and through funding received by Georgetown University, the Department has developed and is preparing to implement a data sharing and Data to Care (D2C) effort to improve linkage to HIV care for persons out of care in those jurisdictions.

Some challenges exist with data sharing; for example, the Department's data sharing agreement with the Florida Agency for Health Care Administration (AHCA) for Medicaid does not allow the Department to share data on Medicaid enrollments of the same clients receiving services in and from the RWHAP

Part A jurisdictions. This leads to duplicative and sometimes costly efforts for the RWHAP Part A programs to run Medicaid verification checks on the clients for eligibility assessments.

3.3 HIV Prevention, Care, and Treatment Resource Inventory

To ensure that the state is meeting the goals and objectives set forth to best address the needs of PWHs, Florida must prioritize the financial resources and assess the capacity to provide the services outlined. The following section provides a comprehensive HIV financial resources inventory for Florida. Components include, but are not limited to, statewide public and private funding sources for HIV prevention, care, and treatment services; the dollar amount and the percentage of the total available funds for each funding source; program or service delivery; and what step of Florida's HIV Care Continuum is impacted.

Resource inventories have been provided by all 14 HIV partnership areas in the state of Florida. Each partnership area provided separate inventories for prevention and patient care, which can be found in Appendix Section 9.3 Partnership Area Resource Inventories. Table 5 represents Florida-specific funding from various sources for HIV-related services statewide, where available, for FY 2021.

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

TABLE 5: FUNDING RESOURCE INVENTORY

Funding Source and Area/Jurisdiction	Funding Amount (\$)	Percentage of Total Funding (%)	Services Delivered	HIV Care Continuum Steps Impacted ¹
HRSA RWHAP Part A (EMA/TGA)²	\$76,146,512	12.67%		
Fort Lauderdale	\$15,724,848		Medical case management (including treatment adherence), oral health care, EIS, mental health services, substance abuse treatment (outpatient), case management (nonmedical), food bank/home-delivered meals, health education/risk reduction, housing services, legal services, medical transportation services, psychosocial support services	2,3,4,5

¹ HIV Care Continuum: 1 = HIV Testing and Diagnosis: Staff, services and systems that help to identify and test persons who are unaware of their HIV status; 2 = Linkage to Care: Staff, services, and systems that help connect newly diagnosed PWHA to care; 3 = Retention in Care: Staff, services, and systems that help PWH remain engaged in care and treatment services; 4 = Provision of ART: Staff, services, and systems that help PWH access and remain adherent to antiretroviral medication; 5 = Viral Suppression: Staff, services and systems that help PWH achieve and maintain viral suppression.

² RWHAP Part A figures represent FY2021 funding amounts.

³ The State Health Office is the recipient of HRSA RWHAP Part B funds.

⁴ State General Revenue to County Health Departments includes 4B000, 4BNWK, and 4BAPS.

⁵ CDC-PS21-2102: Unable to obtain exact funding amounts. Average funding award for each provider was approx. \$441,625.

⁶ CDC-PS18-1807: Unable to obtain exact funding amounts. Average funding awards approx. \$350,000.

⁷ Unable to obtain Florida-specific funding levels.

⁸ Additional private foundation awards exist; however, recipients and award amounts are unknown.

Other sources of funding include funds from the state of Florida general revenue, Housing Opportunities for Persons with AIDS (HOPWA), U.S. Department of Housing and Urban Development (HUD), RWHAP all parts, CDC Integrated HIV Prevention and Surveillance, CDC MMP, CDC NHBS, CDC and HRSA EHE funds, SAMHSA, tribal organization funding, and private foundation funding, where available. More work is needed to identify Florida-specific funds related to HIV services from the Veteran’s Administration (VA) and Medicaid.

The Florida HIV Care Continuum Dashboard Tool was developed as a mechanism to gather information related to how funds are distributed statewide and RWHAP services are delivered by geographic area. The purpose and goal of the tool was to provide a snapshot of HIV prevention and patient care funding and assess HIV prevention and patient care activities across the care continuum by each of the 14 HIV partnership areas.

The tool provides a listing of resources in CHDs and local communities, as well as illustrating gaps and unmet needs by contrasting regional differences and highlighting areas of need. The information in the Florida HIV Care Continuum Dashboard Combined Tool was self-reported by each local area; therefore, slight differences may appear in terms of funding or data reported. Additionally, specific caveats may apply since they may have alternate funding streams coming into their local areas or enhanced best practices or collaborative efforts which result in increased funding as reported by the state.

The purpose of this inventory is to provide a snapshot of HIV prevention and patient care funding by area. The goal of this inventory is to help assess HIV prevention and patient care activities across the continuum of care by area. The inventory provides a snapshot of resources in CHDs and communities. Individual area resource inventories can be found in Appendix Section 9.3 Partnership Area Resource Inventories.

3.4 Gaps, Needs and Barriers

Through the development of Florida’s Unified EHE Plan and through local community engagement activities, additional gaps, needs, and barriers were identified which span across all pillars as described in Table 6:

TABLE 6: GAPS, NEEDS AND BARRIERS

Summary	Description
Meaningful Community Engagement with Priority Populations	The Department received feedback from community partners on the perceived effectiveness of current public health initiatives. Partners identified across all IPC pillars determined there is a need for increased and meaningful community engagement with all of Florida’s populations that are disproportionately affected by and living with HIV, including Black and Hispanic/Latino populations and the LGBTQ community. The Department recognizes that Florida’s racial/ethnic minority populations continue to increase in size and continues to address gaps in diverse community

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Summary	Description
	wellness throughout the state. Improvements in HIV outcomes over the last decade have had great strides. However, populations of racial and ethnic minorities should continue to be prioritized to improve prevention and care access. For Florida’s racial/ethnic minority populations, HIV outcomes should improve among all populations at the same rate – especially among Florida’s diverse population. While Florida has maintained the Business Responds to AIDS (BRTA) and Faith Responds to AIDS (FRTA) initiatives for over a decade, additional efforts are needed to involve faith-based and business leaders. Faith-based leaders, as trusted members of their communities, are well-poised to educate and mobilize Black and Hispanic populations around HIV/AIDS. Feedback indicates there would be a benefit for leaders of faith-based institutions to engage in HIV education and awareness. Challenges exist around maintaining community engagement with and representation from PWH who receive services directly through the RWHAP, both at state and local levels.
Geography and Transportation	Whereas there are major metropolitan areas in the state, 30 of Florida’s 67 counties (45%) are designated as rural per the 2010 U.S. Census.³⁹ Many Floridians live in areas that have both rural and urban characteristics, which makes addressing the needs of these communities challenging. Transportation is often a barrier for clients attempting to access HIV care services and can lead to missed appointments, decreased medication adherence, and disengagement from care.²⁰ County size and lack of affordable, safe, and timely transportation options are also factors contributing to barriers in accessing care. For example, in Miami-Dade County, some clients who live in far south Dade, and fear stigma of accessing HIV care closer to home, opt to ride hours on public transportation, often in inclement weather, to access services near downtown Miami.
Poverty and Education	In 2020, 13% of people living in Florida reported living below the federal poverty level.²⁰ Counties with the highest poverty rates included DeSoto, Hamilton, Hardee, Hendry, and Madison. In 2016–2020, 88.5% of people aged 25 years and older living in Florida had at least graduated from high school (compared to 89.4% for the U.S.).²⁰ Counties with the fewest individuals with at least a high school diploma included DeSoto, Glades, Hamilton, Hendry, and Lafayette. Counties with the lowest education levels were found in central and northern Florida.
Mental Health and Substance Use Disorders	Persons experiencing mental health and substance use disorders are at increased risk for HIV and frequently lack access to HIV and STI education, prevention, and care services.²² In 2020, nearly 18% (7,842) of the 44,577 reported drug overdose deaths in Florida involved opioids.²³ There was an approximate 28% increase in the number of persons treated for addiction with self-reported IDU between 2014 and 2018.²⁴ There was a 2% increase in HIV diagnoses from 2017–2021 among persons with an IDU-related mode of exposure.⁶ Over that same time period, acute HCV infections

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Summary	Description
	increased by 366% in Florida; injection drug use is the primary mode of exposure among persons diagnosed with acute HCV. Efforts are needed to ensure organizations providing behavioral health and substance use treatment services are providing education around HIV, STIs, and HCV and are knowledgeable about local testing and treatment resources. According to the FDCF, 2020 Florida Youth Substance Abuse Survey (FYSAS) State Report, substance use among students in Florida continues to decline. Among middle and high school students in Florida, between 2010 and 2020, the prevalence of lifetime alcohol use decreased from approximately 52% to 35% and the past-30-day prevalence of alcohol use decreased from 29% to 15%. Regarding marijuana use, the prevalence of lifetime and past 30-day marijuana use among middle and high school students also decreased between 2010 and 2020. According to estimates from the 2022 FYSAS among high schoolers, the lifetime prevalence is 2.8% for opioid misuse, 4.1% for stimulant misuse, and 5.7% for opioid and stimulant misuse.⁴⁵ Methadone- or buprenorphine-assisted maintenance treatment (including psychosocial support as needed and if desired) is the evidence-based standard of care used to treat opioid use disorders. According to an analysis of 25,866 Florida Medicaid enrollees diagnosed with opioid use disorders only about 28% go on to initiate medication-assisted treatment. About 56% of newly diagnosed individuals who began methadone treatment continued for 180 days, compared about 19% of newly diagnosed individuals who began treatment with buprenorphine.⁴⁶
Multicultural and Multilingual Issues	Florida population estimates for 2020 show racial/ethnic distributions as follows: 51.5% White (non-Hispanic), 14.5% Black (non-Hispanic), 3.0% Asian American, and 0.2% Native American. Hispanic/Latino persons make up over a quarter (26.5%) of the population. Florida ranks in the top five states with the highest Hispanic/Latino populations in the U.S. and has one of the largest Black/African American populations in the country. Florida's Asian population is growing, particularly in Gulf Coast locations. The state is home to two federally recognized American Indian tribes (the Seminole and the Miccosukee in South Florida) and many more non-federally recognized tribes, bands, and clans. The Miami metropolitan area (along with New York City) maintains one of the highest populations of Caribbean immigrants, with approximately 63% of Caribbean immigrants in the U.S. living in these two metro areas. Just over 20% of Florida's population is foreign-born and nearly 30% of households in Florida speak a language other than English.⁵ There is a lack of bilingual and multilingual health care providers and media and marketing messages in certain regions of the state.²⁵ Florida works to ensure programs and services for PWH and those at increased risk for acquiring HIV align with the National CLAS Standards and that translation services are made available to all clients receiving services at CHD clinics and through funded HIV prevention and care service providers.

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Summary	Description
Racism, Discrimination, and Medical Mistrust	Persons experiencing racism and discrimination are less likely to remain adherent to care and more likely to have poorer health outcomes.²⁶ Medical mistrust tends to be higher among Black and American Indian populations in Florida. The Tuskegee Study conducted by the U.S. Public Health Service left lasting impacts on the way Black persons view health care, particularly public health.²⁷ Similarly, studies have shown the sterilization of American Indian women by the Indian Health Service in the 1960s and 1970s created a culture of distrust of government-funded health care services.²⁸
In-Migration, Tourism, Seasonal, and Mobile Populations	Florida sees more than one-hundred million tourists each year, many of whom are drawn to popular beach towns and cities like Miami, Fort Lauderdale, and Key West.²⁹ Its many theme park attractions and over 8,400 miles of coastline make Florida a destination for tourists from around the world. According to VISIT FLORIDA's latest estimates, during Quarter 1 of 2022 (January–March), Florida saw a total of 36 million visitors. This represents a 14% increase from Q4 2021, and the third consecutive quarter that overall visitation has surpassed pre-pandemic levels. Approximately 34.1 million domestic visitors traveled to Florida in Q1 2022, and there were approximately 1.3 million travelers from overseas who visited the state during that same time period (represents an increase of nearly 169% from Q1 2021).⁴⁷ The state also has a large population of seasonal residents—students, seasonal workers (in industries such as hospitality, agriculture, and tourism), and persons who reside here part time to avoid harsh winters. In addition, Florida is home to several state and private higher-learning institutions, including Historically Black Colleges and Universities (HBCUs). These colleges and universities are often located in Florida's major metropolitan areas, which have higher than average HIV incidence. If tourists, visitors, and persons migrating into the state receive their original HIV diagnosis in Florida, that case counts toward Florida's overall HIV prevalence. The Department's surveillance unit works with other states and jurisdictions to perform deduplication efforts to ensure that persons initially diagnosed in another state or jurisdiction are not counted toward Florida's overall prevalence.
Immigration and Refugee Services	Over the past few years, foreign-born individuals and individuals born in U.S.-dependent areas immigrating to Florida have accounted for roughly half of the population's growth; more than one in five Florida residents is an immigrant.³⁰ Individuals born outside the continental U.S. comprise roughly 20% of the state's population, and in Miami-Dade County, more than 60% of the population is foreign-born. Among non-U.S. born residents in Florida, persons born in Haiti, Cuba, Venezuela, and Colombia experienced the highest numbers of HIV diagnoses in 2021. This presents a need for increased cultural humility to ensure health education, prevention, and care services are delivered in a culturally and linguistically appropriate manner (i.e., National CLAS Standards).

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Summary	Description
	FDCFs Refugee Services Program is federally funded by the Office of Refugee Resettlement in HHS to assist refugees to achieve economic self-sufficiency and social adjustment in the shortest possible time after their arrival in the United States. While in recent years the number of arrivals has decreased nationwide, the state of Florida's refugee program is the largest in the nation, receiving more than 5,000 refugees, asylees, and Cuban/Haitian entrants each year. Eligibility for programs of Refugee Services is determined by federal law and includes the following: Refugees; Cuban/Haitian Entrants; Asylees; Afghan and Iraqi Special Immigrants; and Certified Victims of Human Trafficking.⁵¹ FDCF Refugee Services currently manages more than a dozen refugee services contracts with state agencies, local governments, and community-based organizations. Through their Refugee Health Program, the Department's CHDs provide health screenings to ensure newly arrived refugee clients do not have communicable diseases and to identify health issues. AHCA provides payment for Refugee Medical Assistance services with federal funding and in accordance with Medicaid rules. Of Florida's 67 counties, approximately 32 counties receive refugees for health services on a regular basis. Geographically, new arrivals tend to resettle more frequently in one of the nine following Florida counties: Miami-Dade, Hillsborough, Duval, Palm Beach, Broward, Orange, Collier, Lee, or Pinellas.⁵² From the latest data available from FDCF, in 2021, 30,092 refugees arrived or became eligible for Refugee Services in Florida. Additionally, over the last five years (2017–2021), 97,492 refugees arrived or became eligible for Refugee Services. Florida received refugees from 47 different countries last year, of which 72% of refugees were Cubans, and 50% of refugees settled in Miami-Dade County. Cuban, Haitian, Afghan, Mexican, and Chilean were the top nationalities of new refugees in 2021.⁵³
Criminal Justice	According to the National Corrections Institute, Florida's incarceration rate (prisons and jails) was 371 per 100,000 population in 2020.⁴⁸ In 2020, the U.S. Bureau of Justice Statistics ranked Florida eleventh among states in terms of incarceration rates.³² Most incarcerated PWH were diagnosed prior to entering the correctional system; however, HIV testing in a correctional setting may be the first time persons who are incarcerated take advantage of testing and prevention education. Although condom provision is one of the simplest harm-reduction interventions to control HIV, STIs, and viral hepatitis, condoms are prohibited in correctional settings. Section 945.355, Florida Statutes (F.S.), requires inmates of FDC to be offered HIV testing prior to release, while jails (which are governed by each county) do not have uniform statewide HIV testing policies. Over time, the Department has built relationships with county jails to establish HIV testing and linkage programs. Increased partnerships with county jails are needed to expand HIV, STI, and HCV testing.

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Summary	Description
HIV Criminalization	Established in 1990, section 384.24, F.S., criminalizes non-disclosure of STI status, and separately HIV status, prior to sex. The offense requires the person to be aware of their STI and HIV status, to be informed of the risks of transmission through sex, and to go on to have sex with another person. At the time the law was established there was a modest understanding of how HIV transmission occurred, and treatment options were limited. After 30 years of research and advancements in HIV treatment, the law does not take into account the latest science and measures to prevent transmission (e.g., viral suppression, U=U). Persons with HIV and other community members have reported that criminalization laws may be discouraging HIV testing and perpetuating stigma against persons with HIV.
Environmental Impacts	Severe weather events can disrupt and interrupt HIV prevention and care delivery systems. Florida is a state particularly vulnerable to frequent hurricanes. When Hurricane Michael hit the Florida Panhandle in October 2018 as a category 5 storm, it caused mass destruction. Thousands of homes were destroyed, and many residents were displaced. PWH in the area had trouble accessing services and medications due to widespread devastation. Many people were forced to find housing elsewhere in Florida or even in other states. Emergency medication fills were available through the Department’s ADAP program; however, increased efforts are needed to identify PWH in need of reengagement in care and ancillary services following a natural disaster. Most recently, on September 28, 2022, Hurricane Ian made landfall on Florida’s southwest coast (Fort Myers area) as a category 4 storm, with Lee and Charlotte counties bearing the greatest impacts. More than 100 people lost their lives in Hurricane Ian, with most deaths being attributed to drowning—the record-breaking storm surge reached as high as 18 feet in some areas. Hurricane Ian is being categorized as the deadliest storm to hit Florida since the 1935 Labor Day Hurricane. The Department used the federal emergency declaration to ensure that ADAP clients had access to medication refills ahead of the storm and worked with ADAP staff statewide to communicate to clients that they had the ability to get prescriptions filled at any pharmacy location in their local areas.
Homelessness and Housing Instability/Insecurity	In 2021, the Florida Housing Coalition reported Florida having the third-highest homeless population of any state in the nation, with 27,640 people living in homeless shelters and on the streets. Before the COVID-19 pandemic, 875,259 very low-income Florida households—including hardworking families, seniors, and people with disabilities—paid more than 50% of their incomes for housing. For PWH, housing is one of the primary predictors of their access and adherence to treatment, other health outcomes, and life expectancy. There are several definitions of homelessness or unstable housing, such as lacking a fixed, regular, or adequate nighttime residence, but also including residing in a motel, doubling up with friends or family, or “couch-surfing.” People fleeing domestic violence are also considered unstably housed if they do not have the resources and support to obtain other

State of Florida Integrated HIV Prevention and Care Plan, 2022–2026

Summary	Description
	permanent housing. Responses from Florida’s 2019 HIV Care Needs Assessment survey indicated that, of persons who experienced housing-related barriers, the top three barriers were not having money to pay rent, being afraid of others knowing their HIV status, and not having enough food to eat.⁵⁵
Food Insecurity	The latest data from Feeding America show that in 2020, Florida’s overall food insecurity rate was 10.6% (approximately 2.3 million people). Although Florida’s overall food insecurity rate is lower than the U.S. average of 11.8%, 42 out of 67 Florida counties (63%) have food insecurity rates at or above the national average (>11.8%). Florida’s 2019 HIV Care Needs Assessment Survey revealed that for PWH who reported experiencing housing-related barriers, one of the top three issues reported included not having enough food to eat. Many antiretroviral medications used to treat HIV require they be taken with food and ensuring proper nutrition for PWH is paramount to medication adherence and improved health outcomes.⁵⁶
Persons with HIV Aged 50+	Improvements in ART for HIV over the years have led to people with diagnosed HIV living longer and healthier lives, especially when diagnosed early, maintained on ART, and virally suppressed. In 2021, persons with HIV aged 50 and older living in Florida made up nearly 57% of the state’s total population of persons diagnosed and living with HIV. Persons aged 50 and older living with HIV face several health challenges—HIV-related and other comorbidities (e.g., cardiovascular and liver disease, neurocognitive impairment), concurrent use of multiple medications (i.e., polypharmacy), oral health problems (e.g., tooth loss), and mental health and substance use disorders.
Outbreak Response for Syndemics	Over the past several years, the state has taken a collaborative approach, with RWHAP and other community-based partners, to responding to other outbreaks that impact the care and treatment of PWH (e.g., COVID-19, Mpox virus, hepatitis A, and meningococcal disease), providing trainings, developing messaging, and promoting access to available health resources and services (e.g., vaccine promotion events for hepatitis A and meningococcal disease). Greater coordination is needed to ensure these intersecting conditions are addressed holistically (e.g., whole-person care).
HIV Workforce Infrastructure (public and private)	Current challenges exist with the HIV workforce—both public and private. The Department’s Bureau of Communicable Diseases experienced a high degree of turnover in key leadership positions in 2022, beginning in spring and continuing into fall 2022. Key positions such as the Bureau Chief of Communicable Diseases, HIV/AIDS Section Administrator, Statewide HIV Planning/EHE Coordinator, HIV Patient Care unit manager, Communications unit manager, and Clinical Quality Management Liaison all became vacant during that time. Other positions that had

Summary	Description
	been vacant prior to 2022 are still in need of being filled and include the Performance and Quality unit manager and Statewide Minority AIDS Coordinator. High turnover and staff reaching retirement age have led to gaps in historical program knowledge and staff having to assume interim roles or double-up on responsibilities. Staffing shortages and recruiting challenges have also been reported from CBOs and private sector agencies (e.g., difficulties recruiting health care professionals).
Vulnerable Populations—Human Trafficking, Domestic/Intimate Partner Violence	According to the Florida Alliance to End Human Trafficking, Florida ranks third in the nation for the number of human trafficking cases reported and ranks second in the nation for the number of labor trafficking cases reported. The majority (71.4%) of cases are sex trafficking cases, followed by labor trafficking (14.3%), unspecified trafficking (9.0%), and sex/labor trafficking (5.1%). Persons experiencing exploitation are particularly vulnerable to exposure to HIV, STIs and viral hepatitis due, in part, to substance use, lack of access to health care, lack of autonomy, and exposure to violence.⁵⁷ In 2020, 106,515 crimes of domestic violence were reported to Florida law enforcement agencies and during FY 2020–21 and Florida’s certified domestic violence centers provided 412,360 nights of emergency shelter to 10,287 survivors of domestic violence and their children. Many more survivors of domestic violence are not reporting their abusers to the police or accessing services at domestic violence services due to reasons such as shame, fear, or being prevented from doing so by their abusers. For this reason, the number of cases is thought to be underreported. Women in violent relationships are at a four times greater risk for contracting STIs, including HIV, than women in non-violent relationships and women who experience intimate partner violence are more likely to report risk factors for HIV.⁵⁸

3.5 Needs Assessment

The information gained from the 2019 HIV Care Needs Survey represents a statewide comprehensive assessment of the needs of PWH in Florida. Survey questions were designed to better understand the current demographics of PWH in Florida and the HIV medical care, patient care services, jail and prison release services, and housing services that were needed and delivered during the 12 months prior to the time the survey was taken.

To ensure that services provided through the Patient Care Program are appropriate and contribute to improving health outcomes for PWH, the HIV/AIDS Section conducted the 2019 HIV Care Needs Survey throughout the state. The primary focus of the survey was to determine met and unmet service needs for PWH in Florida. Data collected from this survey are intended to help statewide and local planning stakeholders determine the best ways to distribute funds and resources. This survey was launched on

May 28, 2019, and continued to completion on September 6, 2019. The survey was delivered via Survey Gizmo and paper to Floridians living with HIV who sought HIV care services in each of the 14 program areas of the Ryan White Patient Care Program.

Limitations

Using the convenience sampling method to collect input for this type of assessment has its advantages, disadvantages, and limitations. Surveys collected using this method can yield rich qualitative data for review and planning in a comparatively cost-efficient manner. Data are available relatively quickly to match the pace of planning needs and are useful to signal changes or shifts in attitudes, behaviors, and outcomes. Among the disadvantages of collecting assessment data via convenience sampling are the potential for bias in data collection and sampling errors that could introduce inaccuracies. Surveying processes that use the convenience sampling method have limitations. Survey participants were self-selected.

3.5.1 Methodology

Survey questions were grouped into sections that included general demographics, HIV medical care, and patient care, jail and prison release, housing, and prevention services. Questions were related to the past 12 months of service. Distribution of the survey was facilitated by the 14 consortia lead agencies throughout Florida. A sample size for each county was calculated based on the number of PWH. Each county was provided the minimum number of surveys to be sent to reach 25% of total PWH at a 10% response rate. RWHAP Part B lead agencies, in collaboration with RWHAP Part A recipients, worked with local providers, community members, and other stakeholders to obtain the survey responses. The survey was made available in three languages: English, Haitian-Creole, and Spanish. Paper surveys were collected locally and mailed to the HIV/AIDS Section for data entry and analysis.

A total of 4,114 surveys were conducted by the end of the survey period: 3,758 in English, 334 in Spanish, and 22 in Haitian-Creole. Of these, 3,777 were complete, 147 were partial, and 190 were disqualified. Respondents were required to answer the demographic questions about age, gender, race, and county.

This document presents the key findings of the 2019 HIV Care Needs Assessment. Results from this survey will be used to help guide service implementation and resource allocation in Florida's HIV/AIDS Patient Care Program.

Survey respondents' counties of residence were reported for 66 of Florida's 67 counties. Union County was not surveyed because there are no reported PWH in that county. A total of 3,879 respondents answered the question about residence. Table 7 lists the number of respondents from each county.

TABLE 7: FLORIDA COUNTY OF RESIDENCE

PWH. Each county was provided the minimum number of surveys to be sent to reach 25% of total PWH at a 10% response rate. RWHAP Part B lead agencies, in collaboration with RWHAP Part A recipients, worked with local providers, community members, and other stakeholders to obtain the survey responses. The survey was made available in three languages: English, Haitian-Creole, and Spanish. Paper surveys were collected locally and mailed to the HIV/AIDS Section for data entry and analysis.

A total of 4,114 surveys were conducted by the end of the survey period: 3,758 in English, 334 in Spanish, and 22 in Haitian-Creole. Of these, 3,777 were complete, 147 were partial, and 190 were disqualified. Respondents were required to answer the demographic questions about age, gender, race, and county.

3.5.3 Priorities

The needs assessment process identified the following key priority areas: Demographics, HIV Medical Care, Patient Care Services, Jail and Prison Release Services, and Housing.

Demographics Summary

Appropriate sample sizes for each county were calculated based on the number of PWH. Each county was provided the minimum number of surveys to be sent to reach 25% of total PWH at a 10% response rate. The five counties with the most survey respondents were Miami-Dade, Hillsborough, Pinellas, Brevard, and Duval. Most counties met their quotas, but 13 did not. The three counties with highest unmet quotas were Broward, Palm Beach, and Orange.

Overall, most survey respondents fell into two age groups: 55 to 64 years old and 45 to 54 years old. Stratified by race/ethnicity (see Figure 15), this trend held true for those who identified as non-Hispanic White, non-Hispanic Black, and non-Hispanic multiracial/other. However, for those who identified as Hispanic White, Hispanic Black, and Hispanic multiracial/other, the trend showed that most fell into the 35 to 44 years old and 45 to 54 years old categories as seen in Figure 15.

FIGURE 15: HIV CARE NEEDS SURVEY RESPONDENTS (PWH) BY AGE AND RACE/ETHNICITY

Most survey respondents reported working a full-time job for the past 12 months. The second largest group reported not being able to work due to disability. Approximately half of respondents reported that their 2018 household gross income (before taxes) was less than \$15,000 and roughly one-third reported incomes that were between \$15,000 and \$30,000. Stratified by race/ethnicity, most of those categorized as earning less than \$15,000 and those earning between \$15,000 and \$30,000 were non-Hispanic Black. Most of those categorized as earning between \$30,000 and \$50,000, between \$50,000 and \$100,000, and more than \$100,000 were non-Hispanic White.

HIV Medical Care Summary

Most survey respondents reported that they had seen a doctor about their HIV during the past 12 months. When asked about the frequency of HIV-related care, most reported receiving care two or three times during the past 12 months. For respondents who reported that they had not received HIV-related care or had received care fewer than two times in the past year, the most common reasons overall were that they were not in care, were depressed, or missed their appointments, as shown in Figure 16. When stratified by race/ethnicity, the most common reason given by Hispanic White, non-Hispanic White, and non-Hispanic Black persons remained that they were not in care. The second and third most common reasons given by Hispanic White persons were not knowing where to go and missing their appointments, respectively. For non-Hispanic White persons, the second and third most common reasons were that they were depressed and that this was their provider's decision, respectively. For non-Hispanic Black persons, the second and third most common reasons were that they missed their appointments and were depressed, respectively. The total numbers of responses from those who identify as Hispanic Black, Hispanic multiracial/other, and non-Hispanic multiracial/other about reasons for not receiving care were very low (8, 31, and 8, respectively).

FIGURE 16: TOP 5 REASONS RESPONDENTS HAD NOT BEEN IN CARE BY RACE/ETHNICITY

*Hispanic Black, Hispanic Multiracial/Other, and Non-Hispanic Mutliracial/Other not shown due to low number of responses.

The overwhelming majority of survey respondents received HIV-related medical care in the county where they live. For the small number of respondents who received care in a different county from where they live, the most common reasons given were that doctors or services were not available in their county of residence, preference and better doctors in a different county, continuity of care with an established provider, convenience and closer to home, and confidentiality.

Most survey respondents reported that they always take their HIV medications just as their doctor prescribed them. For those who reported that they did not always take their medications as prescribed, the reasons given included that the medication made them feel bad or sick, they could not afford the cost, they were on a medication break as directed by their physician, they did not know where to get medication, and forgetting.

Patient Care Services Summary

Most survey respondents reported that they did get the patient care services they needed during the past 12 months. For those who did not get needed services, the five most common barriers listed were not knowing where to get services, being depressed, not having transportation, not being able to pay for services, and missing appointment(s). When stratified by race/ethnicity, the most common barrier listed for all race/ethnicity categories (except Hispanic Black persons) was not knowing where to get services. The top barrier to care for Hispanic Black persons was depression.

As shown in Figure 17, the top five patient care services deemed by respondents as most important for the state to provide for PWH were (in order of priority):

1. Medications
2. Case management
3. Dental and oral health
4. Health insurance
5. Outpatient medical care

FIGURE 17: TOP FIVE PATIENT CARE SERVICES MOST IMPORTANT TO SURVEY RESPONDENTS

When stratified by race/ethnicity, the top two services reported by respondents as most important remained medications and case management across all race/ethnicity categories, but the priorities for dental and oral health, health insurance, and outpatient medical care were ranked differently (though they remained in the top five).

Jail and Prison Release Services Summary

The overwhelming majority of survey respondents reported that they had not been in jail or prison during the past 12 months as shown in Figure 18. Of the 211 who reported having been incarcerated (5.9% of all respondents), 82.5% reported that the jail or prison staff knew of their HIV status and most (65.9%) reported that they did receive HIV-related medical care. Upon release from jail/prison, 40.3% of respondents reported that they did not receive any HIV-related information or assistance. Of those who did receive care and assistance, 29.4% received a supply of HIV medication to take with them, 24.2% received referral to medical care, 22.3% received referral to case management, and 10.9% received information about finding housing.

FIGURE 18: SURVEY RESPONDENTS IN JAIL AND PRISON DURING THE PAST 12 MONTHS AND WHETHER SERVICES WERE RECEIVED WHILE INCARCERATED

Of the 240 respondents who answered the question about barriers to getting needed HIV services after release from jail or prison, most (59.6%) indicated that this question did not apply to them because they did get needed services. For those who experienced barriers to care, the most frequent barriers reported were:

- No insurance or financial reasons.
- No transportation to services.
- Did not know where to go for services.
- Could not get away from drugs.
- Had trouble finding trustworthy friends.

- Did not want others to know of their HIV status

Housing Summary

Overall, survey responses indicated that most respondents did not experience barriers to HIV-related care due to their current housing situation as shown in Table 8. Of those who did experience housing-related barriers, the top three barriers were not having money to pay rent, being afraid of others knowing their HIV status, and not having enough food to eat. When stratified by race/ethnicity, barriers varied in rank, but the top three barriers from the overall responses consistently remained in the top three across race/ethnicity categories.

TABLE 8: HIV HOUSING SERVICES RESPONDENTS NEEDED OR RECEIVED IN THE PAST 6 MONTHS

	Received Needed Services		Needed Service, But Could Not Get Service		Needed Service, But Did Not Know About Service		Did Not Need Service		Total Responses
	Count	Row %	Count	Row %	Count	Row %	Count	Row %	Count
Help finding an affordable place to live	357	11.26%	345	10.88%	303	9.56%	2,165	68.30%	3,170
Permanent, independent housing	258	8.62%	312	10.42%	266	8.88%	2,158	72.08%	2,994
Temporary short-term housing	141	4.91%	181	6.30%	152	5.29%	2,397	83.49%	2,871
Housing where my child(ren) can live with me	108	3.80%	69	2.43%	98	3.45%	2,567	90.32%	2,842
Nursing home	81	2.88%	48	1.71%	53	1.88%	2,633	93.53%	2,815
Money to pay utilities	281	9.49%	289	9.76%	319	10.78%	2,071	69.97%	2,960
Money to pay rent/mortgage	304	10.20%	319	10.70%	343	11.51%	2,015	67.59%	2,981
Housing for persons living with HIV	174	5.91%	249	8.46%	237	8.05%	2,285	77.59%	2,945
Assisted living facility	99	3.49%	82	2.89%	91	3.20%	2,568	90.42%	2,840
Column Totals	1,803		1,894		1,862		20,859		26,418

	Received Needed Services	Needed Service, But Could Not Get Service	Needed Service, But Did Not Know About Service	Did Not Need Service	Total Responses
% of Overall Total	6.82%	7.17%	7.05%	78.96%	100.00%

Overall, most survey responses indicated that respondents did not need any of the available housing services offered through Florida's HIV/AIDS Patient Care Program. For those who were in need, the services most frequently reported as being received, needed but unable to get, or needed but unaware of where to get (approximately 30% of all the survey responses given for each of the following services) were:

- Help finding an affordable place to live.
- Money to pay rent or mortgage.
- Money to pay utilities.
- Permanent, independent housing.

Between 65% and 70% of respondents in need of these services either could not get them or did not know about them. When stratified by race/ethnicity, non-Hispanic Black persons represented the largest number of responses across the board for all services respondents needed but could not get. This same trend held true for all services respondents needed but did not know about.

Overall, for those who needed services, most survey responses (approximately 60%) indicated that respondents did not experience barriers to getting needed housing services and were able to get them. But a sizeable proportion of responses (nearly 40%) indicated barriers to getting needed housing services. The top three barriers reported were that the respondent:

1. Did not know where to get services.
2. Did not qualify for services.
3. Was put on a waiting list.

Actions Taken

The following recommendations were developed to identify key activities to address needs and barriers of the key priority areas:

Demographics Recommendations

It is of concern that the three counties with the largest unmet survey quotas are also three of the counties that have high prevalence of PWH. Collectively, those counties were 603 surveys below quota. Given that this represents 20.6% of the total number of surveys needed to meet quota, it may present a significant deficit of information that is important to consider regarding allocation of resources for HIV

care and services. Going forward, planning for increased staffing and concentrated efforts ahead of survey implementation may help mitigate unmet quotas in counties with high prevalence of PWH.

If survey results are representative of PWH in Florida, they indicate that most are non-Hispanic Black males between the ages of 45 and 64 who have fulltime employment but are living below the poverty level. This highlights the continued disparities minorities face and the economic disadvantage of populations most affected by HIV. Giving priority to this priority population for outreach, staffing, and resources may be warranted to promote diverse community wellness.

With the development and release of the 2022 HIV Care Needs Survey and Needs Assessment Toolkit in October, Florida hopes to increase the number of surveys completed by PWH.

HIV Prevention

One of the priorities for the Department's HIV/AIDS Section is the development of a comprehensive HIV prevention needs assessment through surveys administered to and through HIP providers to address services provision (PrEP, HIV testing, Test & Treat, harm-reduction needs) for persons at risk for HIV. Other entities to be included in the needs assessment include CHDs and operational syringe services programs (SSPs). The Department hopes to accomplish this in 2023.

Policy Barriers

Currently, Florida laws do not present barriers to HIV prevention or patient care services. Minor limitations exist in state laws allowing for syringe exchange programs and include prohibitions on using state, county, or municipal funds to support the operation of the program and permitting a one-to-one exchange of syringes. Florida is also a Medicaid non-expansion state and this may have implications for HIV-related service coverage levels for persons who are eligible for Medicaid.

HIV Medical Care Recommendations

The top reasons given for not receiving care or receiving less frequent care were missed appointments and not in care. To ensure that all PWH in Florida receive the appropriate frequency of HIV-related care, it may be necessary to determine why they were not in care and why they missed appointments. Depression was another top reason given for not receiving care. This points to the importance of educating care providers to be aware of potential mental health and HIV comorbidities and the possible need to implement a protocol for mental health screening along with HIV care visits. To best address these needs and allocate resources appropriately, detailed attention to the top reasons for not receiving care in race/ethnicity categories may be helpful.

In counties where providers and services for HIV-related care are not available, the magnitude of those affected should be investigated and solutions to this problem should be explored. The desire for confidentiality was reported as a reason for seeking HIV-related care in a county other than the

respondent's county of residence. More efforts are needed to address HIV stigma and normalize HIV prevention and care seeking behaviors.

Because HIV medications, when taken as prescribed, are highly effective in attaining VLs that are undetectable and therefore not transmittable, it is imperative that all PWH receive appropriate medication and take it as directed by their physician. It is encouraging that most survey respondents reported that they always take their medications just as prescribed. However, even though the number of those who reported noncompliance with taking their medications is low (12.9%), other personal or biological issues may hinder persons from achieving sustained viral suppression. Reasons given by respondents for not taking medications as prescribed should be investigated further, and solutions or services should be found to overcome these barriers.

Patient Care Services Recommendations

Although most respondents received patient care services they needed, a large proportion (43.4%) did not. Barriers to care centered mostly around logistics, depression, and personal finances. To address logistics and personal finance barriers, allocating more resources for outreach and public information campaigns providing awareness of available HIV/AIDS services for those with low or no income may be helpful. Regarding depression, again we stress the importance of educating care providers to be aware of potential mental health and HIV comorbidities and the possible need to implement a protocol for mental health screening along with HIV care visits. Stigma may prevent persons with HIV from seeking mental health services. Additionally, partnering and finding more accessible mental health service providers is key.

As seen in Figure 19, of the four patient care services reported as most important to respondents, (1) dental and oral health, (2) medication, (3) case management, and (4) health insurance was also high on the list of needed services that respondents reported they could not get or did not know about. This is an area of concern; further investigation into this issue is warranted.

FIGURE 19: PATIENT CARE SERVICES

Jail and Prison Release Services Recommendations

Based on survey responses, the HIV status of 17.5% of those respondents who were incarcerated was not known to jail or prison staff. In addition, 34.1% of those incarcerated did not receive HIV-related medical care while in jail or prison, and 40.3% did not receive HIV-related information or assistance upon release. These numbers represent care intervention opportunities lost. Improvement for collaboration with jail and prison systems to improve continuity of HIV care and post-release accessibility is needed.

Housing Recommendations

Overall, survey results show that most respondents did not need housing services. This is likely a limitation of the persons who responded to the needs assessment. An opportunity could be to ensure that there is a separate avenue with HOPWA to address this in the future. Most who did need services did not experience barriers to getting these services, nor did they experience barriers to taking care of their HIV that were related to their current housing situation. But for those who needed housing services, most centered around needing help to find housing and help to pay for housing and utilities. Because needed housing services for a sizeable proportion of survey respondents were unmet, with the race/ethnicity category most represented in this proportion being non-Hispanic Black, further investigation focusing on this disparity is warranted.

Lastly, the most frequently reported barriers to getting needed housing services reveal distinctly different issues. The most common barrier was not knowing where to get services, which may indicate that public awareness campaigns for this may be needed. Florida does have a HOPWA campaign (Housing for Better Health-Assistance for Persons with HIV/AIDS in Florida); however, its effectiveness and reach may need to be evaluated. The second most common barrier was that respondents did not qualify for services. This may indicate a disconnect between actual need and the program criteria currently in place to determine need. The third most common barrier to getting housing services was that the respondent was put on the waiting list. Causes for this may include limited housing availability and resources and a need for more staffing to process housing services.

4 Situational Analysis

Florida is one of the most culturally diverse states in the nation with a vast array of residents from a wide variety of ethnic, racial, national, and religious backgrounds. The state has long attracted immigrants, particularly from Cuba, Haiti, Colombia, Venezuela, and Mexico. In fact, almost 21% of Florida's population are foreign-born persons (US Census Data - Quick Facts - Florida, 2021). With this diversity comes a higher incidence of disease burden from those in the emerging racial/ethnic minority populations from rural, socio-economically disadvantaged, and medically underserved backgrounds.

Florida continues to implement the best strategies to build a path to improve HIV prevention and care access, specifically among racial/ethnic minorities and other underserved groups. Specific demographics of racial and ethnic minorities and communities experience more barriers to accessing prevention and care services. For persons who are already diagnosed and living with HIV in Florida, activities centering around access to HIV care, including ART, retention in HIV care, and viral suppression, should be focused on such priority populations, including: Black heterosexual individuals (with added focus on Black WCBA), gay and bisexual males of all races/ethnicities, and transgender individuals of all races/ethnicities.

To further move the needle in reducing new HIV diagnoses in Florida, the Department's HIV/AIDS Section is proposing several high-impact initiatives based on the status-neutral approach to HIV prevention and care. The HIV status-neutral approach to reducing new HIV diagnoses involves initial HIV testing services as the entry point to HIV prevention and care services irrespective of a positive or negative test result. See Figure 20.

FIGURE 20: STATUS-NEUTRAL APPROACH TO HIV PREVENTION AND CARE

Source: <https://hivgov-prod-v3.s3.amazonaws.com/s3fs-public/NHAS-2022-2025.pdf>

The strategies proposed include:

1. Statewide expansion of routine HIV, HCV and syphilis screening in hospitals, emergency departments and other health care settings.
2. Increasing PrEP and PEP awareness and uptake.
3. Expansion and awareness of rapid antiretroviral therapy (ART) starts, i.e., Test and Treat.
4. Improving stigma, social determinants of health through awareness and education.
5. Improving health outcomes in aging populations with HIV.

To implement HIV prevention and care services based on the status-neutral approach, Florida will employ the initiatives and strategies which align with the EHE pillars below. The information below also highlights the strengths, challenges, and identified needs related to HIV prevention and care in Florida, the subsequent sections describe each of the following areas:

- DIAGNOSE all people with HIV as Early as Possible (Section 4.1)
- TREAT people with HIV rapidly and effectively to reach sustained viral suppression (Section 4.2)
- PREVENT new HIV transmissions by using proven interventions, including PrEP, and SSP (Section 4.3)
- RESPOND quickly to potential HIV outbreaks to get prevention and treatment services to people who need them (Section 4.4)
- Priority populations (Section 4.5)

4.1 DIAGNOSE People with HIV as Early as Possible

Routine HIV, STI, and HCV Testing in Health Care Settings

In July 2015, the Florida Legislature amended Florida’s HIV testing law to remove the need for separate informed consent prior to HIV testing in health care settings. In September 2016, Rule 64D-2.004, Florida Administrative Code (FAC), was adopted to implement the amended HIV testing law. The intent of this amendment was to simplify routine HIV testing in health care settings, improve the identification of new or existing HIV infections, and help to normalize HIV testing as a routine component of primary health care. There was no change in the law regarding non-health care settings. These changes align Florida more closely with the CDC’s HIV Screening Recommendations.⁴⁴

Since 2015, the Department, including CHDs, has developed a collaborative model for routine communicable disease screening with the Gilead Sciences’ Frontlines of Communities in The United States (FOCUS) initiative. The FOCUS program is a public health initiative that enables partners to develop and share best practices in routine blood-borne virus (HIV, HCV, HBV) screening, diagnosis, and linkage to care in accordance with screening guidelines promulgated by CDC, the U.S. Preventive Services Task Force (USPSTF), and state and local public health departments. FOCUS funding supports HIV, HCV, and HBV screening and linkage to the first appointment after diagnosis. FOCUS partners do not use FOCUS awards for activities beyond linkage to the first appointment.

Florida FOCUS partners include FQHCs and large hospital systems. The Department's public-private partnership with Gilead's FOCUS initiative began in 2016 with the establishment of the very first site—Homestead Hospital in Miami-Dade County. A Department DIS or Linkage to Care Coordinator works with each FOCUS emergency department partnership to assist with linkage to care and other services. The partnership with Homestead was expanded to include syphilis screening and the Department supports the cost of these screenings.

Currently, the Florida FOCUS program has 22 partners across the state (see map in Figure 21) and in 2021, institutions that have implemented the FOCUS program conducted 156,288 HIV tests (1.2% positivity), with 86% linked to care. Additionally, 74,910 HCV tests (4.6% HCV Ab positivity) were conducted and 75% linked to care. In 2022, Florida FOCUS projects plan to complete 187,000 HIV tests and 104,500 HCV tests and commits to onboard facilities to also conduct syphilis testing.

There is no monetary relationship between the Department and Gilead Sciences and as the partners age out of their relationship with Gilead, the Department has developed a cost-sharing model to continue to support testing and linkage to care at these sites by assisting with the costs of testing and reagents.

Current efforts to support expansion include the inclusion of this initiative as an objective in the State Health Improvement Plan where, by December 31, 2026, the Department and external partners aim to increase the number of emergency room or acute care hospitals that are conducting opt-out HIV screening, routine HCV screening, and syphilis testing with a smart screen algorithm from 1 (2021) to 15. Figure 21 visualizes 2022 partner reach for the state of Florida.

FIGURE 21: FLORIDA PARTNER REACH IN 2022

Gaps still exist in the implementation of routine HIV, STI, and HCV testing in hospital emergency departments (EDs) and primary health care settings. Accounts of individuals seeking medical care in hospital EDs for symptoms akin to acute HIV infection are frequent, and, oftentimes, persons visit the ED several times before being tested for HIV, diagnosed, and linked to care. Approximately 7 in 10 PWH saw

a health care provider in the 12 months prior to diagnosis and failed to be diagnosed.⁵⁹ Additionally, reimbursement by Medicaid for HIV testing in hospital EDs is a challenge as we move forward with routinizing testing in EDs; in some cases, testing may not be covered unless deemed medically necessary or clinicians may be less likely to bill when they frequently receive rejections.

From June 2019 to April 2020, the University of Miami AIDS Education and Training Center (UM-AETC) performed outreach to health care facilities in the highest HIV incidence areas throughout Miami-Dade and Broward counties to conduct assessments and academic detailing. Facilities included community health centers and primary care and internal medicine clinics. Assessments examined the status of health care facilities in implementing routine HIV testing and PrEP provision in accordance with CDC guidelines and in implementing or extending third-party billing for routine HIV screening. Less than a quarter (20%) of the health care provider practices reported offering routine HIV screening services to all patients ages 13 to 64, regardless of symptoms or demographics. Of the remaining clinics, 28.6% reported that they test patients based on symptoms and demographics and 30% reported testing only those who requested an HIV test. Among barriers to rapid HIV testing, most practices indicated that they never considered rapid HIV testing as a service (30%). Other barriers to providing rapid HIV testing were the perceived need to obtain consent, staff lacking training for administering and billing, the concern that testing would not be reimbursed by payors, and uncertainty about the implementation of in-office rapid testing.

To eliminate these barriers, the Department has done or will do the following:

- Conducted a Routine Screening Expansion Roundtable, which took place May 26, 2022. The purpose of this meeting, hosted by the Lieutenant Governor, was to bring together a wide variety of external stakeholders to discuss how to expand routine opt-out HIV, syphilis, and HCV screenings in EDs and acute care settings and move toward ending these syndemics in Florida.
- Update Chapter 64D-3, FAC, to include the mandatory reporting of all HIV test results. 64D-3 is titled “Control of Communicable Diseases and Conditions which may Significantly Affect Public Health”. Currently, providers and laboratories are required to report only positive HIV test results to the Department.
 1. Improve the reporting and surveillance of stage zero or acute diagnoses to understand the burden of recent transmission for intervention and prevention.
 2. Understand the scope and total HIV testing being conducted in Florida and calculate a state positivity rate that can be used to drive future interventions and prevention efforts.
- Conduct an assessment on current Florida FOCUS partners to understand who is aging out of the program, and when, and use current funding to support testing and linkage to care efforts.
- Work with directly funded RWHAP Part A programs in the six metropolitan areas of the state to collaborate on supporting routine screening efforts in those areas.
- Collaborate with AHCA to develop a Dear Colleague letter from Medicaid to clarify reimbursement support for routine HIV and HCV screening in hospital EDs.

- Explore leveraging Opioid Settlement Funds to help support the expansion of medication-assisted treatment pathways in hospitals.

In addition to the FOCUS program, the HIV/AIDS Section also has a contract funded through federal grants with the University of Central Florida HealthARCH program that aims to assess the readiness of health systems in the seven metropolitan counties of high-HIV burden and onboard them to modify their electronic health records and offer routines screening for HIV.

Rapid HIV Testing through Non-Traditional Settings and Modalities

Considering Florida's percentage of PWH unaware of their status (14%), increased access to rapid HIV testing is required. Feedback received through community engagement indicated a need for expanded use of mobile testing units, HIV self-test kits, social and sexual network screening, and testing at non-traditional settings and hours. The Department currently supports more than 1,600 registered HIV testing sites around the state that conduct targeted HIV testing in non-health care settings in areas and communities with high HIV incidence. The Department supports these sites with rapid HIV test kits at no cost to the site. Sites must register with the Department and submit HIV testing data as criteria to receive rapid HIV test kits. In 2021, the Department conducted 73 rapid test trainings and certified 1,032 individuals to perform rapid HIV testing. The Department will continue to conduct rapid HIV testing trainings to certify individuals to perform rapid HIV testing in non-health care settings.

In June 2019, the Department began an HIV self-test kit distribution program to provide rapid HIV self-test kits to individuals, at no cost, and through an online request form (available at [KnowYourHIVStatus.com](https://www.knowyourhivstatus.com)). This program was particularly important as COVID-19 closures and restrictions fueled increases in the demand for alternative options for HIV testing. As shown in Figure 22, monthly requests for HIV self-test kits rose sharply beginning in April 2020 and continued through July 2020. Monthly requests tapered slightly from September through December 2020. In 2021, monthly requests for HIV self-test kits decreased but are still higher than pre-COVID levels. Since the program's inception, more than 4,600 rapid HIV self-test kits have been distributed. The HIV/AIDS Section continues to look for opportunities to collaborate, especially with internal Department partners such as the Bureau of Tobacco Free Florida to advertise the availability of free, in-home testing kits.

FIGURE 22: HIV SELF-TEST KITS DISTRIBUTED THROUGH KNOWYOURHIVSTATUS.COM, FLORIDA, 2020 vs. 2021

Additional funds will be needed to support and sustain the expansion of the in-home and point-of-care HIV testing program. Concerns around linkage to care for persons using HIV self-test kits exist and mechanisms will need to be developed to ensure appropriate follow up and timely linkage to care.

Partner Notification Services

Per section 384.26, F.S., the Department is the only entity authorized to perform HIV and STI partner services and notification, and these activities are carried out by trained DIS. While Florida maintains a mature and robust HIV/STI partner services program, opportunities to strengthen the DIS workforce and update partner notification mechanisms exist. Extensive training needs, high caseloads, and low staff retention not only contribute to high DIS turnover rates, averaging 40% annually over the past five years, but also impact the effectiveness of partner elicitation. Numbers of claimed partners have decreased as numbers of anonymous partners reported through mobile dating applications has increased, creating challenges for intervention. In 2017, the Department piloted the use of mobile dating applications as an added partner notification tool for persons exposed to HIV/STIs, with marginal success. Additional strategies are being explored to allow for HIV partner notification via text messaging or phone calls. Since summer 2022, the Bureau of Communicable Diseases has been working to secure approval to allow for text messaging by the DIS workforce as a tool to initiate confidential first contact with clients and enable DIS to conduct partner services for STI/HIV partner notification.

Florida is unique in that there are now four qualified staff to teach the week-long Passport to Partner Services training. In 2022, the STD Section will enter a contract with the University of South Florida to establish a learning academy and completely revamp the existing core training curriculum for DIS and STD program supervisors.

Billing and Reimbursement

In April 2013, the USPSTF gave routine HIV screening of all adolescents and adults, ages 15 to 65, an “A” rating, aligning the rating with the CDC’s HIV screening guidelines. The “A” rating has further implications given the ACA, which requires or incentivizes new private health plans, Medicare, and Medicaid to provide preventive services rated “A” or “B” at no cost to patients. Challenges exist with reimbursement by Medicaid for routine HIV screening in hospital EDs and some facilities report only being able to reimburse for those tests deemed medically necessary. As the state moves forward with expanding routine HIV screening in hospital EDs, more work is needed to ensure these facilities have the ability to bill and receive reimbursements from Medicaid for these screenings.

Billing third-party insurance was reported as a barrier to billing and reimbursement by almost one-third of providers assessed by UM-AETC and was the most prominent barrier encountered. Most clinics reported staff lack of knowledge regarding billing and coding and corporate decisions to be the greatest barriers to implementing routine HIV screening. Other notable barriers were lack of time and staffing capacity to perform billing, challenges in contracting with third-party payors, and difficulty managing multiple contracts with third-party payors.

Stigma

Stigma around HIV affects health care-seeking behavior. Stigma related to HIV/STI screening can occasionally lead individuals to state they do not possess insurance coverage for the service. Similar confidentiality concerns exist for young people who receive health insurance coverage through their parent or guardian (i.e., explanation of benefits). Fear of disclosure of confidential health information can deter youths and adults from seeking out HIV/STI screening and PrEP services. HIV testing locations that are associated with HIV/AIDS service organizations are also perceived as more stigmatizing, with clients citing additional disclosure concerns. There is a need for integration of HIV testing locations with other health care services and screenings to minimize stigma.

The MMP surveillance system also conducts a self-reported survey to understand the various types of stigmas PWH have experienced, including anticipated, enacted, and internalized HIV-related stigma using a 10-item scale ranging from 0 (no stigma) to 100 (high stigma) that measures four dimensions of HIV stigma: personalized stigma since HIV diagnosis, current disclosure concerns, current negative self-image, and current perceived public attitudes about people living with HIV. Analysis of the 2015–2020 Florida MMP data found that females (n=44) reported experiencing a higher level of stigma compared to males (n=32). Additionally, thirty-nine (n=39) transgender individuals reported experiencing stigma.

Thirty-seven (n=37) Black persons reported experiencing HIV-related stigma, compared to White (n=32) and/or Latino (n=32) survey respondents.

Thirty-eight (n=38) heterosexual people reported experiencing HIV-related stigma, compared to bisexual survey respondents (n=36).

Lastly, it was found that those ages 18–29 experienced a higher level of stigma (n=43) than ages 40–49 (n=36), and ages 30–39 (n=35). It was also found that ages 50 and higher experienced the lowest level of stigma (n=32).

Findings from a Department project with the University of Florida ⁴³ (a Bayesian spatial-temporal analysis of racial disparities in HIV clinical outcomes and a pilot stigma intervention protocol for people living with HIV in Florida) indicate that disparities in immune restoration and viral suppression vary by county. Identification of counties where these disparities are most severe provides useful information for the Department and other decision makers to reduce racial disparities in HIV clinical outcomes by implementing targeted interventions, with the ultimate objective of achieving HIV elimination goals in Florida. Stigma remains a key barrier to care engagement and ultimately achieving viral suppression and immune restoration. The preliminary work in this project outlines the development and validation of an updated measure of stigma, which could be implemented to better monitor stigma and its impacts, and an intervention to improve patient-provider communication about HIV-related stigma. The intervention was generally well received by participants and several potential routes of dissemination were identified.

4.2 TREAT People with HIV Rapidly and Effectively to Reach Sustained Viral Suppression

Access and adherence to HIV treatment is important to promote optimal health outcomes for PWH and harnessing the benefits of “treatment as prevention”—when someone takes their HIV medications as prescribed and the amount of HIV in the body is kept at such a low level, they reach viral suppression. Those virally suppressed essentially have no risk of sexually transmitting HIV to others. Treating PWH rapidly after diagnosis will help PWH to achieve and maintain viral suppression, which is part of the current HIV treatment guidelines and is a major pillar in EHE. According to the CDC, approximately 80% of new HIV transmissions occurring annually are from persons who are not receiving HIV-related care and medications. One issue is that the availability of treatments is not evenly accessible or distributed, compounding health disparities and the social determinants of health that fuel further transmission of HIV in the community. This represents a need for expanded access points, hours of operation (to include non-traditional hours and locations) and telehealth capabilities to reach persons with transport or other access issues. Other challenges exist around identifying and re-engaging PWH who are not in care to ensure medical adherence and viral suppression. All areas of the state have dedicated the Department’s linkage staff to not only link persons newly diagnosed with HIV but also identify PWH currently not in care and reengage them into HIV care and treatment.

Test and Treat Program and Rapid Access to ART

Since 2016, Florida has had a robust rapid access to ART program called Test and Treat (T&T). This program offers patients newly diagnosed with HIV, as well as those who have been lost to care and are returning to care, an opportunity to obtain expedited practitioner office visits, labs, and ART, combined with a support system of retention-in-care specialists, to reduce barriers to care engagement. In this

expedited “red-carpet” scenario, PWH have immediate access to a medical provider who can start them on ARV (antiretroviral) medications immediately. T&T has assisted in engaging individuals in care at a much faster rate than those not diagnosed through the program. Since the program’s inception, Florida’s T&T program has enrolled more than 7,374 clients statewide (comprising of 3,342 newly diagnosed individuals and 4,032 previously diagnosed individuals returning to care). Compared to persons diagnosed in Florida who are not enrolled in T&T (see Figure 23), it takes on average 38.3 days to initiate treatment compared to 5.6 days for those newly diagnosed through T&T. Furthermore, the average time to achieve viral suppression is much lower for those who initiate treatment rapidly through T&T—92.2 days compared to 146.4 days for those not engaged in T&T. Wider expansion and adoption of this strategy is needed to impact linkage, retention, and VL suppression rates. Almost all of Florida’s 67 counties have a HRSA-designated Health Professional Shortage Area (areas categorized as rural, partially rural, or non-rural), which represents a need to recruit and train more primary health care and dental service providers. Additionally, needs exist for expanded access points, hours of operation (to include non-traditional hours and locations), and expanded telehealth capabilities to reach persons in rural areas. There is also a need for increased access to treatment for persons diagnosed and living with co-occurring HCV/HIV.

FIGURE 23: TIME FROM T&T ENROLLMENT TO CARE INITIATION AND VL SUPPRESSION, MARCH 2016–DECEMBER 2020, FLORIDA

Below are activities that can help overcome the challenges related to T&T:

- Address gaps in the level of knowledge about the RWHAP system of care among non-RWHAP network health care providers. More education and training are needed for providers on the services available to clients (including ADAP), eligibility requirements, and access points in their service regions.

- Address the need for more training and resources for health care providers related to trauma-informed care (TIC) and intersectionality. Past and current traumatic experiences have an impact on whether a person acquires HIV, is diagnosed, is linked to care, is retained, and maintains viral suppression. Because HIV disproportionately impacts marginalized communities, it is important to consider intersectionality in concert with TIC.
- Intersectionality is a framework for conceptualizing a person, group of people, or social issue as affected by several discriminations and disadvantages; it considers people’s overlapping identities and experiences to better understand the complex prejudices they may face. Examples of social categorizations that inform identity include race/ethnicity, class, gender, sexual orientation, poverty and homelessness, and substance use.

Housing

Many Floridians experience homelessness or unstable housing, which presents a barrier to wellness for PWH as well as those at increased risk for HIV acquisition. Stable housing is closely linked with and is often one of the main determinants affecting HIV health outcomes. Florida’s Council on Homelessness annual report showed that prior to the emergence of the COVID-19 pandemic, homelessness in Florida has declined steadily from 57,551 identified as homeless in January 2010 to 28,328 in January 2020—a 50.8% reduction in homelessness over the last 10 years. In 2021, the Florida Housing Coalition reported Florida having the third-highest homeless population of any state in the nation, with 27,640 people living in homeless shelters and on the streets. It is important to consider the spectrum of housing instability for PWH—traditional definitions of homelessness or unstable housing—but also takes into account situations where individuals and families are residing in temporary residences (e.g., motels), staying with friends or family, or “couch-surfing.” While the federal Fair Housing Act makes it illegal to discriminate against PWH in the provision of housing, consumers frequently cite discrimination, fear of disclosure, and stigma as barriers to safe and affordable housing.³⁵

To meet the housing needs of low-income PWH and their families, the Department administers the HOPWA program. The HOPWA program is a federally-funded initiative through HUD that helps people with HIV/AIDS maintain stable housing and have access to treatment and support services—which can all lead to better health. In Florida, through the State HOPWA Program, 11 regional agencies and 6 cities deliver HOPWA-funded housing services. In addition to the state HOPWA Program, there are 6 non-state funded city HOPWA programs administered locally.

The Department oversees the state HOPWA program and contracts with local community organizations and CHDs as project sponsors to provide HOPWA services in 11 Ryan White Part B consortium geographical areas and six cities throughout the state. Six non-state funded cities redesignate their funds to the state for distribution and fund management by the state HOPWA program. However, the re-designated funds are to be spent in the Eligible Metropolitan Statistical Areas (EMSAs) on housing services in those areas, not the state at large. These cities (counties) include City of Palm Bay (Brevard), City of Cape Coral (Lee), City of Lakeland (Polk), City of Sarasota (Sarasota), City of Port Saint Lucie, (Saint Lucie), and City of Deltona (Volusia).

Additionally, six cities or EMSAs receive and retain management of HOPWA funds they receive directly from HUD; the Department does not manage the HOPWA programs for Jacksonville, Tampa, Orlando, West Palm Beach, Fort Lauderdale, and Miami-Dade. The Florida State HOPWA Program serves those areas of the state that do not directly qualify for HOPWA funding. Between 2020 and 2021, over 2,034 individuals received HOPWA services to ensure they could access and maintain a stable living environment for themselves and their immediate families. An assessment of the state's HOPWA program is needed to identify gaps and barriers in order to make changes to the program in 2023.

With EHE funding received directly through HRSA, RWHAP Part A programs are also exploring ways to leverage funds to assist with paying for housing and rental assistance for persons with HIV.

Patient and Peer Navigation

HIV health navigators (both patient and peers) have a positive impact on the health and well-being of people living with HIV. Patient navigation programs for persons newly diagnosed with HIV or those previously diagnosed and returning to care have consistently proven to be efficacious in ensuring individuals get linked to and are retained in treatment. The lived experiences of peers, “near-peers,” and community health workers are drivers for meeting the diverse needs of newly diagnosed individuals who may be overwhelmed by the thought of entering a health care system as complex as the HIV system of care. In addition, peer navigators act as a support line for persons newly entering or re-entering the care system, providing non-judgmental guidance. There is also a need for expanded patient or peer navigation among persons diagnosed with HCV. Expanded patient navigation is also needed for HIV-negative partners of PWH seeking services. Florida plans to establish and disseminate a statewide peer certification training program.

People with Co-Occurring HIV and Hepatitis C

The current opioid and crystal methamphetamine epidemics are fueling the number of co-infections. It is estimated that 60 to 90% of people who contracted HIV from intravenous drug use also have HCV.³⁶ People living with HCV often have difficulty accessing HCV treatment and related health care. In recent years, there have been improved HCV treatments that can cure HCV in as little as 8 to 12 weeks. ADAP clients living with HCV have access to assistance with HCV treatments. The ADAP formulary was updated in 2017 to include HCV treatments without the need for prior authorizations. Between 2020 and 2021, the ADAP assisted over 650 ADAP clients with access to HCV treatment supported by ADAP. There are opportunities for more uninsured HCV patients to be treated at some free clinics, FQHCs, private clinics, and a limited number of CHDs, but many patients are unaware of where to go when they are first diagnosed.

Expanded Pharmacy Benefits Manager (PBM) for Uninsured or Underinsured ADAP Clients

Clients enrolled in ADAP realize important health benefits. ADAP provides access to U.S. Food and Drug Administration (FDA)-approved medications to low-income individuals with HIV who have limited or no coverage from private insurance, Medicaid, Medicare, or the federally facilitated Marketplace®. About

53% of ADAP clients are uninsured or under-insured and receive medication assistance through the ADAP direct-dispense program. These clients receive assistance with approved ADAP formulary medications directly from the program's contracted pharmacy network. The remaining 47% of ADAP clients obtain access to ADAP formulary medications through supported health insurance plans. These clients are enrolled in the ADAP insurance program and receive assistance with insurance premiums as well as prescription co-pays and deductibles associated with ADAP formulary medications. The ADAP aims to achieve at least 95% of clients who achieve viral suppression regardless of their insurance status. For those in the ADAP insurance program, approximately 97% achieved viral suppression in 2021; however, for those enrolled in the ADAP direct-dispense program, there is a clear disparity with only 89% achieving viral suppression in 2021.

In October 2022, ADAP implemented a PBM network of pharmacies to its uninsured direct-dispense client population. With this initiative, ADAP will increase equity among insured and uninsured clients by providing expanded access to medications through a network of independent pharmacies and commercial chains. The PBM will provide the network of 340B pharmacies and manage the claims using a replenishment model in which direct-dispense clients can access ADAP medications statewide with the main goal of increasing access points and convenience for ADAP clients in Florida. The PBM pharmacy network will ensure access to ADAP formulary medications for enrolled clients served in the direct-dispense in 24 hours. ADAP eligibility files are shared with the contracted PBM entity multiple times throughout the day to ensure newly enrolled clients can access ADAP services during the same day they enroll in the program. The PBM entity will assist clients with their prescriptions by reviewing use data, addressing medication adherence issues, and collaborating with prescribers to resolve incorrect regimens and drug interactions. The PBM entity will also develop and provide training to case managers and health care providers, develop educational materials for providers and clients, and maintain a program information website for providers and clients.

Case Management

Case management plays a critical role in the care coordination of PWH as it assists patients in accessing services, identifying needs, and addressing gaps in services. Case managers also perform important functions such as ensuring rapid access to ART; providing medication samples, where appropriate and feasible; and determining eligibility and enrollment into services. Case manager caseloads are high and continue to increase, impacting the ability to effectively manage complex issues, such as providing medication adherence counseling, helping navigate the health care system, and staying informed and educating PWH on available health care coverage plans. There is a need for additional resources and training to support the case management workforce.

Injectable ART

In May 2021, Florida's ADAP added Cabenuva, the first long-acting injectable antiretroviral to the formulary. Uninsured and insured clients are able to access the medication with coordination between their practitioner's office and a specialty pharmacy. The program provided a series of technical

assistance presentations to providers, staff, and case managers to increase awareness and provide best practices for client adherence. Over 500 ADAP clients have accessed Cabenuva since its addition to the formulary in 2021.

Minority AIDS Initiative (MAI)

As shown in Figure 5 (Section 3.1), Florida continues to experience disparities in HIV diagnoses among adults, despite an annual decrease in the HIV diagnosis rate among Black persons in the past five years. MAI seeks to address the gaps in medical care capacity and increase the accessibility and availability of HIV medical care and related HIV services in minority communities through outreach and education. MAI funds are received from HRSA and are designed to improve linkage and reengagement to comprehensive care and ADAP for low-income racial and ethnic minorities who are living with HIV/AIDS. The Department receives the MAI funding allocation through the state's RWHAP Part B grant and these funds support six community-based providers in Florida counties with the highest HIV incidence. In FY 2021, Florida's funded MAI providers enrolled 1,033 clients, of which 64% were Black and 32% were Hispanic/Latino, a 28% increase from the previous fiscal year which saw 806 clients enrolled, of which 62% were Black and 31% were Hispanic/Latino. Many participants are individuals who had a previous HIV diagnosis but have fallen out of care and have not received care for more than six months. The Department's HIV/AIDS Section will continue to look for ways to strengthen the network of MAI providers with the development and release of the next funding solicitation.

Correctional Settings Initiatives

The Department continues to support treatment and prevention services for incarcerated individuals living with HIV. Persons with HIV in prisons and jails are disproportionately represented compared to the general population. The Department addresses this through the following corrections initiatives: the Pre-Release Planning Program (PRPP), the Peer Education Program (Peer-Ed), and Jail Linkage Programs (JLP). The Department maintains two interagency agreements with the Florida Department of Corrections (FDC) to provide PRPP and Peer-Ed.

JLP is concentrated in the higher populated metropolitan areas in Florida. Fourteen CHDs work to provide services to at-risk inmates and PWH inside the county jails. JLP functions include HIV testing and education in the facility, linkage to care following release from jail, linkage to support services, and follow up with individuals for up to three months following release to ensure medication and treatment adherence. In 2021, approximately 1,755 inmates were tested for HIV, of whom 31 had a positive result.

PRPP provides services to inmates with HIV who are preparing to return to their communities. In 2021, the PRPP provided linkage services to 644 inmates, of whom 305 were linked to care and 160 (52%) kept their appointments upon returning to their community. Recidivism, housing, and transportation are recurring barriers to recently released individuals accessing medical care. In addition, FDC conducts peer education train-the-trainer programs for select inmates at FDC's Central Florida Reception Center and Florida Women's Reception Center (the two largest reception centers in the state). In 2021, 53 inmates completed training to become inmate peer educators and conducted 146 peer-led HIV/STD prevention

and risk-reduction sessions to approximately 5,170 inmates. As a result of the peer education training session, 266 inmates requested an HIV test upon completion.

Expansion of Telehealth

The HIV/AIDS Section began offering telehealth (TH) services in January 2018. The TH program provides on-demand and scheduled PrEP, PEP, same-day or rapid ART and HIV and STD primary care evaluation and treatment visits. The HIV TH service is available to all 67 CHDs. As of May 2021, the Department is averaging over 100 services per month and has provided TH services to 1,604 CHD patients. In 2020, the Department launched a TelePrEP program where patients can access PrEP services through the CHD system via a dedicated telehealth practitioner team. Further credentialing of the HIV TH team of three providers in other CHDs is occurring to allow for these services to be provided by the team. Florida plans to expand and promote the use of telehealth and other new technologies to help alleviate barriers and improve access to HIV prevention and care services.

Insurance Coverage and Affordable Health Care

Florida remains a non-Medicaid expansion state and from 2015 to 2020, an average of 12.7% of people in Florida did not have health insurance coverage (compared to 8.7% for the U.S.).³⁸ The ACA has enabled more individuals to enroll in health insurance but some, particularly those who live just above the federal poverty level (i.e., the working poor), are still unable to afford the cost of coverage. Individuals who fall into this category and need health care are often forced to make difficult choices based on competing life priorities.

As a Part B grant recipient through the RWHAP HIV/AIDS Treatment Extension Act of 2009 (Public Law 111-87), the Department administers the ADAP program. Florida ADAP provides FDA-approved medications to low-income PWH between 0 and 100% FPL who have limited or no health coverage from private insurance, Medicaid, or Medicare. ADAP assists with some premiums and with out-of-pocket costs for drugs on the program formulary. Out-of-pocket costs can be deductibles, co-pays, coinsurance, or similar costs for Medicare Part C or D. Health insurance assistance funded through ADAP is part of ADAP, not a separate program. ADAP provides premium assistance for ACA Marketplace® plans for people with HIV whose income is between 75 and 400% of the FPL. The strategy of enrolling these clients in the direct-dispense program is more cost-effective than enrolling them in the insurance program. Clients in the direct-dispense program have access to the RWHAP system of care, which includes access to outpatient ambulatory health services, case management, and other allowable services. ADAP clients enrolled in the direct-dispense program achieved a VL suppression rate of 89%.

In addition, approximately 93% of ADAP clients enrolled in the program for at least six months have undetectable HIV VL, indicating their HIV disease is under control and unlikely to be spread sexually. The ADAP program aims to achieve at least 95% of clients enrolled in the program at least 6 months who achieve viral suppression regardless of their insurance status. For those in the insured program, approximately 98% achieved viral suppression in 2021, however, for those not insured, there is a clear disparity with only 89% achieving viral suppression in 2021. The approach that Florida ADAP takes

constitutes a close working relationship between the ADAP state health office team, Florida’s 67 CHDs, and 3 contracted statewide service providers: CVS Caremark for PBM services for ADAP insured clients, Magellan Rx for PBM services for ADAP uninsured and underinsured clients and Broward Regional Health Planning Council for Insurance Benefits Management (IBM) services for clients seeking enrollment and premium assistance with health insurance coverage. The Department’s ADAP is operationalized at the CHDs, where ADAP staff assist clients with enrollment by ensuring eligibility determinations and re-certifications. ADAP staff at CHDs use the ADAP database, called Provide, to upload client eligibility documentation. Eligibility files are shared with the contracted PBM and IBM providers multiple times throughout the day to ensure newly enrolled clients can access ADAP services during the same day they enroll in the program. Provide also helps ADAP staff keep track of their client caseload; the system helps identify clients who should be enrolled in the direct-dispense or insurance program based on the information presented during their enrollment. CHD ADAP staff also work closely with the provider community and RWHAP case managers to coordinate efforts with clients to promote medication adherence and retention in care.¹⁶

Additional Unmet Needs of Persons with HIV

Further work is needed to address the unmet needs of PWH identified through various mechanisms—including needs assessment surveys and Florida’s MMP project. The MMP is a surveillance system designed to understand the met and unmet needs of PWH. Among those surveyed in Florida from 2015 to 2020, the most common unmet need was access to dental services (24%), followed by shelter or housing services (14%), SNAP or WIC (12%), and meal or food services (9%). Other unmet needs included mental health services (8%) transportation assistance (8%), HIV case management services (8%), HIV peer group support (6%), medicine through ADAP (4%), and patient navigation services (5%).

4.3 PREVENT New HIV Transmissions by Using Proven Interventions, Including PrEP and Syringe Services Programs (SSPs)

Access to PrEP and PEP

The use of ARV medications to prevent HIV transmission in persons at risk for acquiring HIV is an effective prevention tool. Part of CDC’s HIP approach includes PrEP; in 2014, CDC issued clinical PrEP guidelines for health care providers. CDC recommends PrEP as a prevention tool for persons at increased risk for HIV: persons in sero-different relationships, gay and bisexual men who have sexual partners of unknown HIV status, and PWID. As of December 2018, the Department’s CHDs in each of Florida’s 67 counties are providing PrEP services (counseling, medications, follow-up testing) with support from state funding. CHDs provide PrEP primarily through the STI and family planning clinics and medication is provided at no cost to the client (repeatedly) through the state’s supply of medication. Since the launch of the Department’s PrEP drug assistance program in 2018 over 11,319 CHD clients have received PrEP medications. Current challenges to PrEP delivery through the CHDs include clinician

and staffing shortages and limited capacity for clinicians in smaller CHDs (e.g., fewer clinicians performing multiple duties in the clinic).

The Department’s publicly funded PrEP drug assistance program only accounts for a small portion of all PrEP services statewide. Numerous private-sector partners—including private physicians, FQHCs, community health centers, sexual health clinics, community-based organizations, HIP providers—are screening, prescribing, and maintaining people on PrEP throughout Florida. Also, over the past two years, HRSA has funded approximately 22 FQHCs through their EHE Primary Care HIV Prevention funding opportunity for health centers to expand access to medication to prevent HIV (including PrEP and related services), connect people to care, and ensure care services are well coordinated. According to the latest data available on AIDSVu, Florida has seen an increase in the rate of PrEP users per 100,000 population since 2016; as of 2021, the rate was 226 per 100,000. Florida now ranks third among states and jurisdictions with the highest rate of PrEP users, behind Washington D.C. and New York. PrEP data from AIDSVu reflect the number of people prescribed PrEP in a calendar year. AIDSVu uses data from a database that contains anonymized individual-level prescription records collected electronically from U.S. retail pharmacies, traditional pharmacies, specialty mail-order pharmacies, long-term care facilities, and other pharmacies (e.g., in-hospital pharmacies, HMO pharmacies).⁴⁹

Disparities in the uptake of PrEP and PEP still exist among key priority populations (e.g., Black, and Hispanic males and females, and transgender individuals). Taking a sexual history and discussing sexual health with patients should be a routine practice for primary health care providers; however, limited time for office visits and the reluctance of some providers to discuss sex with their patients presents barriers to routinization. There is a need for increased access to PrEP services in non-traditional settings and through innovative practices. PrEP delivery via telehealth (or “TelePrEP”) was recommended by community groups, clients, and providers as a mechanism by which people facing transportation and employment barriers could access PrEP and increase adherence to follow-up testing. Partnerships with retail pharmacies and clinics and through mobile applications may assist in bridging gaps in PrEP and PEP access. In 2020, by leveraging the existing state telehealth practitioner team, the Department launched a TelePrEP program where patients can access PrEP services through the CHD system.

Currently, federal funding requires the implementation of PrEP and PEP services but does not allow states to allocate funding for medications and limitations for covering associated clinical costs exist. While there are patient assistance programs available to offset the cost of medications, medical visits, and lab testing costs still pose a significant barrier to already disproportionately impacted populations. Clients receiving PrEP have reported that returning every three months for follow-up testing is a barrier to remaining adherent; and in rural and semi-rural areas of the state, transportation to follow-up medical appointments can present further challenges. Clients also cited the cost of medical visits and lab tests and not being able to get time off from work for appointments as barriers to PrEP initiation and maintenance. As a result, more clinics and pharmacies have started to offer non-traditional and after-hours services to increase access to PrEP and PEP. In late December 2021, Apretude (cabotegravir extended-release injectable suspension) received FDA approval for HIV PrEP. Injectable PrEP provides a new option to prevent HIV that does not involve taking a daily pill—which for some people presents

challenges. In summer 2022, the Department initiated a pilot project to test the feasibility of delivering Apretude through CHD clinics. Three CHD clinics (Alachua, Hillsborough, and Miami-Dade) were chosen to participate in the pilot project and represent geographic areas with varying HIV incidence.

In 2019, the USPSTF issued a Grade A recommendation for offering PrEP with effective antiretroviral therapy to persons at increased risk of HIV acquisition. Under the ACA, most private insurance plans must cover preventive services with an “A” or “B” recommendation from the USPSTF without copays or deductibles. This means that at least one PrEP option should be available at no cost to qualifying individuals on these plans.

Increased public and private partnerships are needed to fill gaps in access to PEP services. Many CHD clinics have traditional hours, making them ill-suited as delivery points. Access to PEP is needed quickly after exposure to HIV (in 72 hours) to prevent seroconversion. Clients requesting PEP tend to do so more often during evening hours and weekends. Partnerships with retail pharmacies, rape crisis centers, and sexual assault nursing teams in hospital EDs are needed to expand access points to PEP.

Substance Use Disorders, Syringe Service Programs, and Health Care Access

The past-year prevalence of substance use disorders among adults in Florida was 14.8% in 2019–2020, and the prevalence of needing but not receiving treatment for substance use was 7.5%. According to the Florida Association of Managing Entities, 5,117 adults were added to a waitlist for substance use services in FY 2020–2021.⁵⁰

The most recently published prevalence rates for various substances and substance use disorder among young adults (ages 18–25) and adults in Florida are presented in Table 9 below:

TABLE 9: PREVALENCE OF SUBSTANCE USE AND SUBSTANCE USE DISORDER IN THE PAST YEAR, IN FLORIDA BY ADULT AGE GROUP (2019–2020)

	18 and Older	18–25	26 and Older
Marijuana Use	16.6%	32.9%	14.5%
Cocaine Use	1.7%	4.4%	1.4%
Methamphetamine Use	0.6%	0.6%	0.6%
Heroin Use	0.2%	0.1%	0.2%
Prescription Pain Reliever Misuse	3.6%	4.8%	3.4%
Alcohol Use Disorder	9.5%	13.6%	9.0%
